The *treatment* consists in pursuing a regular and nutritious diet, avoiding all active stimulants, bathing the surface frequently, and keeping the bowels and kidneys in as healthy a condition as possible. To lessen the congested or inflamed state of the stomach, various means may be employed, some of which will be found more beneficial in certain cases than others; among these, the following have been very efficacious: 1. Take of Soluble Hydrastin one scruple, Geraniin two scruples, Nitrate of Bismuth four scruples; mix, and divide into twenty powders, of which one may be taken for a dose, shortly previous to each meal.—2. Take of Soluble Hydrastin one scruple, Geraniin two scruples, Fluid Extract of Wild Cherry, Tincture of Cannabis Indica, each, ten fluidrachms, mix. The dose is one teaspoonful to be taken before each meal.—3. Take of Inspissated juice of Oxgall one drachm, Leptandrin half a drachm, Oleo-resin of Iris Versicolor ten grains, Extract of Quassia, a sufficient quantity to make into a pill mass; mix, and divide into thirty pills, one of which may be taken before each meal. This will be found especially useful in cases where there is hepatic congestion, with flatulence, constipation, and eructations.—Other agents will also be found beneficial, as, White Indian Hemp, Black Cohosh, Alum, Capsicum, Xanthoxylin, Opium, Chlorate of Potassa especially in offensive breath, Tincture of Muriate of Iron, and Oxide of Zinc, which agents may be combined to suit each particular case. If there be acid with the mucus, adopt the means hereafter named under Gastric Acidity. Vomiting will also be referred to hereafter.

Excessive gastric acidity is one of the symptoms of dyspepsia, the most difficult, in many cases, to overcome. It may be associated with an excess, deficiency, or normal quantity of the secretion of mucus, and may consist either of an excess of the gastric juice, (hydrochloric acid), or of lactic, acetic, carbonic, butyric, or oxalic acid, which last named acids are frequently the result of decomposition and fermentation of the food detained in the stomach; some-

times one, and sometimes the other being present, according to the composition of the food. It may be remarked, however, that it is rarely the case that there is an excess of gastric juice. The character of the acids, if vomited up, should be carefully examined in order to gain information that will aid in the treatment. If the acid be hydrochloric, it may be due to a secretion of the gastric juice at other times than when food is in the stomach; to imperfect digestion, and to direct as well as reflex irritation. Acetic acid is seldom observed, but may, the same as the lactic, butyric, carbonic, and oxalic acids, be due to imperfect digestion and fermentation of the food. The *symptoms* of gastric acidity vary somewhat with different individuals, although, generally well marked. There may be a deficient or voracious appetite, or, a perfect disgust for food; the tongue will be coated white, the thickness of this coat indicating the intensity and obstinacy of removal of the acid; some cases will present a cracked or deeply-fissured tongue, and the papillæ at its base will be very much elevated; there will often be acid regurgitations, sometimes ex-coriating the fauces, tongue, mouth, lips, and even gradually decomposing the teeth; a sensation of burning along the œsophagus, frequently attended with epigastric pain, (*see Heart-burn*); a dry, parched condition of the mouth, with more or less thirst, is usually present; the urine is scanty, high colored, scalding, and depositing uric acid or urates. Constipation is generally present, occasionally diarrhea; more or less nervousness, and in the more severe cases hypochondria, hysteria, epileptiform symptoms, headache, cough, etc.

It might be supposed that an excess of acid could be readily removed and a further tendency to its formation arrested, but experience has proven that this is by no means an easy matter, and that various and even opposite remedies are required for the different cases. Thus, among some patients, the following powder will be found sufficient to regulate the bowels, neutralize acidity, arouse hepatic action, and impart tone to the whole alimentary canal: Take of good Turkey Rhubarb in powder two ounces, Bicarbonate of Soda, or of Potassa, one ounce; mix, and administer a sufficient quantity, three times a day, say from five to twenty grains, in a little water or glycerin, to produce one, but never more than two, alvine evacuations daily, approaching as nearly as possible to those of health. The soda, in the above mixture, is to be used when the liver is torpid, the tongue is furred or coated, and uric acid or urates are deposited in the urine; the potash when the kidneys are torpid and there is an abundance of uric acid and urates.

Should there be much gastric irritability, magnesia will answer a better purpose than the soda or potash.

It must be recollected that a long-continued use of alkalies injures the tone of the stomach, and favors increased acidity, consequently, their use should be suspended as soon as the symptoms of acidity have disappeared, or when phosphatic deposits occur in the urine. Magnesia and Bismuth are useful where gastrodynia, and epigastric tenderness are also present; and Lime-water will be found useful in cases of acid vomiting with excessive gastric irritability. Prepared Charcoal is useful in most instances; it may be used alone in teaspoonful doses in water or glycerin, three or four times a day, or, it may be used in one of the following combinations, viz.: 1. Take of Guaiac, Rhubarb, and Prepared Charcoal, each, in powder, equal parts; mix. The dose is a teaspoonful in milk, yolk of egg, or Indian meal gruel, and which may be repeated three or four times a day. 2. Take of Prepared Charcoal sixteen parts, Bicarbonate of Soda, (or Potassa) two parts, Rhubarb one part; mix. The dose is a teaspoonful in water, to be repeated three times a day, or enough to keep the bowels regular. If there is hepatic torpor or obstinate constipation, Mandrake one part may be added; and if there is much flatulence, good African Ginger one part, may also be added. These preparations are not as agreeable as could be desired, but pleasant remedies rarely succeed in obstinate gastric acidity. Great attention must be paid to diet and exercise.

It must be recollected that the use of fluids during meals, dilutes the gastric juice, thereby favoring imperfect digestion and acidity; consequently, but little, if any, fluid should be taken during a meal, or, for an hour or two afterward.—In cases where there was a white coat on the tongue, with bad taste in the mouth and unpleasant breath, obstinately persisting and unyielding to other remedies, I have effected permanent cures, by teaspoonful doses, repeated four times a day, of a mixture of Fluid Extract of Mandrake two fluidrachms, Fluid Extract of Leptandra four fluidounces, Fluid Extract of Golden Seal one fluidounce, Compound Syrup of Rhubarb and Potassa one pint.

In anemic cases, where the body of the tongue is pale and flabby, digestion slow, and oxalate of lime crystals are deposited in the urine, mineral acids will be found very efficacious in improving the condition of the stomach and overcoming the acidity; the Nitro-hydrochloric Acid in doses of four or five drops, added to a cold infusion of Colombo and Golden Seal, and repeated every four hours will be found especially beneficial; in some cases the

Tincture of Chloride of Iron, or, Elixir Vitriol will prove useful.—The following will also be of service in many instances: 1. Take of Aqua Ammonia one drachm, Calcined Magnesia two drachms, Cinnamon Water two fluidounces, Water six fluidounces; mix. This may be employed to restore the tone of the stomach, in delicate females, as well as in drunkards. The dose is a tablespoonful as often as required. Or, pure Liquor Potassa may be substituted for the Aq. Ammonia.—Bismuth, either alone, or with Magnesia or Chalk, has also been highly recommended in gastric acidity.—In all cases of acidity where there is an irritable condition of the stomach, with heat, and pain on pressure at the epigastrium, sedatives should be given, as, Hyoscyamus, Belladonna, Conium, and, in cases of diarrhea, Opium; at the same time counter-irritation should be applied over the epigastric region.—In cases where there is a thick white coat upon the tongue, its body pale, papillæ enlarged, constipation, and pain in the region of the liver and stomach, much benefit will frequently follow the exhibition of tablespoonful doses, repeated three or four times a day, of a mixture composed of Salicin ten grains, Tincture of Mandrake four fluidrachms, Catawba Wine five and a half fluid ounces.

Heart-burn or *Cardialgia* is commonly due to acid in the stomach, and may be removed by the means that will neutralize the acidity and restore the tone of this organ.—When heart-burn is only a symptom of gastrodynia, not being attended with disordered secretion, the Trisnitate of Bismuth, Alcoholic Extract of Aletris, Dioscorein, Oxide of Zinc, Extract of Chamomile, or of Scullcap, etc., will be found appropriate remedies. Painful digestion accompanied with heart-burn and pyrosis, has been greatly benefited by Cod Liver Oil. (*See Chronic Gastritis, c, page 698.*)

Deficient secretion of the gastric juice is attended with various symptoms, the principal of which, are, impairment, or loss of appetite; tongue furred, though sometimes not furred but slimy, with a brown streak along its center; digestion is slow and imperfect, even a moderate meal causing a sensation of weight, uneasiness, and distress at the epigastrium, and especially after partaking of albuminoid substances; there is a general feeling of languor, indolence, mental and physical inactivity; and in many instances, nausea, vomiting, flatulence, fetid eructations, headache, cold extremities, depression of spirits, impaired sleep, unpleasant dreams, constipation, pains or cramps, sallow complexion, emaciation, etc., are, one or more of them, also present. This form of dyspepsia,

atonic, may be due to several causes, as, the habitual ingestion of an excess of food, indolent and sedentary habits, habitual use of stimulants, congestion of the stomach, weak digestive power from overexertion of the brain, masturbation, or impaired nervous power, whether congenital or acquired.

The *treatment* consists in restoring the nervous power of the stomach, which will, of course, improve its muscular and secretory functions. Stimulating and tonic alcoholic bitters, Lactate of Iron, Citrate of Iron and Strychnia, Strychnia, Hydrastin, Ipecacuanha, Xanthoxylin, Aletridin, Ammonia, are the agents that will be found useful. Thus, a very excellent pill may be formed of Citrate of Iron and Strychnia two scruples, Soluble Hydrastin, Capsicum, Alcoholic Extract of Aletris, each, one scruple; mix, and divide into twenty pills. One of these pills may be taken shortly before each meal. If there be hepatic disease also present, Podophyllin and Leptandrin may be added to these pills; or, the Compound Tincture of Tamarac Bark may be advantageously employed. A very good pill consists of Ipecacuanha ten grains, Xanthoxylin, Leptandrin, and Extract of Quassia, one scruple; mix, and divide into twenty pills, to be taken the same as the preceding. A mixture of Leptandrin two grains, Hydrastin one grain, Lactate of Iron three grains, Dried Osgall, five grains, given for a dose, and repeated two or three times a day, will be found useful in many long-standing and obstinate cases; and if much gastric debility be present, a few grains of Capsicum may also be added to each dose.

In this form of dyspepsia, emetics as well as purgatives are injurious, as they exhaust and enfeeble the stomach. But the bowels must be kept regular by food or mild agents; and as to the food, the same rules are applicable here, as in other forms of indigestion,—it must be digestible, agree with the digestive organs, be used with moderation, eaten slowly, and masticated thoroughly.—Fetid eructations may be checked by avoiding eating too much, and using Wine of Pepsin, Tincture of Chloride of Iron, Hypophosphite of Soda, or, a mixture of Charcoal thirty grains, Tris-nitrate of Bismuth ten grains. A few drops of Nitro-hydrochloric Acid, diluted; or, Diluted Acetic Acid with half a drop or a drop of Creosote added,—taken shortly before meals, have also been recommended.

Pyrosis, or *Water-brash*, is by no means an unfrequent symptom; it consists in the vomiting or regurgitation of a thin watery fluid

or mucus from the stomach, sometimes as much as a pint at a time, and which may be insipid, or extremely acid. It more commonly occurs when the stomach is empty, and is usually preceded or accompanied by a sense of burning and pain, especially at the epigastric region. Females are more liable to it than males, particularly those laboring under leucorrhœa, and among the poorer classes; and it may not only be present in dyspepsia, but also in other gastric maladies. Whatever exhausts the system, or deranges the gastric functions, may give rise to it, as well as innutritious food, without there being any serious symptoms of stomach disease. Various views have been entertained regarding the nature of the fluid of pyrosis; at one time it was considered as a secretion from the pancreas; Chambers and others consider it to come from the glands at the inferior part of the œsophagus. At present, it is presumed to be saliva, which, from some cause, is secreted in abundance and carried into the stomach, as it possesses all the chemical and microscopical qualities of this fluid from the mouth,—producing sugar from starch, containing sulpho-cyanide of potassium, and presenting pavement epithelial scales. Its acidity is due to the presence of some of the acids of the stomach; occasionally, bile has been observed in it.

The *treatment* of pyrosis consists principally in the use of sedatives to allay irritation and relieve pain, and astringents to check the excess of fluid secreted; as, 1. Trisnitrate of Bismuth five grains, Sulphate of Morphia one-tenth to one-fourth of a grain; mix for a dose, and repeat three times a day; half a grain of Sulphate of Quinia may frequently be advantageously added to each dose. 2. Oxide of Silver one-fourth grain, Extract of Logwood (or of Rhatany) two grains; mix for a dose, and repeat three times a day. 3. Kino, Alum, Geraniin, each, in powder, one grain, Opium half a grain; mix for a dose, and repeat three times a day. Other agents have been found efficacious, as, Sulphate of Iron, in anemic cases; Strychnia or Nux Vomica in cases of nervous debility; Catechu; Nitrate of Silver; and, as sedatives, Hyoscyamus, medicinal Hydrocyanic Acid, Conium, Gelseminum, etc. I have known cases cured by an illiterate practitioner, who administered a powder composed as follows: Take of equal parts of the inner skin of chickens' gizzards, dried and pulverized, sulphur, resin, and alum; mix. The dose is from five to fifteen grains three times a day. In many cases, cures have been performed by tablespoonful doses of a mixture of equal parts of Compound Tincture of Senna, and Tincture of Tolu; also by teaspoonful doses of the mixture of Tincture of Tolu, Gum Hemlock, etc., in *Am. Disp.*, 6th ed., 1864,

page 16. Gallic Acid has also been found highly efficacious, when ulceration, organic malignant gastric disease, and hepatic disease are absent; it increases the appetite, gives tone to the stomach, and frequently removes constipation.

Nausea and *vomiting* may occur separately or combined, and are common with most of the diseases of the stomach, though it must not be forgotten that they, especially vomiting, may arise from causes independent of this organ, as, from morbid states of the brain, liver, intestines, kidneys, etc. The same causes that occasion nausea may also produce vomiting.

Some persons vomit from the slightest causes, while others never vomit. If the stomach be empty when vomiting occurs, it is usually due to other than stomach disease, as, from diseased heart, abdominal tumor, pregnancy, etc. "If the vomiting occurs soon after eating, the smaller the quantity of food, and the sooner it takes place after eating, the nearer to the mouth is the injury. Disease of the œsophagus causes rejection of the food before it has got down; of the cardia, or smaller curvature, very soon after it has got down; and disease of the pylorus, pancreas, or liver, after an interval, sometimes, of as much as several hours. When it is due to congestion of the brain, it is increased by the horizontal posture; when to a deficient supply of blood, that position relieves it, as, in anemia, fainting, etc." The matters vomited up may be food or liquid, sarcinæ, mucus, a thin fluid resembling saliva, bile, blood, pus, or fecal matters, depending upon the cause producing the emesis. The expulsion of food or liquid is usually due to irritation or mechanical obstruction; sarcinæ, to a process of fermentation; mucus, to a catarrhal inflammation of the mucous membrane; the salival fluid, to some functional or organic disease of the stomach, not yet fully determined; bile, to regurgitation from excessive and protracted retchings; blood, to organic disease of the stomach, to a morbid condition of the blood, to an obstruction in the portal system, to ulceration or injury of the stomach, or, it may be vicarious; if the blood be in considerable quantities, containing black clots, it comes probably from an open vessel perforated by an ulcer; pus, to ulcers or abscesses occurring in or near the stomach; and fecal matters, to an obstruction to the passage of feces, to a fistulous communication between the stomach and colon, or, to paralysis of some part of the intestinal tube. (*See Chronic Gastritis, b, page 697.*)

Acidity may occasion vomiting, requiring the treatment heretofore named. If constipation is the cause, pursue the measures

named under this head. If irritability of the stomach, sedatives, and counter-irritation over the epigastric region will be required; as, 1. Muriate of Morphia half a grain, Dilute Hydrocyanic Acid five minims; mix for a dose, to be repeated every four hours. 2. Chloroform ten to twenty drops, Tincture of Camphor five or ten drops, Sulphate of Morphia one-eighth or one-fourth grain; mix for a dose, to be taken in water, or in equal parts of glycerin and water, and repeated every four hours. 3. Dilute Hydrocyanic Acid two or three drops, Creosote from one to three drops, Solution of Sulphate of Morphia twenty to thirty drops, Bicarbonate of Soda one scruple, Water one and a half fluidounces; mix for a dose, to be repeated as desired. This must not be administered if there is any suspicion of ulceration or abrasion of the gastric mucous membrane, and, the soda may be omitted if there exists no acidity. 4. An infusion of Parched Corn, or of Roasted Oatmeal Cake, will answer in many cases. 5. A mixture of Trisnitrate of Bismuth five or ten grains, Sulphate of Morphia one-eighth of a grain, will frequently answer an admirable purpose. 6. And occasionally, half-drachm doses, in an infusion of Spearmint, of equal parts of Tincture of Laudanum, Essence of Peppermint, and Tincture of Camphor, will prove efficacious. 7. A mixture of Tincture of Cyanide of Potassium and Laudanum will also be found efficacious in cases of vomiting, especially when accompanied with diarrhea. Hydrocyanic Acid, or Cyanide of Potassium, is especially useful in those cases where the vomiting is not due to any disease of the stomach, but to the secondary condition of the nervous system, as, in heart disease, peritonitis, phthisis, etc. Opiates are useful when the vomiting is accompanied by much local pain. Chloroform is useful in nervous vomiting, or where there is much gastric excitability; it may be taken internally, or be applied to the epigastrium, on a cloth, and then covered with oil-cloth. Charcoal, Carbonate of Magnesia, etc., are useful in vomiting with excessive acidity. It is often the case that chronic vomiting can only be checked by a diet solely of milk and lime-water, aided by complete rest and absence from excitement.

If the vomiting appears to be occasioned by the presence of food, occurring soon after its ingestion, the very lightest food must be used in very small quantities, and at lengthy intervals; counter-irritation must be applied over the epigastric region and along the dorsal spinal region; and internally, Bismuth, Dioscorein, infusion of Witch Hazle, Oatmeal Coffee, etc. In some very obstinate cases, I have found the following useful in vomiting from the last two named causes, viz.: Take of Strychnia one grain, Essence of

Monarda Punetata two and a half fluidrachms, Chloroform, Laudanum, each, five fluidrachms; mix. The dose is from ten to twenty-five drops in mucilage, or glycerin, and repeated every four or five hours.

Vomiting may also occur from a stricture of the pylorus, in which case there is an enlargement of the stomach, and the vomiting occurs some hours after the meal; this may be overcome to a greater or less extent by making use chiefly of a liquid diet, but it is not curable.—The vomiting due to cerebral, renal, hepatic, or intestinal, etc., disorders, although frequently relieved by the use of sedatives and counter-irritants, can only have a permanent cessation effected by the removal of the particular cause giving rise to it.—Vomiting in gastric ulceration, or cancer, etc., has already been referred to under these heads. It must be remembered that the presence of bile in the matters vomited is not always an indication that the case is one of “biliousness,” as, severe retching or vomiting will often cause a regurgitation of bile into the stomach.

In all cases of severe and obstinate vomiting the bowels should be kept regular either by mild laxatives, administered by mouth, or, by injections; and the patient should be kept in the horizontal position as much as possible.

Not unfrequently the matters vomited up are of a frothy character, or become so after standing for a few hours, presenting a peculiar blackish or brownish, yeasty appearance, and frequently having a very fetid odor. The liquid is ordinarily in large quantities, from two pints to a gallon or two, has an acid odor, and an acid reaction. Upon a microscopic examination of this fluid, it will be found to contain, besides half-digested food, and other matters, numerous minute, square, oblong, or even irregular masses, of considerable consistence, and composed of four, eight, sixteen, sixty-four, or more squarish cells, having a slight brownish color, each cell being about the $\frac{1}{16000}$ of an inch in diameter; they somewhat resemble small pockets bound with cords crossing each other at right angles; they are termed *Sarcine Ventriculi*. Yeast fungi (*Torula Cerevisiæ*) are also observed; and these microscopic vegetable formations, which appear to be the result of a process of fermentation, may exist together, or alone. These bodies may be present, either in functional or structural lesion of the stomach, and especially in dilatation of the organ, hypertrophy, pyloric disease, etc.; and they have been found where no symptoms of gastric disorder were manifest. More commonly these fungi are attended with pain, heart-burn, flatulency, distension of the stomach, disturbed sleep, loss of flesh, and frequently, voracious appetite.

The *treatment* consists in preventing the fermentation of food in the stomach, and destroying the fungi. The means that may be employed to restrain the vomiting and check fermentation, are as follows: 1. Take of Creosote one or two drops, Extract of Opium one-fourth of a grain, Alcoholic Extract of Aletridin a sufficient quantity to form a pill; one of these pills may be taken before each meal. 2. Take of Solution of Chloride of Calcium one fluidrachm, Mint Water seven fluidrachms; mix. This draught to be taken for a dose, and repeated three times daily, before each meal. 3. Sulphite, or Hyposulphite of Soda in doses of from fifteen grains to a drachm, dissolved in water, and repeated two or three times a day, soon after meals. This agent will also destroy these parasitic formations; and its virtues are due to the fact that the soda salt is decomposed by almost any vegetable acid, as well as by the hydrochloric acid of the stomach, and that this decomposition liberates the sulphurous acid of the salt, which has great power to prevent alcoholic and acetous fermentation, and is at the same time a poison to the sarcinæ. Dilute Carbolic Acid, used for a number of days or weeks, will likewise be found an agent destructive to these fungus vegetations.

Vegetable bitter tonics will also destroy these fungi, as well as give tone to the stomach; the following will be found useful: Take of Quassia, Aletris, Ptelea, each, pulverized, three drachms, Water twelve fluidounces. Mix, and make a strong infusion, of which a tablespoonful may be given three times daily. Or, the Sulphite or Hyposulphite of Soda may be added to the infusion, say from four to six drachms. Prepared Charcoal, as well as Tincture of Chloride of Iron, have also proved of service. A sense of distension and spasmodic pain, accompanying this condition, may be relieved by Chloroform and Laudanum. The diet should be mild and unirritating, and the bowels be kept regular.

Pain in the stomach may vary in intensity from a sense of soreness, or, tenderness on pressure upon the epigastrium, to most severe agony and suffering. When the pain is of a spasmodic character, it is termed *gastrodynia*, and is frequently so violent as to demand immediate relief; it is due to the presence of indigestible food, acrid and abundant disordered secretions, functional or structural lesions, etc. When it partakes of a neuralgic character, it is termed *gastralgia*, and may exist independent of any disorder of digestion, requiring treatment similar to that already named under Neuralgia. When due to acidity with accompanying heart-burn, the

pain and the heart-burn together are termed *cardialgia*. (See *Chronic Gastritis*, f, page 699.) Some writers, however, employ these terms indiscriminately, and as referring merely to pain. Gastric pain is common to both functional and organic disorders of the digestive organ, and it is sometimes very difficult to determine with which of these conditions it is associated; it may also exist sympathetically as a symptom of disease of distant organs, as, the lungs, pleura, liver, spleen, kidneys, intestines, etc.

The pain is usually seated in the epigastrium, just beneath the ensiform cartilage, it may be increased or relieved by pressure, and may extend in various directions. The pain is serious in proportion to its severity, its continuousness, and its fixedness constantly at one spot; when seated in or near the median line, it is also more unfavorable; and is the most serious when associated with pains in the spinal column located between the interscapular and lumbar regions, as is usually the case with gastric ulcer, gastric cancer, etc. It may be sudden and temporary; or it may continue more or less severe for a longer or shorter time, with intervals of quiet; and, when violent, is attended with a slow pulse, coldness of the surface, a sense of prostration, and frequently nausea or vomiting.

As a general rule, pain and soreness when attending organic diseases, or a morbidly irritable condition of the stomach, are more severe shortly after meals, or when the stomach is full, and especially so after a heavy meal of animal food and fermented drinks than after a light one of farinaceous food and milk. Pain coming on when the stomach is empty, and relieved by food, may be considered an indication of functional disorder. If the pain does not manifest itself for two, three, or four hours after a meal, it is due to morbid irritability of the mucous membrane of the duodenum, and is often accompanied by pain and soreness on pressure, in the right hypochondrium. If the pain is very violent, coming on in paroxysms at irregular intervals, with a sense of distension, anxiety, and great restlessness, it may be due to over-distension of the stomach, or, it may be seated in the arch of the colon. The history of the case, the appearance of the patient, the irregularity of the attacks of pain, being often quite independent of food or drink taken into the stomach, and the absence of vomiting blood or coffee-ground matters, will aid in determining whether gastric ulcer be present or not. In gastric cancer there is a peculiar cachexia, emaciation, tumor, and coffee-ground vomiting. In chronic gastritis there is no pain nor aggravation of pain on pressure, the course of the disease is irregular, the urine is changeable being rather anemic than inflammatory. In calculus in the gall bladder, hepatic or

cystic ducts, the pain is associated with severe nausea and vomiting.

The *treatment* of pain in the stomach in chronic organic lesions has already been referred to; I will now attend to that more especially connected with dyspepsia. If the pain be due to acidity, or flatulency, it may be relieved by the means named for removing these conditions. The pain attending vomiting, heart-burn and pyrosis may also be removed by the measures advised for these symptoms.

When, however, a sensation of distress or pain occurs, independent of the above symptoms, or, associated with them but not removed by the means referred to, the following will frequently be found a prompt and efficacious remedy: Take of Alcoholic Extract of Aletris one scruple, add to this as much Capsicum as will not destroy its pilular consistency, and divide into ten pills, of which, one or two may be taken for a dose, either shortly before or after a meal, according to the period when the pain occurs; these pills will also be found to relieve the nausea and sinking sensation experienced by some dyspeptics in the gastric region. Sometimes, half a grain or a grain of Alcoholic Extract of Nux Vomica may be advantageously added to the above. If there be considerable gastric irritation, the Capsicum should be omitted and Sulphate of Morphia in proper quantity, be substituted; at the same time counter-irritation to the epigastric region will be of service. If vesication is produced, great relief may be obtained by dressing it with Morphia.—A warm cataplasm of bruised Stramonium Leaves placed upon the epigastrium has been found very efficacious in many instances. Perhaps, anodyne hypodermic injections would afford relief. Occasionally, equal parts of Alcoholic Extract of Aletris, Hydrastin, and Capsicum will be useful. Again, Assafœtida, Opium, and dried Ovgall made into a pill, has been of value. When the distress, or pain is accompanied with, or, is owing to flatulency, five or ten grains of a mixture composed of equal parts of Hydrastin, Caulophylin, Dioscorein, and Ginger, will be beneficial.

If the pain be of a *neuralgic* character, dilute Hydrocyanic Acid, Extract of Belladonna, Sulphate of Quinia, Oxide of Zinc, Tincture of Sheep Laurel, etc., are among the proper remedies.—If it be of a *spasmodic* character, a few drops of Chloroform and Laudanum in an infusion of Sculleap, will be of service; or the Compound Tincture of Virginia Snakeroot; or the Compound Tincture of Lobelia and Capsicum. Relaxation should be effected by placing cloths moistened with hot water (but not hot enough to scald) over the gastric region, changing them frequently; and the bowels should be speedily

evacuated by a warm active laxative injection. Equal parts of Tinctures of Gelseminum, Dioscorea, and Skunk Cabbage, will also prove useful, in doses of a teaspoonful every twenty, thirty, or fifty minutes. In many instances, Chloroform, or, a mixture of Chloroform and Opium, or, a Belladonna Plaster, applied over the epigastrium, will promptly relieve pain; the chloroform should be prevented from evaporating by covering it with a dry cloth or oil silk. Ointment of Veratria, or, of Aconitia, rubbed over the pit of the stomach until a pricking sensation is produced, and repeated every two or three days, will often prove invaluable in obstinate and severe cases. These external measures, when applied alternately to the epigastrium, and to the sensitive region of the spinal column, will be very effectual in many difficult cases.

Aqua Ammonia, Aromatic Spirits of Ammonia, or Carbonate of Ammonia, has been highly recommended in dyspepsia accompanied with painful spasmodic affections of the stomach.—If the pain be due to too much food in the stomach, or to indigestible diet, an emetic may be given; but emetics are rarely required for this purpose, except when the patient has been careless or neglectful of what his diet consists.

Gastric pain may also be frequently relieved by stimulating applications along the dorsal vertebræ.

Headache has already been treated upon; see page 322.—*Hiccough* may be removed by inhaling Chloroform, and repeating it as often as the symptom returns; if the hiccough be intermittent the following will prove useful: Take of Sulphate of Quinia one grain, Opium half a grain, Supercarbonate of Soda three grains; mix, for a dose; to be repeated as required.—*Nightmare* can be removed by partaking moderately of food, keeping the bowels regular, avoiding flatulent diet, as well as that which is indigestible, neutralizing gastric acidity, and avoiding suppers. Persons subject to nightmare should also refrain from lying upon their backs while sleeping. An attack may be prevented by the following draught taken before retiring to bed: Take of Essence of Peppermint ten drops, Carbonate of Potassa ten grains, Tincture of Capsicum five drops, Water one fluidounce; mix.

Flatulency is a very common condition accompanying dyspepsia, as well as other affections of the stomach, and also of the intestines, and frequently occasions severe pain not only at the point where the gas accumulates, but likewise in distant parts; the pain being stationary or shifting. Flatulency may be due to several

causes, viz.: to air, swallowed with food, or otherwise; to decomposition of food in the digestive tube, especially that which is crude, and indigestible, saccharine, or amylaceous; to irritation and diminished tone of the gastric mucous membrane; or to gases evolved during the decomposition of fluids derived from the organism itself. Some authors have also attributed it to a secretion of gas from the blood-vessels, but there is no evidence to my mind that this ever occurs. Flatulency may be a constant symptom, rarely increasing, unless from an error in diet, or, it may appear and disappear suddenly, and in such large quantity as to greatly distend the part occupied by it. When it passes by belching, eructation, or from the rectum, it seldom proves serious, and such exit affords relief to any unpleasant symptoms produced by it. The gases usually formed in the alimentary canal, are, carbonic acid, nitrogen, hydrogen, sulphureted hydrogen, carbureted hydrogen, and ammonia; those which give rise to gastric distension are, principally, the carbonic acid, and nitrogen. Gases in the stomach often give rise to borborygmi, severe pains, sense of distension, or of cramp, or colic; in many instances, the source of annoyance is the presence of a fetid gas, which is required to be more or less constantly passed by belching or per rectum. Pain from gas may be constant, or intermittent, but is not increased on pressure, unless inflammation be likewise present.

In the *treatment* of flatulency, we must first ascertain whether any inflammatory action be present; if there be, it may be overcome by the use of sedatives, demulcents, and swallowing small pieces of ice, together with counter-irritation over the gastric region. If there be no inflammation, but an excess of acidity, the means named under this head may be pursued. If there be a torpid condition of the liver, or constipation, a cholagogue, or purgative will afford relief. An emetic, followed by a cathartic will be of service in those instances, where severe pain and distress, owing to an accumulation of gas, occur shortly after a meal, or, after eating crude substances; a dose of Castor Oil, with ten or twenty drops of Oil of Turpentine, and half a fluidrachm of Essence of Peppermint added, will be found a valuable cathartic in these cases. Sometimes, and especially when the gas collects in the intestines, much benefit will follow the use of stimulating cathartic injections.

Ordinarily, carminatives will relieve flatulency, as, Compound Spirits of Lavender, Oil of Cajuput, Hunn's Drops, etc. But, the gas will continue to collect until the digestive organs have been restored to their tone by the means heretofore named. In many

instances, the following will be found an excellent tonic and carminative: Take of Alcoholic Extract of Aletris forty grains, Alcohol two fluidrachms; rub thoroughly together until the extract is dissolved, and then add Tincture of Prickly-ash Berries, Glycerin, of each, two fluidounces. To this mixture add Strychnia one grain, thoroughly dissolved in one fluidounce of Glycerin and three fluid ounces of Essence of Cinnamon, or, of Ginger. The dose of this preparation is one or two fluidrachms, repeated two or three times daily.—Dioscorein; Fluid Extract of Pleurisy Root; Ginger; Charcoal; a drop or two of Creosote taken at meal-time; or Bisulphite of Soda, taken an hour or two after meals, or as soon as the evolution of gas in the digestive tube begins to be felt,—are among the remedies that have been of service in flatulency.—Suppositories worn in the rectum, one every night, in cases where there is excessive flatus of the lower bowels, are very serviceable; I have found one containing Soluble Hydrastin two grains, Dioscorein two grains, and Oil of Prickly-ash Berries four drops, to be of much benefit.

Persons who are subject to flatulency should always masticate their food thoroughly, should carefully avoid all articles of diet which produce or augment the flatus, should never eat immediately after mental or physical exercise or fatigue, and should never fast too long at a time. A scant diet must be used in cases where there is fermentation or putrefactive decomposition.

The secretion of *urine* is very changeable in dyspepsia; sometimes it is quite scanty, of a deep-red color, extremely acid, and depositing uric acid, or urates, and for which alkalies will be found serviceable, as, Bicarbonate of Soda or Potassa, taken an hour or two after each meal. An infusion of equal parts of Marsh Mallow Root and Spearmint, or, the use of Compound Infusion of Trailing Arbutus, will also be found of much efficacy. At other times, the urine will be very clear, acid, of an amber color, depositing a slight cloud of mucus and crystals of oxalate of lime, for which Nitrohydrochloric Acid may be used, in combination with tonic bitters. In cases of irritative dyspepsia, although high-colored, yet instead of urates, phosphates are deposited, indicating the use of Compound Balsam of Sulphur, nutritious diet, mild stimulants, and tonics; or, the free use of an infusion of equal parts of Dioscorea Villosa, Eupatorium Purpureum and Aralia Hispidula.—When the urine is pale, alkaline, or becomes so shortly after being passed, and deposits triple phosphates with phosphate of lime, or with an iridescent pellicle on its surface, the same measures may be pursued as in the

preceding case; or, Fluid Extract of Hydrangea; Elixir of Cinchona and Iron; or, a pill composed of Eupurpurin three grains, Alcoholic Extract of Nux Vomica one-tenth of a grain, to be administered three or four times a day, may be used as required. The same course may likewise be pursued in cases where there is much nervous excitement, the urine being passed frequently, in abundance, and pale, with phosphatic deposits.

If *disease of the kidneys* be associated with the dyspepsia, or, has been its cause, the treatment will be the same as referred to hereafter, when treating upon renal diseases.

If there exists any *blood disease* as a cause or an effect of the dyspepsia, it must be treated, according to its nature, by the means already pointed out. *Affections of the brain, spinal marrow, or nerves* will require the treatment heretofore laid down for them.

Constipation is a common attendant of dyspepsia, and may exist as a mere habit, or as the result of an intestinal disorder; it may be due to a deficient contraction of the abdominal muscles; impaired peristaltic action; sedentary, inactive life; morbid alteration of the secretions of the large intestine; intemperance; hepatic torpor; anemia; improper and injudicious use of purgatives; working in lead; use of tobacco; lesions of the spinal cord; tumors or growths pressing upon the intestines; overmental exertion, etc. In all cases of constipation the practitioner should endeavor by every means of investigation possible, to determine its true cause, so that if it be owing to certain habits, improper food, tobacco, lead, etc., these may be avoided; or, if to spinal lesions, tumors, etc., the appropriate means may be applied to remove these causes.

In dyspepsia, constipation is generally due to a deficiency of the nervous power distributed to the intestines, to an accompanying hepatic torpor, or to duodenal dyspepsia. It is apt to give rise to pain in various parts of the head, vertigo, disturbance of vision, *muscæ volitantes*, ringing in the ears, and physical and mental languor, besides uneasy sensations in one or more parts of the abdomen. Nausea and vomiting, and anorexia, are also produced by it, as well as loss of sleep, flatulence, bad dreams, apoplexy, etc. Constipation, although not always fatal, is nevertheless always a serious difficulty, and too much attention, or too much perseverance, can not be bestowed upon the efforts made to remove it.

Independently of the hygienic means recommended, which, of themselves, will frequently overcome constipation, we will often require therapeutical remedies. In a great many cases, a mixture of

powdered Turkey Rhubarb two parts, with Bicarbonate of Potassa or Soda one part, will have the desired effect. The dose varies from two to twelve grains, to be taken in a little water, about an hour after a meal, and to be repeated three times a day; the doses must be large enough to produce one, but never exceeding two evacuations daily, resembling in quantity and consistence, as nearly as possible, those of healthy stools. When larger doses of this powder are required, or when it causes gripings, etc., other remedies must be employed.

If there be much acidity or flatulence, the Compound Powder of Rhubarb and Charcoal, referred to under Excessive Gastric Acidity, No. 2, page 743, will be of benefit. In other instances, one of the following preparations may be administered: 1. Take of Alcoholic Extract of Aletris twenty grains, Alcoholic Extract of Nux Vomica one or two grains, Podophyllin five grains; mix, and divide into twenty pills, one of which may be taken for a dose, repeating it three times a day. If anemia be present, Protoxide of Iron twelve grains may be added to the above.—2. Take of Tincture of Mandrake, Tincture of Blue Cohosh, each, six fluidrachms, Saturated Tincture of Nux Vomica three fluidrachms; mix. The dose is ten or fifteen drops three times a day, in glycerin, or mucilage.—3. Take of Podophyllin, Apocynin, each, one drachm, Leptandrin three drachms, Alcoholic Extract of Nux Vomica twelve grains, Castile Soap, a sufficient quantity to make the whole into a pill mass; divide into three grain pills, of which one may be taken every night, or, every other night.—4. The Compound Pills of Leptandrin, as well as the Compound Powder of Leptandrin, will also be found useful. The use of purgatives creates a necessity for their repetition, which impairs the energy of the intestinal action, hence, it is better in all cases to solicit natural evacuations, than to become habituated to cathartic medicines.

In many cases of obstinate constipation, with or without hepatic torpor, the following will be found of great service in maintaining regularity of the bowels: Take of Hydrochloric Acid three fluidounces, Nitric Acid two fluidounces, Water five fluidounces; mix. Add three fluidounces of this mixture to half a pint of water; with which bathe across the bowels, over the region of the liver, and along the inside of the thighs, every night and morning; in a day or two alvine evacuations will occur, often abundant at first, and of a dark color.

Diarrhea is frequently an annoying symptom to both the patient

and physician; it may be of a bilious character, requiring cholagogues and astringents; or, it may be accompanied with griping pains in the lower part of the abdomen and across the region of the arch of the colon, with or without diarrhea and tenesmus, all of which symptoms are aggravated soon after eating; this may be promptly relieved by the following: Take of Alcoholic Extract of Aletris one drachm, Dioscorein two drachms, Nux Vomica, rasped, one drachm, Bruised Prickly-ash Berries two drachms, Alcohol half a pint; mix, and form a tincture. The dose is one fluidrachm in a glass of water, to be repeated three times a day, about an hour before meals.

In ordinary cases of diarrhea with acidity of the alimentary canal, two parts of the Compound Syrup of Rhubarb and Potassa mixed with one part of Fluid Extract of Wild Cherry, will be found very useful, when given, every hour or two, in tablespoonful doses. In obstinate cases, equal parts of Laudanum, Chloroform, and Fluid Extract of Wild Cherry, may be given every one, two, or four hours, in doses of twenty or thirty drops. (*See Chronic Diarrhea.*)

Duodenal Dyspepsia is often met with, and may be confounded with gastric dyspepsia, certain hepatic disorders, as well as certain lesions of the colon. In this form of dyspepsia, the tongue will be coated toward its root, as well as in the center, with a yellowish or brownish fur; vertigo, severe pain in the occipital or superior portion of the head, and derangement of vision, are frequently present; slight palpitations; strong aortic pulsations; dyspnea; cough; yellow or leaden appearance of the skin; nervous irritability; capricious appetite; sense of oppression an hour or two after a meal; troublesome flatulence; colic; borborygmi; epigastric distension; crampy pains; fullness, distension, or a dull aching pain in the right hypochondrium, down the arms, between the shoulders, or across the loins, with or without numbness; bowels torpid with light colored stools, or liquid and extremely offensive; and urine clear, or dark, often depositing urates, or phosphates,—are among the symptoms.

When the *Pancreas* is involved, there will be a disagreeable feeling of oppression; a dull pain, deep in the epigastric region, which is increased when the stomach is full, on full inspiration, and when strong pressure is made. The epigastric region is sometimes swollen; more or less anorexia or want of appetite; vomiting of fluid having the appearance of saliva or albumen; aortic pulsation

is powerful, and felt particularly when the hand is placed on the epigastrium; sinking turns as if the patient were dying; rapid emaciation; anemia; great mental depression; pain in the back; head-ache; chyme passes away undigested, etc. The diseases of these organs are generally complicated with gastric, or hepatic lesion, or both.

The *treatment* is similar to that which is advised for gastric dyspepsia; in addition to which, the use of the Iodine Pill, counter-irritation over the epigastrium, and Nitro-Hydrochloric Acid internally, will frequently be found valuable. Sinking sensations may be relieved by stimuli; and rapid emaciation be checked by nutritious and easily digested diet, and the employment of Xanthoxylin, Geraniin, and Alcoholic Extract of Nux Vomica, combined in appropriate doses. Dry cupping, firing, and active counter irritation along the spinal column, and upon the abdomen over the diseased organs, may likewise be used with advantage.

Dyspepsia is sometimes associated with *tuberculous disease*, and especially with *phthisis*, either as a cause or an effect, more commonly the latter. A careful examination of the patient will enable the practitioner to detect any tendency to tuberculous disease. This form of dyspepsia is best treated by the Iodine Pill, and Cod Liver Oil, as the principal agents; urgent or annoying symptoms may be relieved by the means already named.

CIRRHOSIS OF THE STOMACH.

Also termed Plastic Linitis, and Fibroid Degeneration of the Pylorus. This condition of the stomach has been viewed by some as a cancerous malady, and by others as a hypertrophy of the parts involved, but upon a minute examination of the diseased structure, it has been found to differ considerably from either of these affections. The *causes* giving rise to gastric cirrhosis are not known, though supposed to be a long-continued irritation of the parts, or an obstinate dyspepsia. All persons and ages are equally liable to it; though it is only occasionally met with in practice.

The *symptoms* vary greatly; in many instances the presence of this malady is not even suspected, and its existence is only discovered after death from some other disease, under a post-mortem examination. In most cases, however, there is local pain and tenderness, anorexia, vomiting, febrile reaction, and other symptoms of severe gastric disorder. These symptoms appear and disappear

at regular or irregular intervals, probably being influenced in this respect by the greater or less rapidity of the peculiar deposit forming the disease; they usually come on suddenly, and pass off gradually, being often more severe each time of their re-appearance. As the disease advances, other symptoms will manifest themselves, according to the abnormal changes effected in the parts by its advance. A contracted as well as a dilated condition of the stomach may result from the presence of the deposit occasioning the disease; and in almost all cases the pylorus is contracted from thickening of its tissues. In such instances, there will be, in addition to the previous symptoms, a sense of tightness in the epigastric region, with, as it were a suffocative feeling; insatiable hunger; frequent and excessive vomiting, the matters ejected being in abundance, and fermented or partially decomposed; *sarcinæ ventriculi*; constipation; gradual exhaustion; and the patient dies from inanition.—When gastric cirrhosis results in suppuration, (*suppuration of the areolar tissue, or, suppurative linitis*), the pain and vomiting becomes more and more severe, with high febrile reaction, and a tympanitic condition of the epigastrium, which are followed by jaundice, prostration, delirium, and death by coma. In these cases death may occur in forty-eight hours from the first symptoms of increased severity of the disease.—If the disease results in ulceration, or cancer, which is sometimes the case, the symptoms peculiar to these lesions will be manifested.

Cirrhosis of the stomach may be *diagnosed* from cancer, by its longer duration, less frequent vomiting and hemorrhage, absence of secondary cancer, in the uniform gastric thickening (rather than tumor) which careful manipulation finds in the epigastrium, in the great anorexia, and intense headache usually present, and, the little or no pain or tenderness in the epigastrium under pressure. Its *sequelæ* may be determined by the peculiar symptoms common to each.*

*Dr. W. Brinton observes of this disease:—"As regards its morbid anatomy, it is evidently an exsudation, occupying the areolar tissue of the stomach, and gradually undergoing a change, in which its development into a low grade of fibrous tissue (like that of a fibroid tumor) is accompanied by a constant decrease of its bulk, and increase of its density. The contraction and hardening thus brought about not only seriously damage the function of an organ to which mobility is essential; but they obstruct its circulation, and probably its innervation also; and they inaugurate grave lesions of its mucous and serous coats. Even in the muscular tunic a similar effect sometimes obtains. And though incidentally, the obstacle formed by the exsudation often evokes, in this powerful organ, a change which diminishes and defers its disorganization, and even exalts its nutrition for the time; still in the long run, this salutary effect generally

The *prognosis* is unfavorable; the obstruction can not be removed, though much relief may be afforded if the disease has not advanced too far.

The *post-mortem appearances* are peculiar; the disease appears to begin in the submucous cellular tissue, which undergoes a kind of fibrous thickening, the mucous coat frequently remaining intact. There is an increase in the weight and density of the stomach, it is hard and gristly, or cartilaginous, and an incision through its coats exhibits a vast increase of thickness, although the coats may be detected from each other. The parts affected by the interstitial deposit are opaque and of a pearly white appearance, and creak under the scalpel; the mucous membrane, as well as other parts, are comparatively bloodless. The mucous and submucous coats sometimes present a kind of folding or plaiting, to a greater or less extent, causing elevations above the surrounding gastric surface, and which appears to be owing to the deposit, which, filling and obliterating the meshes of the normal rugæ, destroys their functions, renders them ineffaceable, and often distorts and obliterates the minute stomach tubes. This abnormal condition, when present, is always to be found more greatly developed at the pyloric valve, from whence it extends to a portion or even to the whole of the stomach, gradually diminishing in thickness, however, as it advances beyond the pylorus.—In the advanced cases, where ulceration supuration, or cancer, etc., have occurred the necropsy will reveal the conditions peculiar to these lesions, together with more or less of the appearances belonging to the cirrhosis, above referred to.—Under the *microscope*, the white deposit is observed to consist of a tough, somewhat elastic, imperfectly fibrous mass, consisting of elongated or wavy fibres, less distinct but similar to those of a fibroid tumor, having, however, very few vessels, no yellow or elastic fibres, and presenting, when acted upon by acetic acid, numerous elongated nuclei, or small fusiform cells. The fibres are very irregularly interwoven.—Ulceration, cancer, etc., will present their usual appearances under the microscope.

The *treatment* consists, in the early stage, of fluid and unirritating food; alteratives, as, Chloride of Gold and Soda, Muriate of Ammonia, Bromide of Ammonium, etc.; counter-irritants to epigastrium, as, Compound Tar Plaster; sedatives to allay pain; injec-

yields to the interference produced by the slower but surer agent—to the contracting and hardening of the interstitial deposit. The physical effect transcends the physiological effort; the hare is caught by the tortoise, and then distanced in the race."

tions, to keep the bowels regular; and an entire prohibition of all stimulating food and drink. Every means, that will not augment the gastric disease, must be used to give strength and nourishment to the patient's system. Ulceration, or Cancer, when present, will require the treatment named under these heads.

CHRONIC DUODENITIS.

Chronic Inflammation of the Duodenum, including under this head, irritation, congestion, or inflammation, is most usually due to an extension of similar conditions of the stomach, intestines, and neighboring organs, to the duodenum. Sometimes, however, the disease may commence in this organ, and be propagated to those in its vicinity. The *causes* of this affection, are the same as those producing chronic gastritis, dyspepsia, gastric ulcer, etc.

The *symptoms* are like those common to a similar affection of the stomach, and are very difficult to distinguish from them. Pressure along the fourth, fifth, and sixth dorsal vertebræ, will frequently occasion pain or soreness. The *diagnosis* can only be satisfactorily made by being well versed in the position and structure of the organ, and in a knowledge of its functions, and morbid relations. But we can not, even then, determine whether this organ is the sole, or chief seat of the disorder, as it is most usually associated with lesions of the stomach, pancreas, intestines, or biliary organs. Among the symptoms that may lead us to locate disease in the duodenum, have been named, a sense of uneasiness, fullness, and weight, or even pain, occurring two, three, or four hours after a meal, with, frequently, similar sensations extending to the right hypochondrium, and to the right scapular region; nausea and vomiting accompanying these symptoms, or pain when firm pressure is made toward the organ, render, it is stated, the diagnosis still more positive. In addition to these, a tongue much furred at its base, with the papillæ elevated, a gnawing sensation at the stomach, capricious appetite, irregular, unhealthy, and offensive alvine evacuations, dry or harsh skin, and more or less dejection of spirits, tend still further to confirm the diagnosis. Notwithstanding, cases have been observed, in which no such indications were present, and we should not rely too exclusively upon them as a basis for our diagnosis.

Duodenal disease is often associated with urticaria, and other cutaneous affections,—a recession of which greatly aggravates it.—It frequently accompanies jaundice, giving rise to furred tongue, vomiting, or nausea, pain in the right hypochondrium, disgust for

food, and diarrhea.—The *sequelæ* of congested, or inflamed states of the duodenum, when long continued, are, thickening of its coats, softening, ulceration, etc. Cancer may also attack this organ. The symptoms of these several abnormal organic conditions are similar to those encountered in like states of the stomach, and are extremely difficult to satisfactorily diagnose from those of this latter organ, from chronic disease of the liver, or, from disease of the gall bladder.

The principal *post-mortem appearances* in duodenal disease, are, a gray discoloration of the membrane, from deposition of irregular pigment grains in its substance; thickening of the coats of the duodenum; vascular injection; enlargement of the mucous glands; and, sometimes, softening of the inner coats, ulceration, or perforation. Disease of adjacent organs, cancer of the duodenum, and adhesions of the duodenum to the neighboring organs, may also be observed; yet none of these imply that the disease commenced in this organ.

The *prognosis*, and the *treatment* of duodenitis, or its *sequelæ*, are the same as in like conditions of the stomach. If we can satisfactorily determine that the origin of the disease was in the liver, intestines, etc., or, if these organs are complicated with the duodenal malady, the proper treatment for the disease of these organs must be pursued. (*See Duodenal Dyspepsia*, page 758.)

A few remarks may here be made relative to the *Pancreas*, an organ concerning the diseases of which but little is known. The functions usually assigned to the fluid secreted from this gland, are, 1, to convert amylaceous matter into sugar or glucose during the process of assimilation; 2, to form an emulsion or very fine division of neutral fatty matters, that they may be absorbed into the lacteal system; this decomposition and digestion of fatty substances, does not belong exclusively to the pancreatic fluid, but is, to a certain extent, also effected by the fluids of the intestine alone, though the pancreatic is undoubtedly the most important and direct agent in this chylicification of fat; and 3, the digestion of the albuminous or nitrogenous substances that have not been acted upon by the stomach, assisted by the presence of bile. Frerichs states in addition, that the pancreatic fluid converts the bile into an insoluble compound, thus preventing its resorption into the system, and its expulsion.

The pancreas is liable to chronic inflammation, enlargement, induration, atrophy, hypertrophy, softening, and malignant dis-

eases, all of which are of very obscure diagnosis, and, with the exception of the first named, unyielding to treatment, requiring to be treated upon general principles, and limited, chiefly, to palliation of urgent symptoms only.

In addition to the symptoms of disease of the pancreas, named under *Dyspepsia*, page 758, there is one which was observed by Dr. Richard Bright as early as in 1832, and that is, more or less oily or fatty discharges from the bowels, in cases where malignant disease of the pancreas existed. As to this being an indication of pancreatic disease, there has been considerable dispute, and the question has not even yet been positively settled. But, in the solution of the diagnosis of pancreatic diseases, it would be an important matter to determine whether this organ, or the duodenum, is in any way involved with what is usually termed "*dyspepsia*," and whether the indigestion of proteinous, saccharine, starchy, or oily articles of food, are wholly due to gastric disease, or to duodenal or pancreatic affections, either isolated, or in combination. Sometimes, in disease of the pancreas, there will be a ravenous appetite; pyrosis; obstinate jaundice; and clayey stools, instead of fatty.

CHRONIC ENTERITIS.

Chronic Inflammation of the Small Intestines, may be limited to a part or to the whole of their mucous lining membrane, constituting *chronic muco-enteritis*; it may attack the glands of the intestines, constituting a *chronic follicular* or *glandular enteritis*; or, very rarely, it may partially or wholly involve all the intestinal coats, producing a *chronic sero-enteritis*, which is usually associated with chronic peritonitis, or intestinal ulceration. These various inflammatory conditions very frequently extend to the large intestine, occasioning dysentery, or, to the stomach, giving rise to dyspeptic symptoms.

These several varieties of chronic enteritis may follow the acute form of the disease, or, may be due to irritation from crude and indigestible food, or other irritating substances; to continued exposure to cold and damp; and especially to the improper use of drastic cathartics.

The *symptoms* of *chronic muco-enteritis*, may be very slight; no unpleasant sensations being experienced until some hours after a meal, when there will be uneasiness, heat, pain, flatulence, or distension, manifested in some part of the abdomen. Not unfrequently

firm pressure made on the external surface over the diseased part, will give rise to tenderness or pain; coughing or sneezing will often produce the same result—but, in such cases, the mucous coat is not the only one affected, as, purely chronic mucous inflammation seldom gives pain on pressure, coughing, etc. When the disease has been of long duration, and, sometimes, even from the commencement, especially when it follows the acute form, the symptoms will be more severe, as thirst; dryness of the lips and mouth, and frequently, cracked lips with exfoliation of their epithelium; sallowness, harshness and dryness of the skin; languor and weakness; coldness of hands and feet; small and weak, or corded pulse; slight febrile exacerbations toward evening; impaired appetite; emaciation; nervous irritability; headache; and, in the latter stages, night sweats. There may be constipation or diarrhea; or these may occur alternately. More commonly, however, diarrhea is a constant attendant, the discharges being either pale, clay-colored, greenish, brownish, reddish, or watery, and also slimy, yeasty, mixed with more or less feces; purulent and bloody; or containing shreds of lymph, undigested particles of food, etc. Among children, with whom the disease is of more frequent occurrence, the abdomen becomes enlarged and tympanitic, contrasting strongly with the emaciation observed in other parts; the mesenteric glands are also enlarged and obstructed.

Chronic follicular enteritis presents symptoms similar to the preceding variety, so that it is with difficulty distinguished from muco-enteritis, with which it is frequently associated. It is more generally accompanied by diarrhea, and the stools are mucous, muco-puriform, and more offensive than in the preceding form, in many cases. The tongue is frequently paler than natural, slightly coated, and, perhaps, aphthous ulcerations may also be present. It is very frequently associated with, or consequent upon, phthisis, in which cases, not only the small intestines, but also the cæcum and colon are apt to be implicated. Its progress is usually slower and of longer duration than that of muco-enteritis, and, like the latter, it frequently occurs among children, and may terminate in perforation of the intestines, or in peritonitis.

Chronic sero-enteritis, the enteritis of most authors, may follow the acute form of the disease, or may occur gradually from extension of muco-enteritis to the connecting cellular tissue, and thence to the external intestinal coats. It may also commence simultaneously in these several tissues, or, originating in the serous coat, it may be propagated to the others. There is more or less pain in the abdomen, increased somewhat on pressure, or, no pain may be felt at all

except under pressure, cough, etc.; sudden jolts, and full meals will also give rise to pain, often of a colicky-character, and which, in the latter instance, does not occur for some hours after the meals. If the peritoneal coat is much affected, there will be a distended, tympanitic condition of the abdomen; otherwise, it will be flat and concave. The tip and edges of the tongue are unnaturally red, and, sometimes, the whole tongue and mouth; the appetite is more or less impaired; thirst considerable; skin dry and husky; extremities colder than natural; sometimes nausea; deficient and high-colored urine; great depression of spirits; small, frequent pulse; emaciation and debility. Constipation is apt to be present, unless the disease has extended into the colon, forming an ileo-colitis, in which case, either obstinate diarrhea or dysentery may be present; frequently the former, and which is by no means an uncommon symptom. Pressure along the ninth, tenth, and eleventh dorsal vertebræ, will frequently give rise to more or less tenderness or pain. In many instances, the only symptoms complained of, are, emaciation, debility, and diarrhea. If a harassing cough be present, it may be due to implication of the lungs, or to an extension of the disease upward, inducing what is known as a "stomach cough." The disease may terminate in ulceration, thickening, contraction, or dilatation of the intestinal coats, fatal exhaustion, sphacelation, or peritonitis.

In the *diagnosis* of these several varieties of enteritis, it is of importance to determine the seat and character of the malady, a point not always easily attainable. (*See Chronic Gastritis.*) If the pain or tenderness exists around the umbilicus, or between it and the right ilium, the ileum is the part affected; if it be near the duodenum, in the neighborhood of the transverse arch of the colon, or just below it, and deeply seated, or between the umbilicus and left ilium, and no diarrhea or dysentery be present, the jejunum is probably affected; if the pain be of a griping or colicky character, and be located in the region of the cæcum, or along the course of the colon, and increased in severity some hours after a meal, diarrhea or dysentery being also present, the cæcum, colon, or both, may be affected. The stomach is seldom affected when only the inferior part of the ileum, and the colon are diseased, unless constipation be present. If there be a sense of fullness and pain in the right iliac region while standing, or after a walk, with dullness on percussion, constipation being present, it is probably due to abnormal distension of the cæcum from accumulated feces, in which case pressure on the last dorsal or genito-crural will cause pain in the region of the hip, groin, testicle, etc. But inflammation of the cæcum is gen-

erally accompanied with diarrhea or dysentery, with pain, and also with great exhaustion if all the coats are affected. But, it must be remembered that, severe pain in this region may arise from simple distension of the cæcum, and that diseased spine or renal calculus may also occasion pain in the regions heretofore named. *Percussion* may also be employed to aid in determining the seat of the disease, as well as in determining the parts most distended or obstructed by flatus, adhesion or thickening of the intestinal coats, fecal accumulations, etc.; much pain, upon percussion or pressure, is an indication that the outer coats of the bowels are affected.

If the stools are mucus, or muco-puriform, the mucous membrane alone may be affected, or, the follicular glands may also be involved. If flakes of albuminous matter, or shreds of lymph are present, with a serous condition of the discharges, the serous membranes are diseased. If the fecal matters consist of imperfectly digested food, the upper portion of the intestines are disordered; and, if the peculiar natural odor of the stools is absent, it may be due to disease of the large intestine. A thickened, contracted, dilated, ulcerated, perforated, or cancerous condition of any portion of the intestines, is very difficult, and, in most cases, impossible, to detect during life; and there are no symptoms belonging to either of these conditions that can positively be asserted as peculiar to it.

Grumous or muco-puriform stools are indications of ulceration; considerable pure blood may proceed from the large intestines. Of course, in connection with these various indications, which, although of great aid in the diagnosis, can not be absolutely relied upon, we must take into consideration the anterior conditions of the patient, the causes to which he has been exposed, the anatomical location of the chief symptoms, together with the character, severity, etc., of all the symptoms present,—requiring on the part of the examiner, patience, carefulness, and a proper knowledge of the physiology, pathology, and anatomy of the parts interested.

The *prognosis* of enteritis is more favorable when the disease is of recent origin, and occurs as a sequelæ of acute inflammation, than when it has been of long duration, or, has gradually manifested itself without any anterior acute disease. When the general system becomes greatly disturbed, when there is much emaciation, debility, nervous irritability, and irregular condition of the digestive powers and of the bowels, or, when there has been a long-continued muco-purulent, or bloody discharge, the prognosis is unfavorable. However, an amelioration of these symptoms under treatment, with increase of strength, is favorable, and much more so when it continues permanently advancing. Under any circum-

stances, when curable, from one to two years will be required to effect a thorough cure. (*See Diagnosis and Prognosis*, under Chronic Gastritis.)

The *pathological appearances* met with in chronic enteritis will be found to vary according to the location, severity and extent of the disease, the coats affected, and the morbid alterations produced by it. Numerous red patches may be observed upon the mucous membrane, with or without elevations; or, this membrane may be thickened, indurated, or ulcerated. The villi frequently present a blackish tint; the follicles and glands become enlarged and prominent; and a granular and thickened condition of the mucous membrane often prevails to a greater or less extent. Gray discoloration is frequently observed as minute zones around the solitary glands. Ulceration and perforation of the mucous coat only, or of all the intestinal coats is often observed; and, in some rare instances, cancer, in some one of its forms, may be present. Sometimes false membranes, and abnormal adhesions of the intestines will be observed; and, in other cases, a dilated, or contracted condition of the affected part of the intestine. Most generally, other organs, as, the liver, stomach, lungs, kidneys, or mesentery, etc., will also be found more or less seriously diseased, and especially when the enteritis is not confined to the mucous intestinal coat.—The appendix cæci will frequently be found affected, either increased in length, atrophied, or dilated, and it may contain various indigestible substances that have been swallowed at a previous period, some of which may have developed very serious disorder during life, and perhaps have been the commencement of the enteritic malady. The muscular, as well as the submucous intestinal coat, is sometimes hypertrophied or thickened. And when the peritoneal coat is affected, it will present some of the appearances named under Chronic Peritonitis.

The *treatment* of chronic enteritis is about the same as that laid down for Chronic Gastritis, *which see*, and which it is unnecessary to repeat here; being very careful to avoid the use of all irritating or drastic cathartics. Bismuth, Citrate of Iron and Strychnia in small doses, Sheep Laurel, dilute Hydrocyanic Acid, Cinicifugin, Opium, Hyoscyamus, etc., with demulcent drinks, counter-irritation, diaphoretics, and diuretics, are among the agents to be employed at first; and, as the more active symptoms pass away, we may have recourse to a careful employment of vegetable tonics, alteratives, and diuretics, together with a proper attention to hygiene. Counter-irritation or stimulating liniments along the dorsal and lumbar regions of the spinal column, so as to produce a more

or less constant burning sensation, are of very great utility, and should never be omitted. Should flatulency, nausea, or vomiting be present, treat as named under *Dyspepsia*. Diarrhea is frequently met with in enteritis, and sometimes dysentery; these affections will be separately treated upon hereafter, and the reader is referred to them; under Chronic Diarrhea will also be mentioned the treatment which I have found the most successful among children laboring under diarrhea from chronic follicular enteritis. When the disease partakes more of the character of disease of the peritoneal coat (sero-enteritis) it will require a careful combination of the methods of treatment adapted to both chronic gastritis and chronic peritonitis; or, if the peritoneal symptoms predominate, the treatment for the last named affection may alone be pursued.

CHRONIC PERITONITIS.

Chronic Inflammation of the Peritoneum may follow the acute form of peritoneal inflammation, or, it may gradually manifest itself without any previous acute attack, in which case it is very apt to be associated with a tendency to tuberculous or cancerous formations in some part of the thoracic or abdominal cavity. Sometimes it supervenes on continued remittent fevers, exanthema, acute dysentery, etc. The disease may be partial or general. All ages are liable to it.

When chronic peritonitis follows the acute form, or is due to metastasis of disease, to suppression of cutaneous affections, or, to any previous inflammation of the viscera, the exudations into the peritoneal cavity remain, either in an organized or inorganized form. The usual *symptoms* are, deep-seated pain or soreness across the abdomen, which often intermits, and is increased by motion, fatigue, contraction of the abdominal muscles, or, upon pressure being made over the affected part. In connection with this there may be nausea or vomiting, difficult digestion, thirst, sleeplessness, want of appetite, a rather quick, full pulse, globus hystericus, oppression after eating, and some hours after the meal an increase of pain,—together with constipation, which may alternate with diarrhea; but these symptoms are not present in every case. If these symptoms do not pass away under treatment, or after a few weeks or months, the abdomen gradually enlarges more or less, according to the amount of effused fluid present, and which enlargement is usually the greatest toward evening; percussion will detect the existence of fluid, and will also often augment or produce pain. (*See Ascites*,

page 480.) If there be no fluid in the abdominal cavity, the abdomen will frequently appear diminished, or flat, or, a slight enlargement and hardness about the umbilicus may be observed, which is due to agglutination of the small intestines. As the chronic disease advances, the features become sharp and contracted, and the countenance is sunk, anxious, pale, sallow, and doughy. Debility and emaciation become more and more marked; the skin presents a dry, unhealthy appearance; obstinate constipation usually prevails, but it may, as in the earlier stage, alternate with diarrhea, and, in some cases, especially toward the latter period of the disease, diarrhea will be constantly present. Cough; difficult breathing; and frequent pulse, particularly during the latter part of the day, are often added to the other symptoms. Finally, exhaustion comes on, with hectic fever, and an œdematous condition of the legs, and death ensues from extreme prostration, inanition, or from the fatal character of the lesions caused by the disease.

In many instances, the disease may continue for an indefinite period, with a swollen and hard abdomen, but little pain or uneasiness, and the constipation may be constant, or, alternate with diarrhea.

Chronic peritonitis following the acute attack may be partial or general, according to the character of the active disease in this respect. When it occurs after enteritis, colitis, hepatitis, dysentery, or chronic gastric ulceration and perforation, it is more apt to be partial, and may, in robust habits, continue for years, without giving rise to any very troublesome symptoms, but in debilitated and scrofulous systems, it frequently becomes general, and is more liable to present the symptoms above named.

The disease may terminate in recovery, the effused fluid being gradually absorbed, discharged through neighboring organs, or transformed into tissue. Or, it may result in the formation of adhesions and false membranes, thickening of the peritoneum, suppuration and ulceration, etc.

When chronic peritonitis is associated with a tubercular or cancerous cachexia, it may present many of the symptoms just named for the non-cachectic affection; but most generally, it comes on so insidiously and gradually, that the patient is not aware that anything serious is the matter with him, until the symptoms indicate an advanced state of the disease. Perhaps the first noticeable symptoms are a slight acceleration of the pulse, loss of strength, inability to exercise long at a time, gradual loss of weight, emaciation, variable appetite, irregularity of the bowels, and morbid and offensive stools. Pain is rarely present at an early period, though a sense of fullness or uneasiness in the abdomen is complained of,

and deep pressure not only detects an unnatural hardness, but also occasions uneasiness, tenderness, or pain; sometimes there will be colicky or griping pains, or a sense of heat in the abdominal cavity, especially around the umbilicus.

In an advanced state of the disease, the symptoms are more marked, the tongue is red, glazed, and often irregularly fissured; the pulse is quick, small, and weak; a hectic flush upon the cheeks manifests itself; there is more or less night perspiration; debility much increased; frequently nausea or vomiting; and a scanty, high-colored urine depositing a reddish sediment. Pain is also experienced, usually at irregular intervals; certain parts of the abdomen become very sensitive to pressure, or motion; the abdomen becomes very much enlarged, while the body and limbs are greatly emaciated; the countenance presents an anxious appearance; the eyes are sunken; and diarrhea becomes more persistent and obstinate. The patient may die from exhaustion, from acute inflammation suddenly supervening, or, from ulceration, perforation, etc.—If there be considerable effusion into the peritoneal cavity, the only symptoms observed may be emaciation, anemia, enlargement of the abdomen, and fluctuation. When children are attacked by the disease, pain and diarrhea usually attend from the commencement.

Both forms of chronic peritonitis are apt to be complicated with disease of other organs; the non-tubercular form with chronic enteritis, colitis, inflammation of the cæcum, gastritis, duodenitis, or hepatitis, etc. The tubercular, with strumous disease of the mesenteric glands and other portions of the alimentary canal, phthisis, tubercles in the cerebral membranes, ovarian, renal, and uterine disease, etc. Children are very liable to the latter form.

The *diagnosis* of chronic peritonitis is not always readily made out, except in cases, immediately preceded by the acute form of the disease, or, where the chronic form is general. A constant tenderness or pain in the abdomen, with or without pressure, and especially when confined to one location, a tendency to constipation, and a slight acceleration of the pulse, conjoined with, either, an evident accumulation of fluid in the peritoneal cavity, a full, rather tense, and tympanitic condition of the abdomen, or, a hardness felt in a particular location, are pretty certain evidences of peritoneal disease; and especially when emaciation and debility are also present. The strumous or cachectic form of the disease, is more gradual and insidious in its approach, and pain may be wholly absent; the debility and emaciation are greater, as well as the abdominal enlargement, and the tendency to diarrhea, and

there are almost always evidences of a strumous disposition of the system. If the disease be associated with cancer, it generally occurs during, or after middle age, and, in addition to the debility and emaciation, the face presents the peculiar sallow hue of malignant disease. Severe transient lancinating pains may be occasionally experienced; and careful pressure may detect tenderness, as well as the rounded nodules of cancer under the muscles of the abdominal walls.

When there is no enlargement of the abdomen, nor hardness, and diarrhea is present, it must be remembered that these conditions also accompany intestinal ulceration. (*See Ascites, Diagnosis*, etc., page 480.)

The *prognosis* of chronic peritonitis is favorable when the disease occurs in young persons of good constitution, and has been placed under proper treatment at an early period; in persons somewhat advanced in life, or when the disease has been allowed to progress, it is less favorable. Slight attacks, or cases where the peritonitis is partial; are much more favorable than when the disease is general. When associated with cachexia, chronic peritonitis is rarely, if ever, curable.

The *pathological appearances* vary considerably in this disease. In the non-tubercular variety, more or less effusion of serous fluid, of a clear and yellowish character, or, turbid, grayish, brownish, or even sanguineous, will be observed, and which may be mingled with pus, shreds of coagulable lymph, or, pieces of solid matter. When the abdomen is distended by this accumulation of fluid, the intestines will be found forced toward the spinal column. The peritoneum covering the different viscera presents appearances of inflammation which may be partial or general; this membrane will also be found thickened, and roughened, or covered with granulations, of a lardaceous aspect, and grayish color, with streaks of blood and red spots. Numerous bands or false membranes will be seen, which agglutinate the intestines to each other, or form various adhesions between the peritoneum, omentum, etc., but this is not always the case. Frequently the false membranes are organized, sometimes so much so as to be identified with the peritoneum, and rendering it difficult to determine their exact limits. In many instances considerable gas will be discovered in the intestines, and sometimes in the peritoneal cavity. The omentum is greatly thickened, frequently as thick as a person's hand, red, fleshy, and often occupied with small cysts. Sacs containing a fluid are often formed by the false membranes. Sometimes, there will be no effusion, but the whole surface of the peritoneum

will be coated with lymph. Numerous black patches, resembling a gangrenous condition, are sometimes present, and which have been considered melanotic deposits. Erosions, or ulceration and perforation of the intestines may also be observed, through which openings, either the contents of the alimentary tube may pass in to the peritoneal cavity, causing sudden death, or, pus may find its way to be discharged externally through the abdominal walls. Other coats of the intestines may become involved in the disease, whether the peritonitis be primary, or consecutive upon mucous enteritis, etc., and the disease may be found to extend to various parts of the alimentary canal, either as a partial or general affection, and may even be complicated with hepatitis, nephritis, cystitis, splenitis, etc. Gangrene very seldom happens in chronic peritonitis.

When the peritonitis is associated with cachexia, in addition to the presence of organized or inorganized false membranes, formed by coagulated lymph thrown out from the effused surface; adhesions, etc.; tubercles will be present, covering more or less of the peritoneal surface, and which may contain a hard cheesy substance, be softened, or have proceeded to more or less extensive ulceration and perforation. These tubercles will vary in size from that of a small pin's head to that of a pea. More or less serous effusion may also be present, constituting dropsy, or, it may be wholly absent. The mesentery and its glands are almost always involved, presenting strumous infiltration or tubercles; and it is not uncommon to find tubercles on the peritoneal surface of the stomach and alimentary canal, either in a crude, softened, or ulcerated condition. Frequently a tympanitic condition will be observed, due to loss of the contractile power of the intestinal muscular fibre. More commonly tuberculous affections will also be found to exist in other organs, as, the brain, throat, lungs, etc.—Cancer, cartilaginous indurations, ossification, and calcareous or ossific deposits, are occasionally associated with the disease, either as a cause or as a result.

The *treatment* of chronic peritonitis following the acute form, will consist in adopting measures that will divert irritation from the peritoneum, as, attentions to the bowels, kidneys, and skin, by means of gentle laxatives, diuretics, frequent bathings, and counter-irritants to the dorsal and lumbar spinal region, and across the abdomen. But in those cases that are usually presented to the clinician, and which are generally of long standing, the means pursued should be the same as for the tubercular form of the disease. Daily evacuations must be procured by means of mild

aperients, as, for instance, the Powder of Rhubarb and Bicarbonate of Potassa, heretofore referred to. The surface of the body and limbs should be bathed daily, or every other day, with a weak alkaline solution, or with salt water; and the Spirit Vapor Bath should be administered every one, two, or three weeks, according to the strength of the patient. Internally, those alteratives should be given that are known to be beneficial in tuberculous affections, and that will promote the activity of the absorbents, and remove or prevent effusion, as, Compound Syrup of Yellow Dock, Solution of Iodide of Potassium, of Iodide of Ammonium, of Bromide of Potassium, or of Bromide of Ammonium, etc.; frequently changing the alterative, or alternating it with others, whenever it appears to have lost its original promptness of action. In many instances, I have derived much advantage from the Iodine Pill. If the patient be pale and anemic, some iron preparation will prove useful, as, Carbonate of Iron, Citrate of Iron and Quinia, Citrate of Iron and Strychnia, etc. The following will be found a very valuable agent in this and all other diseases, where it is desired to combat struma, debility, constipation, flatulency, and anemia, and excite activity of the absorbents: Take of Blue Flag Root, Black Cohosh Root, each, in coarse powder, two ounces; Yellow Dock Root, Bark of Bittersweet Root, Peruvian Bark, Sassafras Bark, Prickly-ash Berries, each, in coarse powder, one ounce, Soluble Pyrophosphate of Iron five drachms; Glycerin, No. 2, forty-two fluidounces, Water twenty-two fluidounces; mix the articles, and form a syrup by percolating with heat. The dose is from a fluidrachm to half a fluidounce, three or four times a day. This is a preparation that I prize very highly, and now make known for the first time. Sometimes, instead of the above proportions of fluid, I prepare it by adding to the coarsely bruised articles, Whisky sixteen fluidounces, Glycerin, Water, of each, twenty-four fluidounces.

Stimulating diuretics should also be given, in which one of the above-named Iodide or Bromide Salts may be dissolved, as, infusion of Queen of the Meadow, Thimble Weed, Mountain Pink, Parsley, Juniper Berries, Spearmint, Pipsissiway, etc.; the Acetate of Potassa added to an infusion of Juniper Berries and Water-melon Seed, will be found exceedingly efficacious in many instances. The Compound Infusion of Parsley, as well as the Compound Infusion of Trailing Arbutus, have also proved of service. Counter-irritation along the dorsal and lumbar spinal region should be persevered in by means of active rubefacient liniments, dry cupping, and firing, applied alternately. And, in obstinate cases, a constant purulent

discharge should be maintained from the whole abdominal surface, by means of the Compound Tar Plaster; where this occasions great irritability or debility, it should then be used intermittingly. And where it can not be borne at all, terebinthinate liniments, freely applied over the abdomen, may be substituted; but they will not be so prompt nor as efficacious.—With many persons, and especially among children laboring under strumous disease of the alimentary canal, the following, rubbed freely over the abdomen every day, will be found valuable: To Oil of Juniper two fluidounces, gradually add, in a mortar, one drachm of Iodine; triturate until the Iodine is dissolved. This does not discolor the skin.—Cod Liver Oil has been advised internally, but I know nothing of its effects in this disease; it will, no doubt, prove useful in cases where strumous disease exists, and especially among children. Rubbed freely over the whole surface of the body, every night and morning, it will be found very useful in strumous disease of the alimentary canal, among children.

If there is but little or no effusion, and diarrhea or dysentery is present, treat as named under these affections. But if considerable effusion has occurred, and the above-named treatment does not, after a reasonable length of time, effect any favorable influence upon the disease, it should then be treated the same as advised for Dropsy of the Abdomen, page 480.—Any painful or distressing symptoms that may arise must be treated on general principles. When other organs are also affected, we should endeavor to select and combine our remedies in such a manner that, without rendering them too disagreeable or repeating them too frequently, a simultaneous sanitary influence may be experienced by all the diseased organs.

A nutritious diet should be used, carefully avoiding all articles that disagree with the patient, or that give rise to unpleasant symptoms. Regular moderate exercise is of service, except in cases where fluid is present, when passive exercise, and such as will not cause much increased movement of the abdominal organs, will alone be sufficient. Active purgation must be especially avoided in this disease, except when ascites is the principal symptom.

CHRONIC DIARRHEA.

Chronic Diarrhea is a malady frequently met with by the practitioner, and is sometimes apt to be very obstinate, and even unyielding to treatment. It is generally the result of a previous acute

diarrhea, and may be due to morbid excitability of the intestines remaining after the acute attack has passed away, to a morbid condition of the liver, or, to intestinal ulceration. Very frequently, it is an attendant of chronic enteritis. Dissipated habits, abuse of purgatives, and overworking, frequently give rise to it; as well as uncleanness, exposures to cold and moisture, to malaria, etc. With some persons there is a tendency to diarrhea whenever certain articles of food are swallowed, and which can only be prevented by avoiding the use of such articles.—There are several varieties of diarrhea that have been noticed by authors, as, *diarrhea crapulosa*, where the evacuations are healthy, but too large in quantity, or of too fluid a nature, and frequently discharged. *D. serosa*, where the discharges are of various colors, and consist of thin feces mixed with a watery or serous fluid, albuminous shreds, etc. *D. mucosa*, or catarrhal diarrhea, in which the stools contain a large amount of thin gelatinous mucus, sometimes inodorous, and at other times very offensive. *D. biliosa*, in which more or less bile is mixed with the stools. *D. dysenterica*, in which more or less blood is mixed with the stools.—All these varieties may pass into the chronic form of the disease, more especially the last three.—It must, however, be remembered that obstinate and long-standing diarrhea is not always an idiopathic malady; many cases of alvine looseness occur, in which the discharge is one of the attendant symptoms of an intestinal tuberculous affection, pyemia, scurvy, Bright's disease, etc., and will only permanently disappear after the original malady has been cured.

The *symptoms* of chronic diarrhea are, more or less frequent discharges from the bowels, and which may or may not be attended with tenesmus. The character of the discharges vary very much, being similar in color, quantity, and quality, to what has already been described under Chronic Enteritis. They are usually of a dark color, and quite offensive; and sometimes the diarrhea will alternate with a constipated condition, but without any amelioration of the intestinal irritability. In addition to the looseness, there may be more or less pain or griping, restlessness, thirst, impaired appetite, debility, and gradual emaciation; the skin becomes dry and rough, and of a sallow hue; the tongue dry, and often dark-colored; the abdomen flat or sunken; and great nervous irritability and peevishness. Mesenteric disease, emaciation, and exhaustion, which usually attend chronic diarrhea, will, after a longer or shorter period, occasion death.

The *diagnosis* of chronic diarrhea is very readily made out; but it is not so easy to determine the portion of the intestinal canal from whence the disease proceeds, nor its peculiar pathological

condition. When the stools are whitish or grayish, like mucilage, containing considerable mucus, or muco-puriform fluid, occasionally streaked with blood, or presenting long whitish filaments or shreds, we may generally diagnose the diarrhea as mucous, or muco-purulent. If these products be separate and unmixed with the feces, the disease is probably located in the inferior portion of the colon, in the rectum, or in both,—when in the rectum, tenesmus is apt to be present. If they are mixed up with an abnormal amount of a watery or serous fluid, that coagulates by heat, the mucous membrane of the ileum is probably the part affected, or the superior portion of the colon. The fluid in this form of diarrhea is generally of an alkaline reaction, containing crystals of triple phosphates. It is not uncommon for this disease to alternate occasionally with constipation, as is frequently observed when the looseness is the result of chronic enteritis; in which affection, there may also exist a hepatic disease, causing what may be termed a muco-bilious diarrhea.

When blood is mixed with the discharges, in clots or fibrinous, it is an indication of ulceration, and more especially, if pus be mixed with it. The higher up in the alimentary canal the source from whence the blood proceeds, the more will it be dark and semi-digested; when of a black, pitchy character, it has been acted upon by the gastric juice.—In bilious diarrhea, the stools exhibit various shades of yellow, brown, or olive-green, according to the absorption of oxygen by the bile, and its mixture with the feces; the peculiar odor of bile will also be detected to a greater or less extent,—and the more bile present, the less offensive will be the discharges. It must, however, be borne in mind, that a grass-green discharge, of a putrid or cadaverous odor, without any smell of bile, is due to altered blood in cases of congestive inflammation of the mucous membrane, and is always accompanied by symptoms of febrile reaction.—If there is a large amount of watery fluid present, it may be due to a want of nervous power of the alimentary mucous membrane.—When the diarrheic discharges are putrid, it indicates an imperfect quantity of bile in them.—When ropy, or slimy, with a dark dirty-green color by reflected light, and greenish yellow by transmitted light, it will often be found to consist of algoid cells and filaments, in small gelatinous masses, and is very apt to be accompanied with pain or tenderness, involuntary stools, dryness of skin, emaciation, an increasing enervation of mind and body, and other symptoms of nervous prostration and a peculiar saccharine or fermentative tendency of the secretions. The urine is apt to be scant, and loaded with

urates and oxalates; and considerable flatus is present. This form of chronic diarrhea is common among soldiers in active service, and requires the avoidance of amylaceous and saccharine diet, and a free use of antiscorbutic.

The *prognosis* of chronic diarrhea will differ according to its cause and character. When the result of a muco-enteritis, and of not too long standing, it may be considered favorable; in this case, if the stools become yellow, opaque, evolve the odor of bile, and lose their putridity, the indications are good; on the other hand, they are bad, if the discharges continue white, or tinged with blood, putrid, and alkaline. When the stools are very fetid, and consist of a large amount of watery or serous fluid, presenting matters like the washings of macerated flesh, with progressive emaciation and debility, the indications are very unfavorable. A diminution in the frequency and quantity of the discharges, together with an improvement in strength and appetite, are favorable symptoms. Bilious diarrhea in connection with dyspepsia is not very favorable, though cures have been occasionally effected. Chronic diarrhea from intemperance, or accompanying obstinate dyspepsia, organic disease of the liver, kidneys, lungs, spleen, or a strumous disease of the alimentary canal, intestinal ulceration, or cancerous disease, purpura, scurvy, uræmia, pyæmia, or other depraved conditions of the blood, is always of a serious character. The more the diarrhea assumes a dysenteric character, the more unfavorable is its prognosis.

The *pathological appearances* observed in chronic diarrhea, are various. In mild cases, the intestinal mucous coat may be found pale, or of a dingy-slate color, and bloodless; in some cases, this membrane may be covered by a thick layer of brownish, grayish, or puriform mucus, or, it may present patches of hyperemia scattered here and there, more especially in the neighborhood of the ileo-cæcal valve. Again, the only abnormal condition present, may be an unnatural development of the follicles and villi. In severe, and more advanced cases, there may be an inflamed and congested condition of the mucous membrane, with vascular discoloration in streaks and patches, presenting a variety of tints, from a rose, to a brownish or purplish. The mucous membrane, as well as the submucous tissue may be œdematous, thickened, and very much softened; and the mucous folds are often obliterated, the intestine presenting a smooth internal surface, due probably to flatulent distension. Sometimes, a diminished or contracted diameter of that portion of the canal affected will be observed, due to the irritable condition of the part. Ulcerations may be observed in the ileum, but

more commonly in the colon; either a minute ulceration distributed nearly the whole length of this intestine, and frequently at its lower part; or these ulcers may become confluent, and be attended with a thickening of the mucous membrane. These ulcerations are almost always follicular, and have a dark zone encircling each of them. More or less destruction of the mucous membrane may be present in very severe cases, with a thickening of it, and a very irregular appearance of its surface. Occasionally, perforation will be present, and, still more rarely, peritonitis. In many instances, the appearances are similar to those observed in chronic enteritis, of which disease, indeed, the diarrhea is often only a symptom. Sometimes the mucous membrane of the rectum may present a state of hyperæmia, or thickening, or enlargement of the follicles and villi, and in some instances, an abraded or ulcerated condition of one or more parts of it may be observed, especially in the vicinity of the anus; but these appearances are by no means common except in severe and obstinate cases.—When diarrhea is associated with, or is due to a strumous disease of the intestinal mucous membrane or of the mesentery, tubercles, in some one or more of their stages, will also be present. A tendency to fatty degeneration of the liver is by no means uncommon in obstinate and long-standing cases of chronic diarrhea.

One of the most important points in the *treatment* of chronic diarrhea is a rigid attention to diet, making use of the least irritating and most easily digestible kinds of nourishment, as, milk, rice, toast-bread, arrow-root, sago, or tapioca, good beef or mutton tea or broth, oyster soup, plain chicken broth, soft-boiled eggs, etc. Articles, whatever may be their character, that irritate the alimentary canal, or increase the diarrhea, must especially be avoided; and it will sometimes be found that nearly or quite all articles belonging to a certain class will have to be relinquished on account of their augmenting the disease, as, albuminous or proteinous; fats or hydro-carbons; hydrates of carbon, as, starchy or saccharine substances, especially; salines; aqueous articles, etc.; frequently, it will become necessary to wholly omit the use of all articles containing yeast or fermenting agents. For drinks, barley-water, rice-water, thin gruel, and similar fluids may be used; and, sometimes, benefit will follow the addition of a little wine or brandy, with grated nutmeg or loaf-sugar to flavor; but great care must be had in allowing such additions. In many cases a diet solely of milk and lime-water, will of itself effect a cure, when the diarrhea is not due to a permanent chronic cause; where there is feverish excitement present it may be iced, and, occasionally, a solu-

tion of bicarbonate of soda may be substituted for the lime-water. Well-boiled rice, flavored with cinnamon, or, boiled milk with powdered cinnamon added to it, will often be of service as articles of diet, in cases where they agree, or are not contra-indicated. Not unfrequently the careful use of antiscorbutics, as, boiled cabbage, boiled onions, boiled carrots, ripe acid fruits, etc., will be of service, especially in those cases where the original cause of the diarrhea is the too exclusive use of an amylaceous or saccharine diet. But it must be borne in mind, that in very obstinate cases of diarrhea, it often happens that any article whatever, fluid or solid, that is introduced into the stomach acts mischievously, and it then becomes necessary to allow only a few spoonfuls of warm fluid nourishment at a time, and, perhaps, to suspend the use of all food by mouth until the alimentary canal becomes enabled to endure its presence.

An attention to the surface of the body, is also an important point; the whole surface should be frequently bathed with a warm, slightly acidulated water, and, if the strength of the patient will permit, a moderately acting Spirit Vapor Bath should be administered once in every two or three weeks. Active stimulating liniments should be applied twice a day over the whole of the abdomen, and along the dorso-lumbar region, applying them with considerable friction each time. The feet, chest, and back, should be especially kept warm, and protected from cold. Exercise may in some cases be permitted, where it exerts no mischievous influence,—it should always be of a passive character; but, in very severe and obstinate cases it must be dispensed with, and quiet and rest be substituted.

When the cause of the diarrhea is known, we must endeavor, if possible, to remove it. If the patient be residing in an impure, unhealthy atmosphere, he must change to one of an opposite character. If the alimentary canal is kept in an irritable condition by indigestible food, retained secretions, or scybala, Linseed Oil, Castor Oil, or Compound Syrup of Rhubarb and Potassa, with or without some opiate may be given; and the irritability of the rectum, as well as the removal of its contents, may be facilitated by a laxative enema to which some Laudanum is added. Opiates are especially useful in cases of pain, tenesmus, and dysenteric diarrhea. If the diarrhea be a symptom of chronic enteritis, the successful treatment of the latter affection will be followed by a cessation of the discharges. If it be due to strumous disease of the alimentary canal, the result will be similar to that of the preceding case, by a successful treatment of the tuberculous malady.

If the diarrhea be due to the use of certain articles of food, or active exercise, these must be rigidly avoided. If it be dependent upon other diseases than that of the alimentary canal, the correct measures for removing or relieving such diseases must be pursued. If it arise from disordered secretions, we must endeavor to restore them to a normal condition; and so on, of other causes that may originate the chronic diarrhea.

But, it is not always the case, that the removal of the cause will remove the diarrhea; the disease may have been so severe, or may have continued for so long a time, that certain changes have occurred in the tissues of the alimentary canal, rendering the malady, as it were, independent of its primary cause, and requiring entirely different means to subdue it. We can not always positively determine what these changes are, nor what is their true remedy, so that, to a great extent, the treatment in such cases is more of an empirical character.

Astringents occupy a high rank in the treatment of chronic diarrhea, from their sanative influence upon diseased or ulcerated mucous tissues, and are usually associated with cholagogues, stimulants, carminatives, or anodynes, etc., according to the indications. Various preparations have been successfully employed; as, 1. Take of Leptandrin, Geraniin, Kino, Camphor, each, twenty grains; mix, and divide into twenty powders, of which one is to be taken for a dose, and repeated every two, three, or four hours.—2. Take of Catechu ten grains, Opium one grain, Sulphate of Quinia two grains; mix, and divide into one or two powders according to the urgency of the case; this will also be found of service in the diarrhea of malarial districts.—3. Take of Sulphate of Bebeerine twelve grains, Elixir Vitriol one fluidrachm, Cinnamon Water six fluidounces; mix. The dose is a tablespoonful every two hours.—4. Dr. A. Clark recommends: Take of Elixir Vitriol twenty minims, Paregoric one fluidrachm, Chloric Ether ten minims, Essence of Peppermint half a fluidrachm, Syrup of Red Poppy one fluidrachm, Decoction of Logwood one fluidounce; mix for a dose, to be repeated every four, five, or six hours, according to the urgency of the case. This is not useful in phthisical or dysenteric diarrhea, but is especially useful to correct fecal fermentation.—5. Take of Geraniin five grains, Compound Powder of Ipecacuanha five grains; mix for a dose, to be repeated four or five times a day.—6. Take of Elixir Vitriol half a fluidounce, Compound Spirits of Lavender, (or Tincture of Prickly-ash Berries), Syrup of Ginger, each, one fluidounce; mix. The dose is a tablespoonful every hour. Useful in cases accompanied with much

flatus.—7. Take of Carbazotate of Ammonia, Gallic Acid, each, one grain, Opium one-sixth of a grain; mix for a dose, to be repeated three or four times a day.

Many other articles have also been found useful, as, Decoction of Blackberry Root, Beth Root, Rock Brake, Galium Tinctorium, or Epilobium, etc. The Trisnitrate of Bismuth is very frequently useful, especially in diarrhea from chronic muco-enteritis; it may be given in water, mucilage, or glycerin, or, if much acid be present, in association with calcined magnesia. Tincture of Muriate of Iron, in doses of twenty drops in a gill of water, repeated three or four time a day, and persisted in for some time, will often effect a permanent cure.

When it is necessary to stimulate the liver, and correct the secretions, it will become necessary to employ other agents, as, White Liquid Physic; or, Podophyllin, Leptandrin, etc., may be combined with the other remedies employed.—If much acidity be present, the Compound Powder of Charcoal, (*see* page 743, No. 2), will prove serviceable; Calcined Magnesia may also be used with advantage.—If ulceration be suspected, in addition to the other measures employed, the following will be found of great service: Take of Bugle-weed, Beth Root, Prim Leaf, and Geranium Root, equal parts; make a strong infusion, and use freely.—If much intestinal irritation is present, it may frequently be allayed by the free use of an infusion of equal parts of White Indian Hemp, Solomon's Seal, Sassafras, and Golden Seal.—In cases of strumous disease of the intestines, or in strumous habits, whether among adults or children, the following will be found useful: Take of Iodine thirty grains, Sulphate of Morphia six grains, mix thoroughly together, and then add Sulphate of Quinia thirty grains, Geraniin ninety grains, Alcoholic Extract of Black Cohosh, a sufficient quantity; mix, and divide into sixty pills, of which one is a dose, to be repeated twice a day. I generally use in combination with this, the above infusion of Bugle-weed, Beth Root, etc. For children, the pill may be divided into two, three, or four parts, as required, and be rubbed up with a little burnt brandy. Or: Take of Bromide of Ammonium one drachm, Water two and a half fluid-ounces, Solution of Perchloride of Iron one hundred minims; mix. The dose is a teaspoonful, to be repeated three times a day; this is invaluable in many instances. I now publish it, having used it with considerable success, in conjunction with the above-named infusion of White Indian Hemp, Solomon's Seal, etc. It will also be found valuable in anemia of strumous persons.—Where there is tenesmus, griping pains, or dysenteric diarrhea,

injections will prove of service. A very useful one is composed of Tannic Acid five or ten grains, Water or Port Wine a fluidounce, Compound Tincture of Virginia Snakeroot half a fluidrachm; this injection should be repeated several times a day, according to the severity of the case, and be retained as long as possible, each time. Or, the introduction of suppositories into the rectum, every night, or every night and morning, composed each of Butter of Cacao nine grains, Opium from half a grain to two or four grains, will allay the excessive irritability of the rectum and colon. In dysenteric diarrhea, injections of a weak solution of Perchloride of Iron, or of Nitrate of Silver, will be found very useful.—In the catarrhal diarrhea of children the following may be used: Take of Borax four drachms, Infusion of Golden Seal three fluidounces, Glycerin, No. 2, one fluidounce; mix for an injection.—In cases where there is great exhaustion or paralysis, the stools passing involuntarily, the following has proved useful: Take of Tincture of Prickly-ash Berries four fluidounces, Tincture of Nux Vomica half a fluidounce; mix; add a fluidrachm of the mixture to a fluidrachm or two of infusion of Solomon's Seal, inject into the rectum, and retain as long as possible. This may be repeated three or four times a day.

When there is great prostration and anemia, Nux Vomica may be administered as follows: Take of Alcoholic Extract of Nux Vomica ten grains, Podophyllin four grains, Carbonate of Iron twenty grains, Alcoholic Extract of Black Cohosh, a sufficient quantity; mix, and divide into twenty pills, of which one is a dose, to be repeated every four hours. Or, the following: Take of Bromide of Potassium a drachm, Bromine ten minims, Extract of Nux Vomica three grains, Water half a pint; mix. The dose is a tablespoonful every three, four, or six hours; this will be found useful in cases of chronic diarrhea due to excess of amylaceous food, where there is a torpid condition of the alimentary epithelial surfaces, congestion of the intestinal capillaries, and an obstructed condition of the portal system. Or, the following may be used: Take of Citrate of Iron and Strychnia forty grains, Bromide of Potassium forty grains, Infusion of Sassafras, or of Cinnamon, two and a half fluidounces; mix. The dose is a teaspoonful, to be repeated three times a day. Or, where ulceration is also suspected, the following pill has been of benefit; take of Nitrate of Silver three grains, Extract of Nux Vomica twenty-two grains, Extract of Hyoscyamus twelve grains; mix, and divide into twelve pills, of which one is a dose, to be repeated morning and night. In conjunction with which the preceding infusion of Bugle, Beth, etc., may be used.

Where fermentation continues, as known by the greenish algaic cellules in the stools, Elixir Vitriol, Hyposulphite of Soda, or dilute Nitro-hydrochloric Acid may be given two or three times a day. Pulverized Nutmeg will also be of service in doses of ten grains two or three times a day. Phenol Sodique has also proved useful.

Where the urine is scant, Acetate, Citrate, or Bitartrate of Soda should be administered to increase the flow; if oxalates be present, dilute Nitric, or Nitro-hydrochloric Acid should be given.

In chronic mucous diarrhea, the balsams and terebinthines will frequently prove serviceable. Four or five drops of Oil of Turpentine may be taken in a teaspoonful of Syrup or of Glycerin, and be repeated every three or four hours; or, a tablespoonful of the following may be administered three times a day: Take of Olive Oil one fluidounce, Oil of Turpentine one fluidrachm, Gum Arabic, Water, each, four ounces; mix, and make an emulsion. But I rarely employ these agents.

CHRONIC DYSENTERY.

Chronic Dysentery or Colitis* may be a sequel to the acute form of the disease; may be the result of a diarrhea, or be complicated with a chronic enteritis; it may also take place from irritating substances in the intestines, indigestible food, suppressed perspiration, exposures to cold and dampness, and especially when these are conjoined with malarial influences; or, it may also be associated with an abnormal condition of the blood, as met with in chronic hepatitis, or splenitis. All ages and sexes are subject to it.

The *symptoms* of chronic dysentery resemble those of the acute form, but in a less marked degree. There is less fever, perhaps, no appreciable febrile action; tenesmus is absent, or else is very slight; the stools vary in number from three to forty per day, and consist of blood and mucus mixed with pus, and, in some instances, of nearly pure blood. Diarrhetic evacuations, without any admixture of blood, are by no means uncommon, and may vary in consistence, color, and character; and, in such cases, great intestinal irritability is apt to exist. The discharges are almost invariably fetid, and are very apt to be preceded by sharp, griping pains in the course of the colon, or, by obscure pain and flatulency. Occasionally, the dysen-

*It must be recollected that colitis may exist without dysentery; and that dysentery instead of being a mere colitis, may be due to some abnormal condition of the blood.

teric discharges alternate with constipation. Feculent matter may also be discharged either in a fluid form, or in scybalous masses.

In addition to these symptoms, the general system will suffer more or less; manifested by some acceleration of pulse toward evening; increased redness of the body of the tongue; dry and parched skin; pallid or sallow, and often a bloated appearance of the countenance; debility, irregular appetite; hard and tumid abdomen, but not very painful on pressure, except about the cæcum or sigmoid flexure of the colon; gradual emaciation; impaired action of the kidneys; headache; and sleeplessness. These symptoms will be more marked in some cases than in others; and may be so severe as to confine the patient to his room or bed. As the disease approaches a fatal termination, the extremities become œdematous, the features shrunk and pallid, and not unfrequently, before death closes the scene, jaundice, or ascites may supervene.

Chronic dysentery may be complicated with hepatic disease, chronic enteritis, intermittent fever, scorbutus, rheumatism, disease of the pancreas, or of the mesenteric glands, etc., which are often difficult to detect, requiring considerable care and attention on the part of the examiner. After a person has once had the disease, he will be very liable to relapses, especially upon exposing himself to the exciting causes. Death usually occurs from exhaustion, sometimes from ulceration and perforation of the intestine, and not unfrequently from pulmonary, cerebral, or hepatic disease induced by the asthenic influences of the dysentery upon the system.

The *diagnosis* of chronic dysentery is based principally upon the presence of more or less blood, or bloody mucus in the discharges, offensiveness of the stools, and the griping, or tenesmic pains. However, the practitioner should endeavor to ascertain whether the blood comes from some local disease of the rectum, as, hemorrhoids, cancerous or fungoid growths, etc.; also, whether in connection with the dysentery there exists any abnormal condition of the blood, or any complication with lesions of adjacent or distant organs,—conditions not always easy to determine.

The *prognosis* of chronic dysentery can not be said to be favorable, as we can not determine accurately the extent and character of the local morbid conditions that occasion it. Recent cases, of a not very severe character, in which there has not been much involvement of the general system are, as a general rule, curable; but, severe or long-standing cases, in which the general health is more or less affected, with complications or structural changes, are, to say the least of them, of very uncertain prognosis.—In cold climates the prognosis of dysentery is more favorable than in hot; and when

dysentery occurs in connection with malarial fevers, or is due to malarial influences, the danger is much greater than under opposite circumstances. Under the most favorable conditions, and on account of the great amount of mischief that has to be repaired, the cure of chronic dysentery is very protracted, frequently requiring six, ten, or even eighteen months.

The *pathological appearances* observed in chronic dysentery are often of such a moderate character as not to account for the severity of the phenomena observed during the life of the patient, and such as would lead to the supposition that the dysentery was not wholly due to a colitis. In instances, however, where the reverse of this obtains, more or less extensive inflammation of the mucous membrane of the colon will be observed, presenting reddish, brownish, or ash-gray discolorations; sometimes contraction of some portion of the colon will be present, with a dilated condition just above the strictured part; the texture of the mucous membrane may be altered, thickened, or divested of its epithelium wholly or partially; or, there may be a softening of the internal coats of the colon; or, perhaps, ulcerations, small and numerous, or large and few, and of a sloughy character. Occasionally, a laceration or perforation of the coats will be observed, allowing the contents of the intestine to enter the peritoneal cavity, and give rise to a fatal peritonitis. In most cases, an inflammatory or disorganized condition of adjacent organs will be observed, as, of the cæcum, the appendix vermiformis, the small intestines, the rectum, mesentery, liver, spleen, etc. When the disease has been of a scorbutic character, the mucous membrane will present a dark or livid color, with ecchymosed spots, excoriation, ulceration, and sphacelation; and the liver, spleen, heart, etc., will generally be found more or less disorganized, soft, and spongy.

In the *treatment* of chronic dysentery, and more especially in severe or obstinate cases, rest in the recumbent position is a highly important condition, and must positively be insisted upon. The intestines are not efficiently supported while sitting or standing; and in walking, not only is there an increased peristaltic action induced, but likewise direct intestinal irritation from the action of the abdominal muscles. The recumbent posture alone supports the intestines the most efficiently, and keeps them quiet.

Another very important consideration is diet. Those articles only should be allowed that are easy of digestion, that give the least work to the bowels, that induce the least peristaltic action, and that are more readily assimilated. Bland and unirritating articles, as, milk, boiled milk, farinaceous articles, buttermilk when it

agrees, mucilaginous fluids, etc., only, should be allowed in any case. But more especially when ulceration is present must a rigid attention to the diet be observed; in these cases meats, and irritating or not easily digestible articles, produce or aggravate the griping, irritation, and other symptoms, retard the progress of cicatrization, and either develop ulcers, or, when already present, render them more extensive.

As regards the therapeutical treatment, this will vary much according to the degree and character of the disease. In many instances, the treatment advised for chronic enteritis will prove successful; in others, that for chronic diarrhea; and in others, again, that named for chronic peritonitis; while a fourth class will only yield to a persevering use of astringents. In most cases the cure is effected slowly, with frequent relapses, and requiring on the part both of the patient and practitioner great care, patience, and perseverance. However discouraging a case may appear, its treatment must not be given up prematurely; for it must be borne in mind that remedies which at first were followed by beneficial results, are very apt to lose their sanative influence after having been employed for a short time, and that consequently, and particularly in severe and obstinate cases, the greatest advantages are to be derived from a change of remedies, instead of constantly persevering in the use of any one. The rule to follow is, to continue a remedy as long as it proves efficacious, and as soon as its efficacy begins to wane, then commence immediately with some other remedy, and so on.

Among the agents administered internally, from which I have derived the greatest amount of benefit, are the following: 1. Take of Rhubarb two ounces, Black Cohosh, Wild Cherry, Geranium, each, one ounce, good French Brandy, Water, each, two pints, White Sugar a sufficient quantity; mix, and form a cordial, the dose of which is a tablespoonful every hour or two.—2. Take of Beth Root, Geranium, Blackberry Root, Wild Cherry, Cinnamon, each, one ounce, Brandy, Water, each, one pint and a half, White Sugar a sufficient quantity; mix, form a cordial, and use the same as the preceding. Other astringent tonics have been found valuable in this disease, as, Tannic Acid, Statice Caroliniana, Pteris Atropurpurea, Cerastium Vulgatum, Heuchera Americana, etc.—3. In many instances, and especially when the disease is associated with a malarial influence, the White Liquid Physic, given every day in tablespoonful doses, repeated every hour or two until an alvine evacuation occurs, has proven of great value. Indeed, it will always be found useful to remove feculent matter and putrid secretions in the treatment of this disease; such accumulations in contact with an

irritated or ulcerated part, not only tend to keep up irritation, but likewise interferes with the sanative influences of astringents and other agents upon the irritated or ulcerated surfaces.

4. Take of Ipecacuanha twenty grains, Sulphate of Morphia one grain, Leptandrin ten grains, Geraniin twenty grains; mix, and divide into ten doses, one of which may be repeated every three or four hours.—Other agents have been recommended, and may prove occasionally useful, as, the Compound Tincture of Benzoin twenty drops on sugar, repeated three times a day; Trisnitrate of Bismuth eight to ten grains, mixed with Sulphate of Morphia one-fourth to one-half grain, for a dose, to be repeated three times a day; Creosote Mixture, both internally and by injection, one part of the mixture to six of glycerin, or, of whatever other enema is to be used,—this is said to be especially useful to allay irritability, tenderness on pressure in both iliac regions and tenesmus. I must not omit to state here that the Compound Powder of Charcoal has frequently proved a valuable auxiliary to the other treatment.

In strumous habits of body, I have derived considerable benefit from the following preparations: 1. Take of Iodine half a drachm, Sulphate of Morphia six grains; mix thoroughly together, and then add, Sulphate of Quinia half a drachm, Geraniin one drachm, Alcoholic Extract of Black Cohosh a sufficient quantity; mix, and form into sixty pills, of which the dose is one, to be repeated three or four times a day. In connection with this, inject into the rectum a dilute solution of Perchloride of Iron, repeating it two or three times daily.—2. Dissolve an ounce of Bromide of Potassium in a pint of Water, and give a fluidrachm of the solution for a dose, repeating it three times a day, about an hour before meal-time. Also administer twenty drops of the Tincture of Chloride of Iron, in water, for a dose, repeating it three times a day about an hour after meal-time. In conjunction with this, inject into the rectum, three or four times a day, the following mixture: Take of Bromide of Potassium six grains, Perchloride of Iron, in solution, five to ten drops, Water a fluidounce; mix for one injection.—Balsam Capaiba has been lauded in strumous cases, and in intestinal ulceration, but I have never used it; it is given every four hours in doses of fifteen minims, associated with some pleasant oleaginous mixture.

Where much prostration is present, wine, or other stimulants should be administered; and where anemia exists, preparations of iron, especially the astringent salts, are indicated. In strumous cases, and where there is much debility and emaciation, Cod Liver Oil, Hypophosphites, Elixir of Wine and Iron, or, the preparation named under treatment of Chronic Peritonitis, page 774, contain-

ing Soluble Pyrophosphate of Iron, will be found of benefit. If symptoms of scorbutus be present, Citric Acid, Lime-juice, Lemon-juice, or other antiscorbutics must be used in addition to the other remedies. If the patient has been subject to erysipelas, which is apt to render the disease very unyielding, the Tincture of Chloride of Iron will be found useful; or, in conjunction with the other treatment, the patient may drink freely of an infusion of equal parts of Maiden-hair, Elder Blows, Burdock Seed, and White Indian Hemp.

In all cases of dysentery, injections into the rectum must be used, once, twice, or thrice a day, according to the indications, and the effects upon the patient; they should be carried as high up into the rectum as possible, for which purpose, I usually take a number 12 or 14 bougie, make a sufficiently large orifice in its closed extremity, pass it up into the rectum, and inject through it. I have already named some of the articles I use for this purpose. Nitrate of Silver, ten to twenty grains to the fluidounce of Water, may also be advantageously used; but it is more troublesome than the others, requiring the mucous membrane to be previously cleansed by an injection of warm water; and, subsequently, to neutralize an excess of the nitrate by injecting a solution of common salt, to which, if much pain be present, ten or twenty grains of laudanum may be added. A very excellent injection for some cases, is formed of Compound Tincture of Virginia Snakeroot one fluidrachm, Tincture of Chloride of Iron half a fluidrachm, Tannic Acid five or ten grains, Water one fluidounce; mix for an injection. As already remarked, the addition of Creosote to these injections often increase their efficacy. Prof. J. M. Seudder, in his Manual of Practice, refers to a case of seven years duration, in which the disease seemed to be confined to the sigmoid flexure and rectum, and which was cured in about four weeks, by injections, repeated three times a day, a pint being used each time, of a decoction of *Alnus*, *Rumex* and *Quercus Rubra*.—Some patients can bear injections only once a day, or every other day, a matter to which the practitioner should pay especial attention.

When there is pain or tenderness on pressure along the course of the colon, it may often be relieved by rubbing the iliac and hypogastric regions gently with a liniment composed of Laudanum three drachms, Camphorated Soap Liniment two fluidounces and a half, Oil of Turpentine one fluidounce; mix. But in very obstinate and long-standing cases, either the Croton Oil Liniment, or the Compound Tar Plaster, should be applied over the tender part, to produce either pustulation or suppuration, which should be

kept up continuously or intermittently, according to the effect produced.

In addition to the other means pursued, it is of the utmost importance to keep up healthy action of the skin, kidneys, stomach, and liver, by the measures heretofore so frequently named. Bathing the inside of the thighs, along the course of the colon, and over the region of the liver, with the diluted Nitro-muriatic Acid, named under Constipation, on page 757, will be found beneficial in many instances.

Sometimes, the disease will prove intractable, owing to the presence of hemorrhoids, a fissure or prolapsus ani, which keeps up the irritation and discharges; consequently, in all obstinate cases, the parts around the anus, externally and internally should be carefully examined. If one of the conditions named be found to exist, it must be specially treated, either by the application of strong astringent decoctions, nitrate of silver, or nitric acid to the hemorrhoids, and also to the thickened and relaxed portion of prolapsed mucous membrane, or, by removing hypertrophied portions with the knife or scissors, etc.

I have recently cured a very bad case of chronic dysentery by the use of the following preparation, aided by injections of Perchloride of Iron, attentions to the skin, diet, rest, etc.; Take of Podophyllin one grain, Leptandrin ten grains, Ipecacuanha twenty grains, Myricin twenty grains, Sugar of Milk one hundred grains; triturate thoroughly together, and divide into ten powders, one of which may be administered every four hours, in some Blackberry-jelly, or Mucilage flavored with Cinnamon.

Before entering into an examination of the diseases of the liver and the spleen, I will briefly notice two conditions more especially with regard to their treatment, and which are often associated with many other affections, either as a cause or as a result, and in either case increasing the severity of the co-existing malady.

Worms, (Vermes). The worms that usually infest the intestinal canal, are: 1. The *ascaris lumbricoides*, or long round-worm, and the *tenia solium*, or long tape-worm, each of which generally inhabits the small intestines, and the former of which frequently wind their way out through the mouth and nostrils. 2. The *tricocephalus dispar*, or long thread-worm, and the *oxyuris vermicularis*, or small thread-worm, occupying the large intestine; the first is also frequently found in the small intestines; and the latter chiefly confines itself to the rectum.

The *symptoms* of intestinal worms are very equivocal, and the

only certain evidence of their existence is their presence in the stools: the tape-worm usually passes away in jointed portions of greater or less length, or in isolated parts or articulations, resembling melon or cucumber seeds.

The symptoms attributed to the presence of tape-worm, are, irregular appetite, but usually voracious, gnawing pain in the region of the stomach, deficient nutrition and emaciation, though these are not invariably present, a hard, convulsive cough, headache, vertigo, nervous affections, great thirst, etc.

The symptoms of thread-worms are an intolerable itching in the anus, and more or less nervous irritability; tenesmus and prolapsus ani are sometimes occasioned by these worms. The more constant and less uncertain symptoms of intestinal worms are: offensive breath; unhealthy condition of the gums; capricious and irregular appetite; irregular colics; mucous stools; abdominal gripings; great thirst; ptyalism; short, dry cough; pale, whitish, and frothy urine; desire for salt, salted meats, and salted fish; peculiar pale, unhealthy, and bloated countenance, with a dark hollow circle around the eyes; though these symptoms may be present with other abnormal conditions, where no worms are present. Sometimes a slow fever, swoonings, drowsiness, cardiac palpitations, cold sweats, convulsions, and many unaccountable nervous symptoms.

If, during the existence of any malady, worms are discovered, we must not suppose that they are necessarily the cause of the malady, as they may not have been at all instrumental in its production. They may have been in existence long previous to the appearance of the malady, and may have been compelled to change their location in consequence of the conditions and circumstances attending the malady. Their presence, however, is due to a debilitated condition of the intestinal mucous membrane, with, in most instances, an augmented secretion of mucus, probably, due to irritation of the mucous membrane by the parasites. Yet, whenever worms are observed, the better course is to remove them as promptly as possible, because their presence not only aggravates, but often renders serious, a disease, in the production of which they had no creative agency, but which has caused them to migrate, and occasion more or less irritation, which, through sympathetic or reflex action, aggravates the existing symptoms of the co-existing disease.

The *treatment* of worms consists in first removing them, and then making use of tonics to impart tone and vigor to the intestinal mucous membrane, in order to prevent their future reproduction. The best vermifuge remedies that I know of are, the Compound Powder of Spigelia, the Compound Fluid Extract of Spigelia, or,

the Vermifuge Cordial named in the American Dispensatory, sixth edition, page 534, under Properties and Uses of *Juniperus Virginiana*; this latter preparation is a very pleasant and efficacious one, and I have been surprised that our practitioners have not made greater use of it. With me, it has always been a favorite vermifuge, especially among children; and may be used as a tonic, in strumous habits, by the addition of Tincture of Black Cohosh. Thread-worms in the rectum can only be removed by injections of bitter vermifuge infusions, to which some Tincture of Assafetida must be added. Tape-worm may be removed by decoction of Pomegranate Bark of Root; Oleo-resinous Extract of Male Shield Fern; or, the free use of an infusion of Pumpkin seeds.

Numerous other agents have been advised for the removal of worms, as, Oil of Turpentine, Santonine, Oil of Wormseed, etc., but those named above are the ones I almost invariably employ.—After the removal of worms, not only should some tonic preparation be employed for sometime, but particular attention should be bestowed upon the diet, avoiding fats and acids, and allowing salted meats, salt, onions, garlic, ginger, cloves, mustard, etc.

Hemorrhoids, or *Piles* are a very common affection among both sexes, and may be *caused* by anything that will irritate the large intestine, or produce a determination of blood to it, as well as by anything which prevents the healthy return of the blood from the vessels of the rectum. Among these may be named, the use of drastic cathartics, habitual constipation, straining at stool, congestion or other obstructive disease of the liver, tight stays or corsets, violent horseback exercise, use of heating, irritating food, sexual excesses, sedentary habits, pregnancy, standing long in certain positions, etc. When the piles are external to the rectum and around the anus, they are called *external piles*; when seated within the rectum they are termed *internal*; when they discharge blood they are called *bleeding piles*; and when no blood appears, *blind piles*. External piles are always dry and cuticular, have a light uniform bluish tinge, rarely bleed, and are dilated hemorrhoidal veins; they may be cut or snipped off with impunity, while to ligature them would risk phlebitis and purulent absorption.—Internal piles are moist and slimy, have a bright florid color, or more or less livid or purple, according to the intensity of their congestion, almost always bleed, very rarely consist of dilated veins, but are, as a general rule, prolapsed folds of the mucous membrane lining the sphincter, extremely vascular, and hypertrophied and thickened by long con-

striction; they may be ligatured with safety, while to excise or cut across them is to risk fearful, perhaps fatal, arterial hemorrhage.

External hemorrhoids consist of one or more external swellings, or tumors of various sizes, located at the verge of the anus, outside the sphincter, are covered with the skin, and may at first give rise to no unpleasant symptoms, but ultimately occasion irritation, pain during stool, bearing-down sensation, and itching about the anus. When the tumor becomes inflamed, it occasions most excruciating pain all the time, and, defecation, or attempts to push the tumor up, which affords relief under ordinary circumstances, causes so much pain as to oblige the patient to desist. The suffering may be so great as to confine him to his bed for several days with considerable sympathetic fever, and great restlessness.

Internal piles consist of one or more tumors, are usually within the sphincter, and covered by mucous membrane, and, like the preceding variety, may exist for some time without occasioning any very annoying symptoms. Generally, more or less profuse hemorrhage occurs, which may continue for a considerable time, and may not recur for some weeks or months. More or less weight and uneasiness are experienced at the anus, pain during defecation, pain and uneasiness in the loins and down the thighs, and a sense of weight and obscure tenderness in the back and hypogastric region, sometimes inducing a supposition of disease of the kidneys or neighboring organs. The hemorrhoidal swellings often increase in size, rendering defecation more difficult and more painful, causing considerable straining, with external protrusion of the tumor. At first this may be returned without difficulty or pain, but eventually becomes both difficult and painful; and frequently the tumors will protrude externally whenever the patient stands for a length of time, or takes some walking exercise. If from any cause, internal hemorrhoids become inflamed, it gives rise to violent pains in the pelvic region, more or less constitutional disturbance, and even mortification of the hemorrhoidal masses. Long-standing internal piles affect the general health, giving rise to pallor, flatulency, indigestion, and indolence; hence, their cure should always be undertaken at an early period. Prolapse of the rectum, anal fistula, etc., and even fatal hemorrhage, have followed this variety of piles.

The *treatment* of external piles consists in keeping the bowels regular, removing any derangement of the liver or digestive organs, together with a rigid avoidance of all those habits, which produce and keep up the disease. When the tumors are painful or inflamed, a poultice of Elm Bark and Lobelia Leaves, equal

parts; or, of Stramonium Leaves; or, of Poke Leaves, will be found efficacious. In obstinate cases, relief will be procured by exposing the part to the steam arising from a hot decoction of bitter herbs. In some instances the application of cold will be found to answer a better purpose. A very painful, blue, distended, circumscribed external tumor, that occasions much suffering from the accumulation and coagulation of the blood, and that is not relieved by the measures just named, may be punctured freely with a lancet, and, after the escape of the semi-fluid blood, ice-cold water may be applied.

After the inflammatory symptoms have passed away, local applications will frequently remove the disease, as: Take of Tannic Acid one scruple, Cerate of Acetate of Lead one ounce, Extract of Stramonium one drachm—rub thoroughly together. Or, other astringent preparations may be applied, as, Solution of Perchloride of Iron, or, Persulphate of Iron thirty grains to an ounce of Simple Cerate, etc. When the swellings form distinct tumors around the anus, more or less pendulous, they should be removed, especially if they are liable to become swollen and inflamed. For this purpose, the parts may first be benumbed with applications of ice and salt, then seize each tumor with a hooked forceps, and excise them with the scissors placed flat upon the skin; but little bleeding will occur, unless some of the mucous membrane has been cut. Great care must be taken not to snip any of the mucous membrane, and also not to take away too much of the lax skin or natural folds around the anus, else, when cicatrization occurs a severe contraction of the anus may follow.

Internal hemorrhoids in their early stage may often be readily cured by a strict attention to diet, avoiding all acrid, stimulating, or indigestible articles, and keeping the bowels regular, either by diet, injections, or laxatives. Straining at stool should especially be avoided. When the tumors protrude externally, they should be carefully returned by the patient. In cases of bleeding piles I have met with much success from the internal administration of the following preparation, in tablespoonful doses, repeated every one, two, or four hours, according to the urgency of the case: Take of Turkey Rhubarb, Rosin, of each, in very fine powder, two and a half drachms, finely-powdered Alum one and a half drachms, Molasses or Glycerin four fluidounces; mix. In conjunction with this, the following ointment should be applied within the rectum, two or three times a day: Take of Styptic Powder one drachm, Canada Balsam (or Sweet Gum) one drachm, Stramonium Ointment six drachms; mix thoroughly together.—When the hemorrhage is pro-

fuse, the patient should be kept as quiet as possible in the recumbent position. If inflammation is present, it must always be first overcome by injections of anodyne fluids, and the means advised for inflammation with external piles; occasionally, ice poultices to the anus will afford prompt relief; or, an opium suppository may be employed.

Among the other remedies that have been found efficacious in internal piles, are the following: Fresh Linseed Oil in doses of two ounces, repeated twice daily; Castor Oil and Copal Varnish, equal parts; ordinary Coal Oil; ointment of Sweet Gum; Cream three parts, Oil of Pennyroyal one part; mix; Oil of Flea-bane, Oil of Pumpkin Seed, Oil of Fire-weed, Oil of Horse-mint, Linseed Oil, equal parts; mix; Decoction of Solomon's Seal (internally); Oil of Horse-chestnuts, etc. With the exception of the Linseed Oil, and the Decoction of Solomon's Seal, these are all to be used as local applications. Cold water injected daily will give tone to the vessels of the rectum.

When the cellular tissue of the parts becomes thickened and infiltrated in a more or less circumscribed space, with thickening of the mucous membrane, one or more distinct, solid tumors are formed, which can not be removed by the preceding measures. In the early period of these tumors, Nitric Acid, Perchloride of Iron, or Chromic Acid, carefully applied to them, will frequently effect a cure; but where the tumors are large, indurated, and of a deep-blue color, the ligature will be required. In applying Nitric Acid, the bowels should be evacuated a couple of hours previously, and the patient should sit over hot water for some minutes, or have an injection of very warm water, in order that the hemorrhoidal disease may be well brought into view; then carefully wipe the part to be acted upon with a piece of lint, and afterward, carefully and lightly touch the diseased surface with the extremity of a small, flat piece of soft wood that has been just dipped into pure Nitric Acid. This done, smear the part and its neighboring mucous membrane well with oil, and then return the part within the orifice. If the part can not, from any cause, be brought down, the acid may be applied by means of a silvered glass speculum, introduced so as to bring the hemorrhoidal tumor into view. The acid may be applied, if necessary, every two or three days; it is not apt to occasion much pain, unless the surface close upon the verge of the anus is touched with it, which, of course, should be carefully avoided; an ulcer, or a fissure, in conjunction with the pile tumor, must first be healed before applying the acid, else much suffering will be produced. A careful examination of the parts to discover such affections, should always be made.

Nitric Acid, similarly applied, will be found of great service in *Prolapsus of the Rectum* when not very large, of recent origin, where the mucous membrane has not become very much thickened and changed in its appearance and structure, and where one or more large folds of mucous membrane are continually down, with a smooth velvety appearance, or a superficially-ulcerated and readily-bleeding surface, the tissue being extremely vascular. The acid should be applied to only a part at each operation.—When there is a considerable redundancy of loose skin, or long flaps of thick integument around the margin of the anus, this must be excised with the scissors after the disappearance of the prolapsus, or it will be reproduced. In long-standing cases, with structural changes of the mucous membrane, the ligature must be applied. If the prolapsus be due to pile tumors, the cure of the latter will be followed by a disappearance of the former.

Chromic Acid is a much more painful application to piles, occasioning a slough, and a shrinking of the tumor.—The modes of applying the ligature, the clamp, or the ecraseur for the permanent cure of internal piles, are laid down in most works on Surgery. In cases of constantly protruding piles, as well as in obstinate prolapsus of the rectum, where the patient will not submit to the application of nitric acid, or to operation by ligature, etc., or, where these are not deemed very advisable by the physician, great relief may be had by wearing a properly-made spring and pad to give support to the parts, and keep the protrusions within the rectum. Solution of Perchloride of Iron, so frequently serviceable in hemorrhoids, will also prove of equal efficacy in prolapsus of the rectum.

Chronic Tympanites is an inordinate accumulation of gas in the intestinal tube, giving rise to a very great prominence of the abdomen, which may be mistaken for ascites. It may be *caused* by the use of certain articles of food, by a habitual constipated condition of the bowels, and is frequently associated with hysteria, uterine and spinal disease; sometimes, it occurs as a result of enteritis, or peritonitis. In these instances it is more apt to take place among those of weak digestive powers, or who are great eaters. It is also frequently associated with intestinal adhesions, stricture of some part of the intestinal tube, compression of the tube by abnormal growths, and organic lesions of the biliary, digestive, and other adjacent organs.

The chief *symptom* is the gradual enlargement of the abdomen, the tympanitic sound elicited by percussion, and the absence of fluc-

tuation, which will determine it from dropsy. With the tympanitic condition there may be a sense of lassitude, indolence, or debility, sometimes cutting pains or shifting pains, palpitations, a sense of discomfort when the clothes are worn too tightly around the abdomen, or when this is pressed upon, sometimes borborygmi, indigestion, and a sense of fullness after meals. In some cases, the only symptom observed will be the tympanites. Although the disease usually develops itself gradually, I have known instances where it became manifested rapidly, in a very few hours.

The *prognosis* is usually favorable, except in those cases where it is associated with intestinal adhesions or organic lesions of adjacent organs, and which lesions are generally observed in cases proving fatal.

The *treatment* consists in avoiding those articles of food that give rise to flatus, and administering stimulating tonics to impart tone to the mucous lining membrane of the alimentary tube. The introduction of a long tube into the rectum, and removing the air by means of a large syringe or air-pump, should not be neglected, as it is often followed by happy results. In addition, the bowels should be injected, two or three times a day, with a mixture of Tincture of Prickly-ash Berries four fluidounces, Tincture of Nux Vomica ten or twenty minims, Infusion of Capsicum four fluidounces; mix for one injection.* The bowels should be frequently rubbed with some stimulating liniment, as, for instance, a mixture of equal parts of Oils of Cajuput, Juniper, Sassafras, and Olive Oil,—rubbing for half an hour or an hour at a time, and as hard as can be borne. Internally, the Tincture of Prickly-ash Berries, with or without the addition of Tincture of Nux Vomica, will be found an efficacious remedy. If acidity be present, Charcoal, or the Compound Powder of Charcoal will be required. In some cases, electro-magnetism will be found useful.—When organic lesions exist, these must be removed by the appropriate measures before we can expect the tympanites to disappear.

DISEASES OF THE LIVER, ETC.

Notwithstanding that the liver is an organ that has been the subject of much research for many centuries past, its anatomy, physiology, and functions are still incomplete and not satisfactorily

*The Infusion of Capsicum to be made by pouring Boiling Water one pint, upon powdered Capsicum half an ounce; allow it to stand until cool, and strain for use.

defined; and though pathological anatomy reveals to us the sequelæ of hepatic inflammation, as, sanguineous, lymphatic, and purulent exudations, as well as the conditions of atrophy, hypertrophy, cancer, tubercle, fatty degeneration, etc., of the organ, we are still in a state of much obscurity and uncertainty as to the symptoms, causes, and treatment of these various states.

The lungs, the liver, the kidneys, and the skin, appear to be the great depurating organs of the system. The hydrogen and carbon are thrown off by the lungs and liver; the nitrogen by the kidneys, while the skin eliminates carbonic acid, nitrogen, etc. But the liver appears to be an organ fulfilling other than mere excretory functions, performing an important part in secretion, in purifying the blood, in the production of animal heat, and in nutrition. Among those who have investigated the functions of the liver, and who has thrown much light upon them, is Austin Flint, jr., M. D., of New York city.

This gentleman, in a series of investigations regarding, what he terms, "a new excretory function of the liver," has demonstrated that the bile is a complex fluid, containing among other principles, a substance formed by the disintegration of brain and nervous tissue, viz., cholesterine. This substance, being an excretion, pre-exists in the blood, which has absorbed it from the brain and nerves, where it acts as a poisonous, injurious body, its accumulation in the blood being to the liver, in a manner, what an accumulation of urea is to the kidney; cholesterine being, in health, separated from the blood by the liver, it is thrown with the bile into the upper part of the small intestine, becomes transformed into ster-corine (seroline), in which form it is evacuated from the rectum.

The secretory function of bile appears principally to consist in the manufacture of glyco-cholate and tauro-cholate of soda, substances which, like all other secretions, do not pre-exist in the blood, are found in no other organ or situation, are first met with in the substance of the liver itself, and are not discharged from the body, but become absorbed in their passage along the alimentary canal. The same may be said concerning another principle (amyloid substance, hepatine, glycogene), formed by the liver, designed more especially for manufacturing fat, but which may be readily converted into sugar by a process allied to fermentation. These salts are observed principally at a certain period of digestion, and are designed to aid in some of the nutritive processes, which would become defective if they were not secreted. There is no doubt but what these discoveries of Prof. Flint, jr., will lead to important and valuable results not only in the diagnosis and treat-

ment of liver diseases, but also of many maladies of the brain and nervous system, which have been, and are still enveloped in great obscurity.

Beside these, the bile contains other elements, as biliverdine or coloring matter, water, chloride of sodium, phosphate of soda, of lime, and of magnesia, fats, with oleates, margarates, and stearates of soda and potassa, carbonates of soda and potassa, etc. The practitioner should, therefore, in the investigation and treatment of diseases of the liver, bear in mind this two-fold function of the organ, and its relations to the lungs as an eliminātor of hydrogen and carbon; remembering, likewise, that from the lack of an accurate knowledge of all the functions and pathology of the organ, its therapeutics must necessarily be of a more or less empirical character.

In the examination of liver affections, palpation and auscultation may be employed, but percussion will be of the most value, enabling us to define the boundary of the organ, especially its upper and inferior borders, anteriorly and laterally; its posterior margins can not be determined. A sense of resistance and dullness on percussion are signs that a solid organ is underneath; these are the signs of the presence of the liver, on percussion; resonance, is the sign of a hollow organ, or cavity.—Inspection of the stools to determine the absence or presence of bile in them, is also another mode of examination frequently employed.

It must not be forgotten that an examination of the urine forms a valuable and important means in the diagnosis and treatment of hepatic disease. Thus, by the application of nitric acid to the urine, the presence of biliary pigment in this fluid may be detected. If the urine, though at first of a normal color, becomes darker and darker upon standing, from a slow oxidation of the pigment, it contains melanine, which is indicative of melanotic cancer of the liver. If the needle-like and star-like crystals of tyrosine, or the round, yellow, occasionally spiculated, balls of leucine are found in the urine, it is an evidence of chronic atrophy of the liver. If bile acids are found in the urine in any quantity, it is an indication that there exists an obstruction of the common bileduct, either along its course, or at its termination, as is observed in some forms of jaundice. The bile acids may readily be detected by adding to the urine containing them a small piece of white sugar, and then pouring on gently, in such a manner as not to mix the two fluids, a little strong sulphuric acid. If, after standing for a few minutes, a deep purple, or scarlet color, be observed at the line of contact of the two fluids, it is a sure indication that the bileducts are

obstructed. If, on the other hand, a brown color be observed, the jaundice present is due to suppression of the biliary function.—M. Cunniset states that bile may be detected in the urine, by the following method: to forty or fifty parts of the urine under examination, in a test tube, add four or five parts of chloroform, and then shake the mixture. If bile be present, the mixture assumes a fine yellow color, and on allowing it to rest, the chloroform falls to the bottom of the tube, taking with it the fatty matters of the urine colored by the yellow biliary substance.

Among the symptoms more commonly observed in the various affections of the liver, one or several of which may be present, are the following: tenderness or pain upon pressing along the right side of the sixth, seventh, eighth, and ninth dorsal vertebræ, but which is apt to be absent when structural degeneration has occurred; pain in the right side extending even to the shoulder-blades and pit of the stomach; at times a sense of uneasiness and tightness; sallow complexion; yellowness of the eyes; bowels irregular, generally disposed to looseness; irregular appetite; nightmare; palpitation of the heart; asthmatic symptoms; shortness of breathing; piles; urine high-colored, sometimes scalding or unnaturally hot, and depositing a sediment if allowed to stand,—sometimes it is scanty, then quite free; tongue white, but sometimes brown or yellow toward the base or root; bitter and disagreeable taste; a dry, harsh, constricted state of the skin; or a greasy skin; a short, dry cough; numbness of the limbs; cold hands and feet; blotches and pimples on the face; tightness or constriction of the chest; yellow and scaly or branny eruptions on the skin; erysipelas; itching of the skin; swelling of the right side; and in the last stage of induration, hemorrhages from the stomach or bowels.

CHRONIC HYPEREMIA OF THE LIVER.

Chronic Hyperemia of the Liver is a very common morbid condition, met with among sedentary persons, the intemperate, those who are addicted to high living, as well as among individuals residing in hot countries, or in malarial districts. Persons once attacked with it are liable to its return upon an exposure to the slightest causes. It may be present in various degrees, and under different associations. The most dangerous forms of chronic hepatic disease are often the result of chronic hyperemia of the liver.

The *causes* of hepatic hyperemia are various; thus, an impediment to the flow of blood through the liver, from diseased heart,

especially of the valves on its left side, giving rise to an accumulation of blood in the hepatic vessels; or, an obstruction to the circulation in the portal vessels, from overeating, diseases of the abdominal viscera, etc.; and the degree of the congestion and of its symptoms, will be due to the existing amount of obstruction offered to the circulation in the vessels referred to. Other causes may also depress the nervous energy of the liver, and impair its venous tonicity, as, sudden changes of temperature; exposures to cold, dampness, or malarial influences; intemperance; want of exercise; dyspepsia; periodic fevers, etc. Hyperemia may also be the result of an unhealthy condition of the blood, independent of any obstruction to its circulation, as, in scurvy, purpura hemorrhagica, leucocythemia, etc.

Whatever may be the origin of the hyperemia, the *symptoms* will be about the same, though varying in intensity according to the degree of congestion. Actual pain is seldom if ever present; there will be a sense of fullness or weight in the right hypochondrium, which is sometimes very annoying; more or less derangement of the appetite; tongue coated white, with more or less of a brownish fur at some part of it; debility or indolence; a more or less yellow tinge of the conjunctiva; lowness of spirits; a dry or clammy condition of the skin, with a dingy appearance, and, if the congestion be considerable, the skin will present a decided appearance of jaundice, from a diminished secretion of bile; urine scanty and turbid; dull headache; disturbed sleep; unpleasant dreams; and frequently a sensation of tension or heaviness will be felt across the shoulder-blades, or below the right scapula. Constipation may be present, or it may alternate with diarrhea, and the stools will show a greater or less deficiency of bile; the bile is not only diminished in quantity, from lessened functional activity of the organ, but may also be more or less acrid or unhealthy. Sometimes, lying upon the left side will give rise to more or less discomfort.

Enlargement of the liver from an unnatural fullness of its vessels, generally accompanies an intense or long-standing hyperemia, and which may be detected by percussion yielding dullness over a larger extent of surface than that accompanied by the healthy organ. If the hyperemia be constant, owing to cardiac, abdominal or other disease, the secreting hepatic cells, and the bileducts will alternately become abnormally altered. In the *diagnosis* of enlargement of the liver from hyperemia, we have no positive indications that will enable us to determine it from hypertrophy of the organ, or enlargement from other causes, and will have to rely

for such discrimination upon the symptoms present, and the previous history of the case.

The *pathological appearances* that have been observed, are, dark red spots upon the yellow parenchyma of the liver, presenting a mottled appearance, resulting from congestion of the central vessels of the lobules; or, when the portal system is alone implicated, the parenchyma of the organ will be dark-red, and the spots yellowish, from congestion of the vessels in the interlobular fissures and spaces. If the hyperemia affects both the hepatic and portal venous systems, no yellow color will be observed in any portion of the liver. The organ is more friable than natural.

The *treatment* of chronic hyperemia of the liver, when not associated with any blood or organic disease is very simple, consisting in an avoidance of the cause, regularity of the bowels, with an occasional cathartic, frequent bathings, and in severe cases, hot-air baths, proper attention to diet, and exercise in the open air. Emetics occasionally administered may be of service in cases associated with asthma, chronic bronchitis, etc., but unless they are preceded by a cathartic, they are apt to prove hazardous. In severe cases, counter-irritants over the region of the liver will be very useful, as, the Compound Tincture of Camphor.—When the congestion is due to functional or organic diseases of other organs, no great benefit can be derived from treatment until the organic or functional disease has first been removed by the proper remedies.

Where there is a tendency to habitual congestion, as well as in the hyperemia common to our Southern and malarial States, manifested by sallowness of complexion, tumidity of the abdomen dryness of the skin, sometimes an œdematous condition of the inferior extremities, shortness of breath on the least exertion, furred tongue, deranged appetite, indigestion, ash or clay-colored stools, constipation, scanty, dark, and turbid urine, indolence, peevishness, lowness of spirits, increased heat of breath, dryness and scaliness of the lips, tenderness on pressure upon the hepatic region, and ultimately, an irritative fever, with nocturnal sweats, and colliquative diarrhea, anasarca, or other fatal termination,—in addition to the means already named, the patient should use internally, regularly and for a long period of time, preparations variously composed of some one or more of the following articles, as, Podophyllin, Leptandrin, Sanguinarina, Oleo-resin of Iris, Alcoholic Extract of Black Cohosh, Strychnia, etc., so compounding them that they may exert a sanitary influence upon the blood, liver, and nerves of the patient. In many instances, and espe-

cially those connected with malarial influences, the White Liquid Physic will be found an excellent remedy. Anemia will require some chalybeate in conjunction with the other treatment.

CHRONIC HEPATITIS.

Chronic Inflammation of the Liver may be the result of the acute form, or, it may have been chronic from the commencement; the surface of the organ may alone be affected, or the disease may be seated in its substance, or both may be involved. Formerly, this disease was considered of frequent occurrence; at the present day, it is doubtful if it is so prevalent as hyperemia of the liver in temperate climates; though it is by no means improbable that a persistent hyperemia may, as well as an obstinate inflammatory condition, terminate in such an organic lesion of the liver. Since the recent discovery of many other chronic maladies of the liver, it is strongly to be presumed, that the term "inflammation" has heretofore been applied indiscriminately to many of these organic lesions, and that gastric as well as duodenal diseases have also been often confounded with an abnormal state of the liver. A persistent hyperemia is with difficulty determined from a chronic hepatitis. In hot countries, chronic inflammation of the liver is much more common than in temperate climates.

The *causes* of chronic hepatitis are the same as those of the acute form, of which it is frequently the sequel. Exposures to cold; blows, as well as continued compression, on the right hypochondrium; powerful muscular efforts; sedentary and inactive habits; improper diet; irritations produced in the neighborhood of the organ; drastic cathartics; intemperance, or the moderate but habitual use of alcoholic liquors, which, however, also involves the stomach, gallducts, etc.; hyperemesis; excesses, of various kinds; deficient amount of sleep; and the use of mercury, may be named among the principal causes in cold and temperate climates. In the torrid regions of the globe, the disease is very common, especially among those who are indolent, indulge in stimuli and high-seasoned food, are intemperate in eating, and neglect the necessary attentions to hygienic measures. But the heat alone tends also to produce the disease, from its general enervating effects upon the system, and the erethism which it occasions along the mucous membrane of the intestinal tract, which may be readily carried to the liver. Local influences are also frequently observed where the disease is unusually common, and in all hot countries, the long-con-

tinued influence of malaria, is an important agent in developing the disease.

The *symptoms* of chronic hepatitis resemble those of the acute form, being more or less severe and equivocal in proportion to the degree of the inflammation. They are numerous, and vary very much in different individuals, and are frequently so similar in many respects to those of some other chronic disorders, that a practitioner may, without a very close and careful examination, be in doubt as to the hepatic or other origin of the malady presented to him. And this is probably owing to the fact that so many organs, as the brain, nervous system, lungs, stomach, duodenum, etc., are greatly indebted for their normal condition to the integrity of the liver, and vice versa, that a disease of this latter organ may involve one or more of the other organs, and, on the other hand, an abnormal condition of one or several of these organs must necessarily implicate the liver to a greater or less extent. It must, however, be borne in mind, that the slighter and obscure forms of the disease are apt to present no distinct phenomena, and also that a similar obscurity of symptoms may sometimes exist where the inflammation is of considerable severity.

Among the symptoms more commonly met with are the following: a dull heavy pain in the hepatic region, and which is sometimes increased by rather deep pressure, by percussion, or by lying upon the left side; this pain frequently extends to the back and shoulder-blades, and to the epigastric region; not unfrequently the liver becomes enlarged, or there may be a fullness in its region; at times, a sense of uneasiness and constriction in the hepatic and gastric regions; the conjunctiva becomes more or less yellow; the skin dry, harsh, and sallow; the urine usually of a high color, but changeable as to quantity, often being unnaturally hot or scalding, depositing a sediment, and frequently giving indications of the presence of bile, or of some of its constituents, upon applying the proper tests; the bowels are usually deranged, with dark or greenish, offensive, slimy or watery stools; the tongue is usually coated with a brown fur, thicker toward its base, with, at times, a bitter and disagreeable taste in the mouth. As the disease progresses there will be acceleration of pulse at night, with fever and restlessness, night sweats, emaciation, and a prostrating diarrhea. The disease may prove fatal by terminating in some form of dropsy, hemorrhage, or one of the structural maladies of the organ hereafter treated upon.

When the surfaces of the liver are involved in the disease, the symptoms are much more distinctly marked. If the convex or

superior surface is affected it is apt to be associated with symptoms of pulmonary disorder; and if the concave or inferior surface be affected, the symptoms will be associated with those of gastrointestinal, and sometimes even renal derangement.

“When the superior and exterior part of the right lobe is affected, the patient then lies with most ease on the right side, and often feels, at an advanced stage of the disease, more or less acute pain, or a dragging sensation, upon turning to the left. If this latter occur, the existence of adhesions between the liver and right side may be inferred. He therefore prefers the semi-recumbent position, or lies on his back or right side.” (*Copland.*)

It is seldom the case but that one or more of the other organs of the body become either functionally or organically implicated with the hepatic disease, owing to the intimate relations existing between them, as, the brain and nervous system; the skin, the lungs, digestive organs, uterus, etc.; and consequently additional symptoms to those named above, will be observed, and which, to a great extent, will indicate the organs implicated. Thus, there may be a slight, hacking, and dry cough, dyspnoea, asthma, or dull thoracic pains; a white coat on the tongue associated with the brown, a roughness of the tongue, nausea, vomiting, impaired or capricious appetite, gastric acidity, fullness and distress in the epigastric region, with other symptoms of gastric disease; a constipated condition, with light-colored stools; or an obstinate diarrhea or dysentery, hemorrhoids, pains in the hypochondriac and iliac regions, etc.; palpitations of the heart; more or less headache, chilly sensations, disturbed sleep, nightmare, disinclination to mental or physical exertion, more or less depression of spirits, despondency, capriciousness, irritability of temper, peevishness, etc.; or an unnatural, greasy appearance of the skin, yellowish and scaly or branny eruptions, or pimples, blotches, or troublesome itching, will be observed upon the face, neck, or other portions of the cutaneous surface; and so on.

When the inflammation has continued for some time, palpation may detect the enlarged liver extending beneath the false ribs, and perhaps in the direction of the umbilical and epigastric regions, and sometimes it will be found more swollen in the right hypochondrium; its degree of tumidity, and the hard and thickened condition of its border may be detected by percussion. Dr. Walshe, of London, has given an auscultatory sign of enlarged liver, which he terms “*hepatic compression rhonchus.*” While the sound may be absent, or escape detection for several days, he states that it has always been present in cases examined by him where there was a notable increase of bulk in the organ, and that he has never met with it in

other conditions of disease. It commences at the time the inspiration murmur is about at an end, is peculiarly slow and drawling in its evolution, and exists independent of any lung affection. This sound consists of a great number of excessively fine, dry crepitations, rather superficial than deep-seated, and is wholly different from crepitant, subcrepitant, and dry crackling, pulmonary rhonchi, and from pleural rhonchus. It is rendered audible by forced inspiration only, and may be heard in front, at the side, and in the back of the right half of the chest, at or near to the upper edge of the liver.

The *diagnosis* of chronic hepatitis must be wholly based upon the history of the case and the existing symptoms; but, as these symptoms are equally common to other chronic hepatic maladies, we will not always be able to positively and satisfactorily diagnose a chronic inflammation from any other chronic affection of the liver. The *prognosis* in recent simple chronic hepatitis is almost always favorable; but it must never be lost sight of, that a previous mercurial treatment is apt to render the disease very obstinate of cure, and, in many of these cases, which admit of great relief by the means hereafter named, a permanent cure is absolutely out of the question. This may be due to the actual presence of the mercury in the liver, or to some commencing organic lesion produced under its influence. Where structural changes are present the prognosis is more or less unfavorable, in accordance with the duration and character of the changes. Long-standing chronic hepatitis, without organic degenerations, is generally curable, but requires a long period of treatment.

The *pathological appearances* of chronic hepatitis vary very much, with the exception of enlargement of the liver, which is almost uniformly present; this enlargement may be complete or partial. The tissue of the organ may present either a paleness or a diffused redness; it may be more dense, indurated, and friable; or, may present abscesses, a flabby condition, and adhesions. Sometimes it will have a brownish, slate-colored, or blackish color, but usually in spots or patches. Ordinarily, some form of degeneration may also be observed, as, atrophy, hypertrophy, cirrhosis, fatty liver, etc. In most instances, some other organs will be found involved with the hepatic affection.

In a work on Diseases of the Liver, by Dr. Budd, this author has divided inflammatory diseases of the organ, according to the nature of their causes and termination; though in our present knowledge, such a division is hardly practicable. He ranges them as follows:

1. *Suppurative inflammation*, or that which leads to suppuration

and abscess, and which may be caused by mechanical injury, contamination of the blood with pus from a suppurative phlebitis, ulceration of some part, the blood of which is returned to the portal vein, and which is a very common cause of hepatic abscess.

2. *Gangrenous inflammation* terminating in gangrene of the liver, and due to the occurrence of gangrene in other parts, the septic agency being conveyed by the blood.

3. *Adhesive inflammation*, or inflammation that causes effusion of coagulable lymph, due to spirit-drinking, to the presence of tubercles, cancer, hydatid tumors in the liver.

4. *Inflammation of the veins of the liver*, which may be of a suppurative or an adhesive character, or, both combined.

5. *Inflammation of the gall-bladder and gallducts*, which may be of a catarrhal, suppurative, croupal (plastic), or ulcerated character.

This arrangement may, possibly, be of more value to the dissector than to the attending physician, as it may assist him in the determination of the various pathological conditions exposed by the knife.

The *treatment* of chronic hepatitis will vary somewhat according to its duration. If it be of recent origin, sudorific, diuretic, and cathartic medicines composed principally of Podophyllin, Oleo-resin of Iris, Leptandrin, etc., together with vapor baths, and stimulants applied externally over the hepatic region, will be found sufficient. But, more commonly, the disease is not presented to the physician until after it has been in existence for some time, or has resulted in some structural lesion of the organ,—lesions which should be constantly remembered by the practitioner.

In these cases of long duration it will be found in practice that no one course of remedies will be found applicable to all patients; that which may be of service to one will be of no avail to another,—hence, a general description of the more important agents is all that can be laid down. An emetic, or a succession of emetics, at intervals of two, four, eight, or sixteen days, will be rarely required, except in those cases where there is a general torpor of the nervous system. The principal indications to fulfill are, to overcome the chronic inflammation of the organ, to restore its functional activity, and to remove abnormal conditions of other organs that are present, either as causes or effects.

To accomplish these results we must produce and maintain an influence upon the liver, as well as upon the digestive canal, in order to keep up regularity of the bowels, which latter is a very important consideration in the treatment of this malady. Among the preparations that have proved useful for this purpose may be named

the following : 1. Compound Pills of Podophyllin ; 2. Compound Pills of Leptandrin ; 3. Compound Powder of Leptandrin ; 4. Take of Iodine twenty grains, Strychnia five-sixths of a grain (or a grain), Leptandrin, Xanthoxylin, Alcoholic Extract of Black Cohosh, each, one drachm ; mix, divide into sixty pills, of which one is a dose, to be repeated three or four times a day ; 5. Take of Citrate of Quinia and Strychnia forty grains, Oleo-resin of Blue Flag forty grains, Leptandrin forty grains ; mix, and divide into forty pills,—to be taken in the same manner as the preceding ; 6. Take of Podophyllin ten grains, Leptandrin forty grains, Sanguinarina five grains, Alcoholic Extract of Aletris forty grains ; mix, and divide into forty pills,—to be taken same as preceding ; 7. White Liquid Physic ; 8. Dilute Nitro-muriatic Acid Baths over the region of the liver, or the liquid cathartic mentioned on page 757. If the stomach is acid, this must be obviated by the means named under Gastric Acidity, on page 742. An irritable state of the stomach may be overcome by the internal use of anodynes, and sinapisms or other counter-irritants over the epigastric region. Pain in the stomach, nausea, or vomiting may be removed by the means named for these symptoms under Dyspepsia, page 748.

Another class of agents which should never be omitted in the treatment of long-standing cases of chronic hepatitis, is that chiefly addressed to the blood, and termed “alterative.” Among these may be named, 1. Bromide of Potassium ; 2. Bromide or Iodide of Ammonium, the latter especially in cases associated with syphilis ; 3. Take of Tincture of Black Cohosh, Tincture of the Bark of Bitter-sweet Root, each, two fluidounces, Tincture of Bloodroot one fluidounce, Tincture of Sheep Laurel Leaves half a fluidounce ; mix, and give from ten to twenty drops three times a day in a little sweetened water ; 4. Take of coarsely-bruised Blue Flag, and Black Cohosh Roots, each, two ounces, coarsely-bruised Yellow Dock Root, Bark of Bitter-sweet Root, Cinchona Bark, Sassafras Bark, Prickly-ash Berries, each, one ounce, Soluble Pyrophosphate of Iron five rachms, Whisky, Water, Glycerin, No. 2, each, twenty-four fluidounces ; mix, and form an elixir, the dose of which is from two to four fluidrachms, repeated three times a day ; 5. Take of Compound Syrup of Stillingia, Compound Syrup of Sarsaparilla, each, one pint, Tincture of Black Cohosh two fluidounces, Iodide of Potassium one ounce ; mix, and give from two to four fluidrachms three times a day in a wineglassful of water.—The Compound Tincture of Tamarac is frequently used in hepatic affections, more especially when complicated with diseases of the digestive apparatus ; it acts as a laxative, alterative, diuretic, and tonic, and may frequently be

beneficially employed in conjunction with attention to the skin, the diet, and exercise.—Chlorate of Soda, Phosphate of Soda, Nitrate of Soda, and other salts of this alkali, are very useful in hepatic affections, and are generally to be preferred to those of Potassa; though it must be borne in mind that a want of this latter alkali may become a source of disease. In the bile, soda preponderates over the potassa; in the liver tissue it is the reverse of this; soda also prevails in the blood, and potassa in the muscles.

Another very important part of the treatment is, the administration of diuretics, to render the urine more normal in quantity and quality, and among the agents that may be beneficially employed for this purpose are, Acetate of Potassa, Citrate of Potassa, or infusions or decoctions of Wild Carrot, Winter-green, Queen of the Meadow Root, etc. A very useful diuretic is an infusion of Marsh Mallow Roots, two parts, Spearmint Leaves one part, which may be drunk freely. However, if the urine is in proper amount and presents a healthy character, or if the remedies heretofore named effect such a favorable result upon this fluid, the employment of diuretics may then be dispensed with.

It is also a very important measure in the treatment of chronic hepatitis to attend to the functions of the skin, by daily bathings, as heretofore explained,—frictions, and the occasional use of the Spirit Vapor Bath.

In obstinate and unyielding cases, the intermittent employment of the Compound Tar Plaster over the region of the liver will be found very useful; it will relieve the fullness, tenderness, and weight complained of, as well as aid in the reduction of the size of the liver. A solution of Hydrochlorate of Ammonia, or of Iodide of Ammonium frequently rubbed over the region of the liver will also prove serviceable, as well as active stimulating liniments applied two or three times a day along the spinal column. The Ammonia Solutions may be employed alternating with the Compound Tar Plaster.

Any complications that may co-exist, as, of the heart, lungs, stomach, or intestines, (diarrhea, dysentery), etc., will require the treatment to be so modified as to exert an influence upon the hepatic disease as well as the complication. And in such cases, it is generally preferable to employ those agents only that have been found efficacious in both the hepatic and other maladies, when existing separately and independent of each other.

The diet should be nourishing,—indeed, in regard to diet, exercise, exposures, etc., the practitioner should be guided by the rules heretofore laid down.

HEPATIC ABSCESS.

Abscess of the liver may follow either the acute or chronic forms of hepatitis; it is a frequent termination or consequence of these inflammations in hot countries, and is especially apt to occur among those of strumous habits, or who are laboring under a vitiated condition of the blood, (phlebitis, pyemia, dysentery, ulceration of parts, etc.) In temperate climates it is much less frequent. Mechanical injury may occasionally give rise to it.

There are no *symptoms* by which we can positively diagnose hepatic abscess, either in its period of formation or of suppuration, except when a large cyst contains the matter and is located near the surface. The special symptoms are, pain in the hepatic region, swelling, jaundice, febrile symptoms, throbbing in the region of the liver, sense of weight, rigors, and night sweats; though an abscess may be forming, and these symptoms be wholly absent. Rigidity of the rectus muscle, ascertained by palpation, is considered by some medical men as a sure indication of a deep-seated abscess; but it has been met with in other hepatic maladies. Another set of symptoms are, pain in the right shoulder increased by pressure on the side, vomiting immediately after eating or drinking, a short, dry cough, not of pulmonary origin, and rigidity of the abdominal muscles. When either of the group of symptoms named are present, we may infer a forming abscess. In other cases, the diagnosis will be very imperfect and unsatisfactory, and will in a great measure depend upon our knowledge of the antecedent circumstances under which the disease arises, carefully and rigorously analyzing all the circumstances and symptoms that can be ascertained, and repeating these examinations daily, until we are fully satisfied regarding the nature of the case. We must especially determine abscess from a distended gall-bladder, from a pleuritic effusion on the right side of the chest, from hydatids in the liver, and from hepatic cancer.

A *distended gall-bladder* forms a globular tumor, circumscribed, hard, and equally resisting in every part, while the tumor from an abscess is more diffused, is soft and fluctuating at its summit, while its base is hard and resisting. (*Budd.*)—In *pleural effusion*, the signs named under Pleurisy will be present; but if the hepatic abscesses open into the pleural cavity of the right side, the signs of the abscess will exist prior to those of a pleural effusion; besides, the matter from the abscess frequently passes through the lung tissue into this organ, from whence it is expectorated; in this instance, the pleural disorder will scarcely be observed, or will

be very limited, while the inferior extremity of the right lung will yield dullness, tubular breathing, and other signs of inflammatory action—the expectoration being of a rusty color, and followed sooner or later by a purulent expectoration of a reddish or whitish color, and containing some of the bile constituents and minute fragments of liver tissue. Occasionally the pus escapes through the thoracic walls.—In *hydatids* there is seldom if ever any pain, derangement of nutrition, or febrile reaction; but if the hydatid cyst contains pus, the diagnosis will become very difficult, if not impossible. In *hepatic cancer*, there are no marked febrile symptoms, no fluctuation, and hard knotty-like masses may be distinguished on palpating along the hepatic region; beside which, cancerous disease is apt to be manifested in other parts of the body. Medullary cancer sometimes gives a sense of fluctuation, yet it is not so distinct nor so diffuse as in abscess, and some of the hard knotty masses may frequently be detected upon a careful examination.

When the abscess has formed, and is seated near the surface, the swelling and fluctuation will reveal it; but if it be deep seated, or be very small, we will have no positive indications of its existence. Though if of an indolent character, or if occurring in enfeebled or broken-down constitutions it is apt to be attended with hectic fever, night sweats, faintness, syncope, great debility, perhaps, also, dyspnœa, diarrhea, or dysentery. Emaciation, sunken and icteric countenance, a turbid, purulent, or muco-purulent urine, and a disposition to recline in some position, may also be noticed in many cases. In obscure or doubtful cases the examination should be conducted in the same manner as named in the preceding paragraph.

Abscess may prove fatal without being discharged from its seat in the liver; but in most instances it opens and discharges its contents in a direction depending upon the part of the liver occupied by it, and with symptoms indicative of the direction it has taken. Thus, it may discharge its contents into the peritoneal cavity, giving rise to pain, vomiting, and symptoms of fatal peritonitis from perforation. If the abscess opens into the stomach, a distressing vomiting of purulent matters will at once take place. If into the intestines, sudden diarrhea with discharge of pus will occur; if it perforates the diaphragm it may enter the pleural cavity giving rise to suppurative pleurisy, or, as more usually happens, from an adhesion being formed between the lung and diaphragm, the matter is discharged into the lungs from whence it is expectorated or coughed up, in the form of a dirty-red or brownish puriform matter.

In all these cases, any pre-existing tumor formed by the abscess will greatly diminish in size, though pain or soreness, hectic fever, and constitutional disturbance may remain. Adhesions may also form between its peritoneal covering and that of the stomach, etc.

The *prognosis* of abscess of the liver is unfavorable, yet cases sometimes recover, more especially among those in whom the abscess is seated at the surface or lower border of the organ, and is thus enabled to discharge itself through the abdominal parietes; and probably, also, in cases where the abscess is of small size and the subject of a robust constitution. We must not be misled by the presence of alternating favorable and unfavorable symptoms; an apparent recovery may ensue, and the patient ultimately die with symptoms of purulent resorption. A proper treatment will frequently prolong the patient's existence even when it will not effect a cure.

The *pathological appearances* are, more or less enlargement of the liver or of some portions of it, and presenting morbid appearances similar to those named under Chronic Hepatitis. In various portions small abscesses may be observed, having a narrow congested circle surrounding them. These small abscesses are frequently non-encysted, while the larger ones are encysted, the cyst being thin or thick, and more or less imperfectly organized. In some parts may be observed inflamed portions, with incipient supuration in the midst, especially in those cases where the inflammatory affection has assumed a more active form. Abscesses are more apt to occur in the posterior edge and right lobe of the liver, and are more frequently deep-seated and large; the superficial are generally smaller and more curable. The pus is inodorous, but occasionally very fetid. The serous covering of the liver is often thickened, opaque, dense and more or less resistant, with laminar depositions beneath it of an atheromatous character. Sometimes, it will be found to have formed adhesions to contiguous surfaces. According to the seat of the disease, its causes, etc., other organs may also be found diseased, as, the lungs, intestines, spleen, stomach, etc.

The *treatment* of hepatic abscess consists in subduing any active inflammation that may manifest itself, and to sustain the strength of the system and impart health to the vitiated blood by means of tonics and alteratives. To accomplish the first indication, anodynes, or Veratria, Aconite, Stramonium, etc., may be employed. In very severe cases leeches or cupping over the tender, inflamed, and enlarged part, is admissible. After the inflammation is subdued, the same alterative agents may be administered as named under

Chronic Hepatitis, together with a nourishing diet, and all other means to impart health and strength to the general system. The use of a dilute solution of Nitro-hydrochloric Acid internally, as well as applied externally over the hepatic region, will be very beneficial, unless it deranges the bowels. It must be borne in mind that but little influence can be exerted upon these abscesses by medicines, after they have formed and encysted, and the only hope of safety lies in imparting such tone to the general system as to enable it, not only to delay the rupture of the abscesses, but to withstand the prostrating influences of the rupture and discharge.

When the various symptoms attending the formation, presence, and discharge of pus are present, as, formication, rigors, cold profuse sweats, depression, dyspnoea, cough, hiccough, suffocating sensations, pain, great thirst, vomiting, etc.; these must be treated upon general principles, the same as when they occur with abscesses in any other organ, bearing in mind that the most the practitioner can do, will be to palliate urgent symptoms, and to sustain the strength and vital powers of the system.

In no case should the abscess be tampered with by endeavoring to open it; such a course has been advised by some practitioners, and has occasionally proved successful, but in the majority of cases it is a dangerous practice, as the pus is apt to escape into the peritoneal sac and occasion a more or less severe peritonitis. Again, air is very liable to enter the cavity, and perhaps some blood also from slight hemorrhage, then decomposition ensues, a secondary inflammation is excited, and death may speedily ensue.—If the abscess points toward the surface, it will be better to allow it to rupture spontaneously, favoring this, however, by poultices. When open, the matter should not be pressed out, but should be allowed to escape on the poultices, which act as a valve to prevent the ingress of air into the cavity. The disease has sometimes been cured by passing an exploring needle into the abscess, or by opening it gradually by means of caustic potassa applied to the prominent part; these operations may prove useful in cases where the liver adheres to the abdominal walls, and where there is but one abscess. In other cases their utility is doubtful; besides, there is, frequently, more than one abscess.

We may determine whether the liver adheres to the abdominal walls, by observing that at a certain part, the prominent edge of the organ remains there unchanged, no matter what position the body may be placed in, and also that over the abscess, there is a circumscribed œdema, or a slight blush on the skin. If the skin, however, retains its natural appearance, and the liver shifts its

position when the patient changes his posture or draws a deep breath, there is no adhesion. (*Budd.*)

WAXY LIVER.

This condition of the liver has been variously termed, Scrofulous Enlargement, Amyloid, Lardaceous, and Albuminous Liver; it is a true degeneration, due principally to a "metamorphosis of the glandular structure of the organ into a much more dense albuminous material than in the normal condition; a change which results in total destruction of the function, as well as the structural characteristics of the gland cells, and in a great increase of the solids of the organ at the expense of the fluids, the blood ceasing to circulate freely, and the water being diminished from three-fourths to three-fifths, or possibly in some cases to one-half of the weight, the solids being correspondingly increased, the fat either increased or unchanged." (*W. T. Gairdner.*)

The *causes* of this disease are not well understood. Males appear to be more subject to it than females. Constitutional syphilis appears to be a common cause, though it is frequently met with among scrofulous and phthisical individuals, as well as among those who have been under the influence of mercurials. It is also met with co-existent with scrofulous caries, and may likewise result from a series of attacks of intermittent fever. Intemperance in alcoholic liquors also appears to be a frequent predisposing cause.

The *symptoms* of waxy liver are very equivocal, being those peculiar to hepatic disorder, as made known by its complications with other organs, as, digestive derangements, nausea, vomiting, tympanitis, defective nutrition, discoloration of the feces, diarrhea, etc. The disease comes on insidiously, without much pain, tenderness, or any inflammation. The first indication of the disease is, the great enlargement of the liver, passing considerably below its normal boundary, and accompanied with more or less enlargement of the abdomen. Jaundice is seldom, if ever present; but there is a gradual emaciation, and the urine is apt to be loaded with albumen; if albumen and waxy-looking casts of the secreting tubules of the kidneys are observed in the urine, these organs are also implicated. The spleen is likewise apt to become enlarged. In some cases, after the disease has existed for some time, the superficial abdominal veins enlarge, a little fluid collects in the peritoneal cavity, and the skin becomes slightly yellow. The appetite may continue good for a long time.

If we find the liver enlarged, and can feel a smoothness of its surface, and a rounded condition of its lower edge, and there is also more or less enlargement of the abdomen, with emaciation, and no antecedent inflammation or pain has occurred, and the patient has scrofulous disease of the bones with suppuration, or is disposed to phthisis, scrofula, or secondary syphilis, we may safely *diagnose* waxy liver; and more especially if, at a later period, the urine becomes albuminous. When the kidneys are involved ascites or anasarca soon takes place.

The *prognosis* is unfavorable, and is much more grave when the kidneys become implicated. If the original affection or cachexy can be cured before the liver has become very much enlarged, the kidneys remaining healthy, the disease may be greatly benefited, and the patient's life be prolonged.

The *pathological appearances* are peculiar; the size of the liver is greatly increased as well as its density, which may reach as high as 1085; and conveys a wax-like sensation to the touch, though the knife passes more readily through it than it would through wax. To the eye the organ presents the semi-transparency of bacon-rind, or melted wax. The organ is very pale, and after death contains only a little pale, watery blood. In a slighter degree of the disease the lobules appear remarkably clear and well defined; in an advanced degree, the lobules can scarcely be distinguished, or no trace of structure will be observed in the interior of the organ, save an occasional blood-vessel. The albuminous material is deposited within the lobule and among, but not within, the secreting cells, and is sometimes mixed with fat, producing an opaque white material,—though the fat is no essential element of the disease. A dead white opaque matter running in the course of the portal vessels, may, from this cause, be frequently observed, and between these the transparent lobules themselves, with the hepatic vein in their center. The waxy liver is but very slightly affected by water, alcohol, acids, alkalies, or ordinary re-agents, and may be preserved for a long time without decomposition; under the microscope, the peculiar element which has changed the organ appears only as a refracting, corneous-looking substance, of no particular form or structure. (*S. Wilks.*) Other organs will frequently be found involved with the liver, as, the spleen, kidneys, etc.

In the *treatment* of waxy liver, we should endeavor to find out the peculiar condition of the system upon which it depends; if it be due to scrofula, syphilis, use of mercury, or spirit-drinking, the remedies and means used must be such as are suited to the partic-

ular eachexy, whatever that may be. Dr. Budd has known the liver to diminish very much in size from the prolonged use of Ammonia; in one case, he also derived considerable benefit from the prolonged use of Sesquicarbonate of Ammonia in doses of five grains twice a day, together with a properly regulated diet. A long course of dilute Nitric Acid, twenty minims, repeated three times a day, in cases due to syphilis and syphilitic osseous affections, and, dilute Nitro-muriatic Acid, in tuberculous disease, have also been recommended, to be used in conjunction with the other remedies employed.

FATTY LIVER.

In the normal state there is always a certain proportion of fatty material in the liver, amounting on an average to three or four per cent. of the whole mass; but it is only when this oily material becomes enormously developed in the hepatic cells, increasing both the size and weight of the organ, that it becomes a fatty degeneration; the structure of the organ itself, however, is not degenerated. This disease is very apt to occur in indolent persons, persons who are addicted to the use of alcoholic or malt liquors, and those who are large eaters, or who use much fatty diet. It may also follow or accompany certain diseases, as, the exanthematous, long-continued diarrhoea, phthisis, etc. Indeed, among a large proportion of persons who have died of pulmonary consumption, fatty liver has been found to exist, independent of the presence of any tubercles in this organ. Tuberculous disease of other parts may likewise be accompanied with a hepatic fatty degeneration. It would also seem that the long-continued use of mercurials, acute affections, as well as other causes that permanently impair the functions or the nutrition of the liver, may dispose to its fatty degeneration. Young persons appear to be more subject to it than old; and females oftener than males.

The *symptoms* of fatty disease of the liver, are by no means characteristic, being those also met with in hepatic enlargement or congestion. There is considerable enlargement of the liver; no jaundice, or if it does exist, it is in a very slight degree; emaciation; no ascites nor anasarca; and a pale, greasy or velvety character of the skin. The urine is apt to be neutral, contains considerable mucous flocculi, and has a specific gravity less than natural. The enlargement of the liver often occasions a sense of fullness and weight in the abdominal region, shortness of breath, and even nausea and vomiting. There are no positive diagnostic signs of this affection.

The *pathological appearances* met with in fatty liver are, a considerable enlargement of the organ, which has occasionally been so great as to occupy the whole of the abdominal cavity. The liver is also paler, softer, dotted with brown or red, and more greasy than natural, greasing the scalpel when cut into. The oily matter, which is principally composed of olein, is found in the biliary cells, (and not in special fatty cells), which cells acquire two or three times their natural size, lose their secretory character, and no longer contain biliary granules; but little bile will be found in the gall-bladder, which becomes contracted. The amount of oil in the organ may vary from ten to fifty per cent. of the whole mass, or even more. If the quantity of oil becomes so great as to rupture the hepatic cells, some of the oily matter may be observed outside of these cells. When fatty and waxy liver co-exist, the organ will be found greatly enlarged; dense, opaque, and yellow when cut into; small fatty granules and globules, as well as a degenerated epithelium will be seen under the microscope. Fatty liver may also exist in conjunction with other affections of the organ, as, atrophy, cirrhosis, etc.

The *treatment* of fatty liver consists in avoiding indolent habits, intemperance, etc., as well as abstaining from fats, sugar, starch, and butter. The patient should rise early, take active exercise, live principally on lean meat, with considerable salt, and drink water; the meals should never be full or hearty, but always moderate; he should bathe the whole surface of his body with a stimulating weak alkaline bath, repeating it every day or two; occasionally, a Spirit Vapor Bath should be taken; and such medicines should be taken internally as will increase the secretion and the flow of bile, as, Podophyllin, Leptandrin, Oleo-resin of Iris, Kalmia, Cider, Chelidonin, Berberin, etc. In addition to this, any existing tuberculous or other malady, should be subjected to the appropriate treatment therefor.

CARCINOMA OF THE LIVER.

Cancer of the liver is an affection occasionally met with, though Dr. Budd states it to be of frequent occurrence in England. The liver may be the only organ in which the cancer is seated, or it may be manifested also in some other organs, as the breast and stomach. The hepatic carcinomatous tumors may be white and fibrous, *scirrhus*; but more frequently they are soft, *medullary*. But every variety of cancer may be met with in the organ.

The *cause* of cancer is not well understood, though it may be

due to a low grade of vitality, or faulty nutrition of the parts affected, arising from anything that will obstruct or interfere with the natural functions of these parts.

The commencing *symptoms* of hepatic cancer are very obscure, being those peculiar to other affections of the organ. After a longer or shorter time, an enlargement of the liver is observed, with tenderness upon pressure, and more or less pain in the hepatic region. In conjunction with these, will be nausea, vomiting, a short dry cough, pain in the right shoulder, rigidity of the abdominal muscles, impaired or changeable appetite, emaciation, anemia, and depression of spirits. In some cases jaundice may be present; and, in others, ascites. As the disease progresses, pains will be experienced in the back and loins, febrile paroxysms will occasionally occur, the pulse will become frequent, the surface-temperature increased, the tongue red and furred, and the urine high-colored, giving a red or pinkish sediment; finally, colliquative night sweats and diarrhea, sometimes hemorrhages from the stomach or bowels, aphthous ulcerations of the mouth, with great exhaustion, which increase more or less rapidly until death takes place.

The *diagnosis* of hepatic cancer is almost impossible during its early period, unless in connexion with the liver symptoms cancer, be found to exist in some other part; and even then, the liver may be free from the disease. Dr. Harding states that if in connexion with symptoms of hepatic or stomach derangement in the female, he could find a small tumor varying in size from that of a pea to that of an almond, seated just beneath the skin of the breast, and most usually a little to the outer side of the nipple, he should positively diagnose cancer in the liver. In the male, a similar small mass had been found in the subcutaneous tissue of the loins.

Cancer of the liver may be determined from *waxy liver*, in which the spleen is apt to be enlarged, and the urine to be albuminous, in addition to which there is apt to be present either a scrofulous caries, secondary or tertiary syphilis, phthisis, or other antecedent conditions peculiar to waxy liver. In cancer, if the liver be very large, its surface can generally be felt uneven or nodulous; there is also pain,—both of which are absent in waxy liver.

From *fatty liver*, in which there is no pain, less constitutional derangement, the enlargement comes on less rapidly and more uniformly, and the patient is not a drunkard, nor consumptive,—the previous history is also unlike that of cancer.

From *hepatic syphilis*, in which the patient previously suffered from syphilis, and was treated by mercurials; in which syphilitic ulcers or cicatrices in the throat, are present, as well as a pale,

cachectic, but not jaundiced appearance, perhaps enlargement of the spleen, a want of tenderness in the region of the liver, and if any nodules are felt upon its surface, they are smaller and not so hard as those of cancer.

From *affections of the gall-bladder*, in which the enlargement at the lower border of the liver is rounded or somewhat pyriform, beside which the patient has previously suffered from one or more colicky attacks due to the passing of gall-stones, and his skin presents a deeper tint than in cancer. Cancer of the gall-bladder may co-exist with hepatic cancer, or cancer of other parts, is more common to persons somewhat advanced in years, and presents more marked symptoms of the cancerous diathesis.

From *cancer of the stomach*, in which the pain is more toward or in the epigastrium, and shoots into either hypochondrium; the vomiting is more frequent; the matters ejected are of dark color; the location of the tumor is different; and the symptoms of hepatic disease are absent, or not so well marked as those of the digestive organs.

From *cancer of the omentum*, in which there is no jaundice, no alteration in the appearance of the feces, and, in which, generally, but not invariably, the rest of the tumor and its boundary is different from that of cancer of the liver.

From *enlargement of the right kidney*, in which percussion yields a dullness of a different periphery from that of hepatic cancer, which is marked externally by the abdominal tympanitic sound, and is not affected by deep inspiration; in addition to which, the prominent symptoms present will be those of diseased kidney, functional or organic, instead of liver disease.

The *pathological appearances* of cancer of the liver vary according to the stage and character of the malignant affection. Tumors of various sizes will be found disseminated throughout the liver, having a yellowish appearance, a hard and firm texture, and making a peculiar noise under the scalpel. Not unfrequently their central portions will be soft, containing a dark-colored fluid. These tumors give an uneven, knotty or nodulated feel to the surface of the liver; or of softness when they have become softened; and sometimes they will be met with in the same liver, of every shade from light brown to black, as in the melanotic tumors. Usually the tumors are inorganized; though their internal structure, when hard, will often present fibrous variations from the center, or, concentric circles. The liver tissue surrounding the cancer may be healthy, or it may present at some parts a pale and fatty appearance, etc. Scirrhus is of slow progress, and has a dense, fibrous basis; en-

cephaloid progresses rapidly and has a loose cellular basis. The disease may also be found in other parts, either as a cause or as an effect, as, in the gall-bladder, stomach, kidneys, uterus, breast, etc.

The *treatment* of cancer of the liver is purely palliative, as its termination is always fatal. Anodynes and sedatives are indicated to relieve pain and promote sleep; counter-irritation to allay peritonitis when it is excited into action, aided by fomentations, sedatives, etc. Blisters or pustulating applications are inadmissible. Tonics and good diet are required to sustain the patient's strength and prolong life. And, as a general rule, the less interference with medicines the better for the welfare of the patient and the reputation of the practitioner.

HYDATIDS OF THE LIVER.

The liver is more liable to hydatid development than any other organ, and the affection is by no means an unfrequent one. Hydatid tumors consist of a sac apparently formed of condensed liver tissue and the remains of obliterated vessels, which incloses a thin bladder or cyst containing a clear liquid, in which float more or less numerous similar, but smaller globular cysts or bladders, of various sizes. Both these and the parent cysts are termed, *acephalocysts*, or, bladders without heads. A peculiar microscopic animalcule has been observed to occupy these cysts, termed *echinococcus*. The most frequent seat of hydatids is in the right lobe of the liver, very near the surface. Hydatids are parasitic growths, the germs of which, probably, are introduced into the body by means of drink, diet, etc., and become developed under favorable circumstances, as, from blows on the side, excessive dampness, poor diet, etc.—Although recoveries often occur, nevertheless, the disease may be considered a very dangerous one.

The *symptoms* of hydatids in the liver at their early period, are very obscure, as they occasion no pain, no jaundice, no dropsy, nor any hepatic, or gastro-intestinal derangement; it is only when they have increased in size so as to mechanically disturb the hepatic functions, that attention will be directed to the cause of such disturbance. But as their growth is usually very slow, years may pass from their first development before there will arise any marked symptoms to attract notice, and, the symptoms may often be so obscure, that a life-time may pass without their presence being suspected.

The first symptoms usually observed are, a sense of weight and fullness in the hepatic region, more or less disturbance of the digestive functions, and perhaps dyspnœa. Upon making an examina-

tion, the liver will be found enlarged, either extending downward into the cavity of the abdomen, or else, enlarging upward so as to materially interfere with the action of the diaphragm and lungs, occasioning eventually a hard, dry cough, or cardiac palpitation. If it interferes with the circulation of the portal vein, or of the vena cava, anasarca of the inferior extremities and ascites may be the result. The tumor formed by hydatids is usually without a hardened base, is circumscribed, soft, and yielding, and is not accompanied by the usual signs of abscess, nor by the constitutional effects of cancer. Percussion yields a very irregular outline of dullness; and if the blows be made abruptly and consecutively, a peculiar vibration may be perceived, greatly resembling that which is experienced on percussing a quantity of jelly.

The *diagnosis* of a hydatid tumor is rather difficult in its early period, or when it is small and deep-seated; but when it is large, and especially when seated near the surface, it may readily be distinguished from other affections with which it is possible to confound it, by the following symptoms:

From *abscess of the liver*, by its slow growth, the presence of little or no pain, and the entire absence of fever, as well as of any disturbance of the general system; in abscess, there is pain, fever, constitutional derangement, more rapid growth, and, perhaps, jaundice or ascites at an early period.

From *cancer*, by the absence of local tenderness, slow growth, and general health of the patient; in cancer, there is more or less pain or tenderness, a more rapid growth, emaciation, anemia, and other evidences of constitutional disturbance, with an unevenness of the surface of the liver in other parts, occasioned by the projection of other cancerous tumors.

From a *distended gall-bladder*, by the shape and position of the tumor, by the patient having previously suffered from colicky pains, and by the deep jaundice present; in hydatids, the tumor is not seated in the normal region of the gall-bladder, jaundice is absent, as well as colicky pains.

From *aneurism of the aorta* in which there is a distinct pulsation in the tumor, great pain in its region, and a bellows sound heard over the last dorsal, or the upper lumbar vertebræ; besides, aneurism is generally ushered in with a sudden cramp-like pain in the epigastric region, without either vomiting, purging, or jaundice.

In cases that are rendered obscure by the location of the tumor,—its slow growth, absence of tenderness or pain, non-interference with the hepatic, gastric, intestinal, or pulmonary functions, except at an advanced period, and the usual health of the patient remaining

undisturbed,—may lead us to suspect their hydatidic origin. The recommendation to explore the tumor with a fine exploring trocar, is not wholly void of danger, especially when it is small and deep-seated.—When the hydatid tumor becomes painful, and accompanied with rigors, febrile action, and constitutional disturbance, these indicate suppurative action.

The *prognosis* of hydatids of the liver is not necessarily unfavorable; usually, the affection continues for many years without giving rise to any serious symptoms, although the walls of the sac are liable to ulcerate at any time, rupture, and discharge its contents. If the fluid be discharged into the stomach or intestines, so that it may pass by stool, or by vomiting, the sac may ultimately close up, and the patient recover. The same result may ensue if the fluid is discharged through the lung and expectorated, provided no inflammation of the lung or air-tubes, nor any great amount of constitutional suffering is produced. (A microscopic examination of the fluid expectorated, or vomited, etc., will reveal its source, by the presence therein of the acephalocysts, and hooks of the echinococci. A hard, dry, straining paroxysm of cough usually precedes their expectoration from the lungs.) In all these cases, recovery is not apt to occur very rapidly. If the fluid is discharged into the peritoneum or pleura, a fatal peritonitis or pleuritis is apt to result therefrom. And a fatal result is likewise liable to follow those cases in which suppurative inflammation of the sac, or of some of the neighboring tissues, is excited. If a secondary hydatid tumor forms in the lung, the patient may be destroyed by suffocation; if numerous primary or secondary tumors form, nutrition will be interfered with, and death may ensue from exhaustion.

One difficulty is, to determine whether one, two, or more tumors are present, as they frequently exist in great numbers, disseminated throughout the tissue of the liver. “Experience proves, however, that it is seldom that more than three or four are developing in various parts of the organ at one time; but it is this circumstance which constitutes the difficulty, and we may say the danger of interference; for if one is collapsed through evacuation of its contents, the others enlarge, and the patient dies at last from exhaustion.” (*Garrod.*)

The *pathological appearances* observed are, sacs formed of hepatic tissue, of various sizes and in greater or less numbers, which inclose, each, the acephalocyst; this is composed of friable, minutely laminated envelopes, which are not adherent to the inner surface of the sac containing them, and which contain a clear fluid, of a salty taste, non-albuminous, neutral or faintly alkaline, and of specific

gravity 1.008 to 1.013. In this fluid float numerous accephalocysts, and, under the microscope, the hooks or the teeth of the echinococci may be seen. The membranous wall of the cyst appears to be albuminous, and contains phosphate of lime. Ulcerations, suppuration, etc., may also be observed, when they have taken place, as well as alterations of the tissues in which these effects have occurred.

The *treatment* of hydatids should have in view their destruction without rupturing the sac containing them; if this can be effected, the tumor shrinks to a certain degree, its further growth is arrested, and there is no longer any danger to be feared from it. Certain agents have been advised to destroy the vitality of the hydatids, as, common Salt, and Iodide of Potassium, which may be given internally, as well as applied locally in strong solution or ointment. But these do not always succeed. Tobacco fomentations have, in a few instances, been successful, applying them upon the side over the tumor; the objection to them is, the nausea and depression they are apt to occasion. In one case, I derived great benefit from fomentations over the region of the liver, composed of Tobacco one part, Balmony three parts. A mixture composed of American Petroleum, Aqua Ammonia, Oil of Turpentine, Tincture of Stramonium Seed, equal parts, and rubbed several times a day on the side over the tumor, continuing its use for a considerable time, is also said to have been found serviceable.

But medical means frequently fail, and tapping the tumor has been advised, so as to empty it of its contents, which is followed by a destruction of the vitality of the hydatids. This, however, is attended with some risk, as, the entrance of air into the sac may give rise to suppurative inflammation; or, some of the fluid may pass into the peritoneal cavity, exciting a fatal peritonitis. Nevertheless, in many instances the operation has proved successful. The instrument used is a fine exploring trocar, which should be inserted downward, the outer end being kept at a higher level than that in the body, in order to prevent the admission of air, and the water be drawn off by means of an exhausting pump, being very careful not to allow a particle of air to enter the cyst. By this means, each cyst may be evacuated, as it enlarges and becomes prominent. Long-standing hydatids should not be treated in this manner; it will be better to allow them to rupture spontaneously.

CIRRHOSIS OF THE LIVER.

This disease,—also known by the names of Gin-drinker's or Hobnail Liver; Granular, Tuberculated, Nutineg, or Mammillated Liver;

Chronic Diffuse Inflammation of the Liver, (*Frerichs*), etc.—consists in an atrophy of the lobular substance of the liver, the organ being much diminished in bulk, hard, dense, and studded with yellow granules or small roundish bodies of various sizes. The disease never affects the liver partially, but always attacks all parts of its substance simultaneously, and in pretty equal degree. Males are more liable to it than females, and generally between the ages of thirty and forty-five, though it may occur at any age.

The immediate *cause* of this disease is unknown; “it may exist as an independent degeneration, or it may spring from the waxy or the fatty conditions.” (*W. T. Gairdner*.) It is frequently preceded by inflammation of the fibrous structure of the liver (Glisson’s capsule), resulting in a thickening of this capsule. Yet inflammation is not essential, as, in some cases, it has not prevailed; and it is not yet satisfactorily solved whether the thickening of the capsule be due to the inflammation, or to one of the lesions accompanying organic atrophy. The habitual excessive use of alcoholic drinks is probably one of the most common determining causes of cirrhosis, more especially among those who dilute their drinks very little, if any. Alcoholic drinks may occasion the disease from the ready inflammatory condition of the liver produced by them when absorbed into the blood, and, probably, also by determining impediments to the pulmonary or cardiac circulation. Occasionally, the disease is met with, in which the only discoverable cause is, bad and insufficient diet, or faulty digestion, etc.

Hepatic cirrhosis is mostly complicated with organic disease of other parts, as of the stomach, Bright’s disease of the kidney, and various lesions of the heart and lungs, which may exist either as a cause of its presence, or as one of its results. Pulmonary consumption, so frequently accompanied with fatty liver, is very rarely found with cirrhosis.

The *symptoms* of cirrhosis are not sufficiently characteristic to enable us to positively determine its presence during life. At an early period they are similar to those met with in chronic hyperemia, as, a dull pain in the side, tenderness on pressure, deranged digestive functions, and, perhaps, a jaundiced skin. Sometimes, instead of appearing thus insidiously, cirrhosis may come on suddenly, with more or less severe febrile, local, and constitutional symptoms, constituting the acute form of the disease, which form may also be developed as a result of the disease in a more advanced stage,—and yet its true character may not be known until after death.

In the first stage of the disease, which is the only one in which a cure may be effected, many patients are very apt to have what they

term "colicky pains," which come on a few hours after dinner, accompanied by quick pulse, slight fever, vomiting, and constipation. With each attack these symptoms become more intense. The skin is dry, the tongue red and smooth in the center, pain at the top of the right shoulder, and a gradually appearing jaundiced hue of the skin. There is also some slight pain in the region of the liver and duodenum, and the stools contain much mucus, and perhaps are streaked with blood.

At an advanced period of the disease, when the contraction or atrophy of the liver is fairly effected, other symptoms will be present, the most constant of which is ascites, and, if Bright's disease of the kidney, or disease of the heart be also present, anasarca. There is no pain or tenderness in the abdomen, unless peritonitis be present. The decrease in the size of the liver may be detected by palpation and percussion, the former enabling us to detect the hard, irregular granulations seated upon the border of the liver as well as upon its inferior surface; the latter, to determine the diminution or total absence of percussion dullness in the region of the liver. But, if there be much fluid effused within the abdominal cavity, these signs can not be had, until after the tense and swollen state of the abdominal walls have been removed by tapping. The urine is very scanty, of a deep-orange or reddish-yellow color, of increased specific gravity, strongly acid, and gives an abundant precipitate of a bright-red urate of ammonia. If jaundice be present, the coloring matter of bile may be detected in it; if Bright's disease of the kidney exists, albumen will be found.

In addition to these symptoms, others may exist, as, a sallow, earthy complexion, a dry, rough skin, emaciation, debility, impaired appetite, dilatation of the veins on the surface of the abdomen, hemorrhages from the nose, stomach, or bowels, enlargement of the spleen, acid eructations, and more or less derangement of the gastro-intestinal functions. Small spots, resembling purpura hemorrhagica frequently appear on the face, or on the surface of the abdomen. Death may occur from gradually increasing exhaustion, from colliquative diarrhea, from the drain caused by paracentesis, or from hemorrhage from the stomach or bowels.

The enlargement of the abdominal veins, the ascites and hemorrhage from the stomach or bowels, are due to obstructed portal circulation. When anasarca is present, and appears previous to the ascites it is due heart or kidney disease; if it appears in the inferior extremities after the ascites has formed, it is owing to compression of the vena cava, and of the iliac veins. The jaundiced complexion is probably due to an obstruction to the flow of bile from the

lobules, which is occasioned by the hardened tissue in the portal canals.

Although the *diagnosis* of cirrhosis is difficult, still there are certain marks of distinction between it, in its fairly developed stage, and some other diseases with which it may be confounded; thus—*chronic hyperemia, waxy liver, fatty liver*, present more or less enlargement of the organ, no ascites, no evidences of any serious impediment to the portal circulation, and an entirely different history as to the habits of the patient, etc.

Hydatids of the liver presents an enlargement of the organ, with irregular outline, softness and fluctuation of the tumors, and no great impairment of the general health and strength; besides, the patient may be temperate. No ascites.

Cancer of the liver presents an enlargement of the organ, with hard prominences or nodules on its surface, the organ is painful, and tender to the touch, ascites may be absent, or, if present, not sufficient to render the walls of the abdomen tense, the skin perspires more or less, the patient may be temperate, and cancer may exist in some other organ. Hectic fever and night sweats are common in cancer.

Enlarged spleen produces ascites, but it may present a history different from cirrhosis; the patient may be temperate, have previously suffered from malarial fever, the skin is moist, and the enlarged spleen may be felt in the left side.

Peritonitis has a different history, there is abdominal pain and tenderness, an absence of the sallow look of cirrhosis, fluctuation is less distinct, a tendency to tuberculous disease, hectic fever, and sweating.

Ordinarily, the accumulation of fluid in the ascites of cirrhosis is greater than that due to other affections, and, after a paracentesis has been performed, it returns with much greater rapidity.

The *prognosis* of this disease is unfavorable; "Its course is uniform and continued, and it always proceeds more or less quickly to a fatal termination, being apparently uninfluenced by any plan of treatment." (*Becquerel*.)

The *pathological appearances* are a liver more or less diminished in size, and in weight, with rounded edges, and small, round nodules projecting from all parts of its surface. It is usually united to the abdominal walls, to the diaphragm, or to both, by false membranes or bands of adhesion. On cutting into the substance of the liver, the organ will be found tougher and much paler than natural, containing but little blood, and presenting a mottled appearance, due to numerous roundish bodies varying in

size from the smallest perceptible to that of a pea, or even to that of a nutmeg. These rounded bodies vary in color from pale yellow to brown, presenting a contrast with the pale or gray color of the intermediate substance, and are pretty uniformly distributed throughout the substance of the liver.—The capsule of Glisson is thickened, whitish, or opaque, more close and resisting, and intimately adherent; in the interior of the parenchyma, this thickening appears as whitish lines inclosing the hepatic lobules, and sometimes the rounded bodies. The hepatic tissue is apt to be dry from paucity of blood, and, from obliteration of many of the vessels and ducts of the organ, it is difficult of injection. The gall-bladder is almost always quite natural.—If other organs are affected, as the kidneys, spleen, heart, lungs, etc., they will present evidences of diseased action.

The *treatment* of cirrhosis of the liver is palliative, being careful not to pursue measures that will lessen the power of the heart, but to adopt those that will sustain strength, check hemorrhages, and overcome vomiting and diarrhea; for the latter two, large doses of Bismuth will frequently be found to answer. Spirituous drinks must positively be abandoned, and, for a time, good newly-made cider may be substituted for them, to which, some alkaline carbonate may be added, if deemed necessary. The ascites should be kept down as much as possible by diuretics or hydragogue cathartics in its early period; but, at a later stage, when the strength and flesh are much reduced, they should not be used, as they are apt to augment instead of lessen the amount of fluid. Tapping is never of much service, as the fluid returns rapidly; yet it may be performed only when there is great difficulty of breathing, or other symptom requiring immediate relief from the abdominal distension. Pure air, an attention to the skin, and local applications of the alkaline iodides or bromides, with stimulants, over the hepatic region, are important. Sedatives often afford considerable comfort. It is seldom, if ever, that attention is called to this disease in its early stage, when there is a possibility of effecting a cure.

There is another form of *Atrophy of the Liver* due to an obliteration or closure of the common duct, the only symptom indicating its presence being jaundice, and which possesses, at the present day, no interest for the therapist.—Both tyrosine and leucine exist in the urine in either acute or chronic atrophy of the liver.

JAUNDICE. (*Icterus*.)

One of the most significant indications of disorder of the biliary apparatus, and one that presents itself very frequently, is jaundice; indeed, there are very few hepatic affections in which this symptom is not manifested in a greater or less degree. In consequence, although a mere symptom, it has been considered of sufficient importance, among medical writers, to be treated upon separately. This affection is especially characterized by a more or less marked yellowness of the skin and of the conjunctiva, whitish or clay-colored stools, and a bilious or saffron-tinted urine, which stains linen a deep-yellow color. It is generally sporadic, but occasionally appears as an epidemic, especially during very wet seasons, or after the close of military campaigns.

Causes.—Jaundice is undoubtedly owing to the presence of one or more of the biliary elements in the blood; but it is still a matter of inquiry how these elements get into this fluid. Many suppose, that when there is an obstruction, preventing the flow of bile into the intestine, this is re-absorbed and carried into the circulation; again, others maintain that jaundice arises from a suppressed or defective secretion of bile; in the latter instance, certain elements remaining in the blood, as, the biliary acids, coloring matter of bile, or cholesterin. Dr. Geo. Harley believes that jaundice may arise from suppression of the biliary secretion, or, from re-absorption of the secreted but retained bile. And his method of distinguishing between the two, is by an analysis of urine, as explained heretofore, on page 799. His views are the ones generally received at the present day.—Other views have been presented to the profession to account for certain indefinite forms of jaundice: Thus, Frerichs advances an idea that the action of some poison in the system converts the colorless bile acids in the blood, into bile pigment, and thus a form of jaundice be produced.

I have heretofore, (page 798), referred to the discovery of Prof. A. Flint, Jr., that cholesterine derived from the brain and nervous system, is taken up by the blood, from which fluid it is separated by the liver, and is discharged from this organ as a product of excretion, in the form of stercorine.

Frerichs is opposed to the view that jaundice may be the result of an imperfection in the secreting functions of the liver. He says: "All the means for detecting traces of the essential elements of the bile in the blood generally, and in that of the portal vein in particular, have been exhausted without any result: neither the

coloring matter, nor the acids of the bile, substances for which we possess tests of considerable delicacy, have been found." May not this be owing to the fact, that these substances, (the glyco-cholate and tauro-cholate of soda, etc.), do not pre-exist in the blood, but are solely products of secretion, which subserve for assimilation? Indeed, under no circumstances are these secretory substances ever found in the blood.

Again, Frerichs continues: "In the same way that urea accumulates in large quantities in the blood in granular degeneration of the kidneys, so ought the biliary acids and bile pigment to accumulate in the blood in cases of granular liver." It is not the bile acids and pigment that accumulate in the blood, but the product of excretion that pre-exists in this fluid, cholesterine. And this substance, according to Prof. Flint, holds the same relation to bile, that urea does to urine; and its accumulation in the system, the same as the accumulation of urea, occasions poisonous results. In simple jaundice, in which the coloring matter of the bile is resorbed from the biliary passages, the disease is not dangerous; but in grave cases of jaundice, in which there is usually some structural change in the liver, cholesterine is retained or accumulates in the blood, and the disease like uræmia almost invariably terminates fatally,—this latter condition, Prof. Flint terms *Cholesteremia*. These are points which should receive the serious attention of every medical man, and Prof. Flint's article, upon the subject, which may be found in the American Journal of Medical Sciences, October, 1862, is well worthy a careful perusal.

The various abnormal conditions in which jaundice may exist as a symptom, are as follows: a temporary or permanent obstruction of the common duct, during the passage of a gall-stone; cancer of the liver, or of the pancreas; temporary or permanent obstruction of the ducts from adhesive inflammation; enlargement of one of the lymphatic glands contiguous to the common duct; obstinate constipation, in which the intestine, filled with fecal matters, presses on the common duct; duodenal disease, obstructing the common duct, etc.,—all of which occasion an impediment to the flow of bile into the intestine. Most of the structural lesions just treated upon in the preceding pages, are apt to be accompanied by jaundice, from their suppressing the secretion of bile, or rendering it defective both in quality and quantity. A suppression of bile may also arise from excesses of various kinds; an inactive, sedentary life; powerful, or long-continued mental emotions; a poisoned condition of the blood, which may occur during the course of certain diseases, or from poisonous matters

introduced into the circulation; gastric derangements; suppression of certain cutaneous eruptions; and occasionally the jaundice may appear without any known attributable cause.

Symptoms.—The condition of jaundice is very readily determined by the yellow color of the skin and conjunctiva, which may vary in tint from a bright-lemon to a dark-olive color. When the color is of a green tinge, it has been termed *green jaundice*, and is apt to result from closure of the common duct; when the color is of a very dark hue, it has been termed *black jaundice*. Not unfrequently an icteric discoloration pervades the internal tissues, as ascertained by investigation after death; and in some rare cases, from the cornea or the humors of the eye becoming jaundiced, all objects appear either yellow, or covered with bright-yellow spots.

Jaundice is frequently preceded by a state of languor, inactivity, drowsiness, loss of appetite, flatulency, and constipation, which may continue in a greater or less degree during the presence of the icteric affection; sometimes, on the contrary, diarrhea may be present, with an offensiveness of the discharges; and again, the stools may be natural, or nearly so. And, in serious cases, the drowsiness may pass into coma or delirium, and fatal cerebral disorder, probably, from retained cholesterine; and this may occur even when the jaundice has existed for many weeks without presenting any alarming symptoms. During the presence of the affection, various symptoms will be associated with it, depending upon the character of the hepatic disease giving rise to it, and its complications. Among the symptoms more usually encountered, may be named,—tongue coated with a dirty-yellowish fur; mouth dry, with a bitterish taste; pain in the head; more or less pain in the right side, which is increased on pressure, and there may also be pain at the top of the right shoulder, beneath the right scapula, or between the shoulders; or, there may be pain or uneasiness in the epigastric region; the pupils are apt to be more or less dilated; sometimes a sense of heat and excessive itching of the skin; perhaps nausea or vomiting; intestinal derangements; constipation, with a drab or grayish color of the stools; frequently a variable pulse; high-colored urine. In nearly all cases the patients become thinner; and, sometimes, there is more or less peevishness, irritability, or extreme sensitiveness, the person crying even from imaginary causes. Frequently, the affection is so mild as not to interfere with the ordinary pursuits of the patient; while in other instances, there will be more or less interference presented, even to an absolute necessity for confinement in bed.

The jaundice may come on slowly or suddenly, according to its cause; and the more severe its symptoms, the more serious is it in its character. The darker the discoloration the more grave the disease; but the same can not be said of a slight icteric hue, which may be present during some grave hepatic lesion, as, for instance, cirrhosis. Simple, uncomplicated jaundice usually lasts from one to six weeks, or even longer, and, as a general rule, terminates in health; but when complicated with hepatic, cardiac, or cerebral disease, it is apt to prove fatal.

Jaundice, having manifested itself, the physician is still in the dark as to its prognosis and treatment, unless he can determine the hepatic disorder giving rise to it, or can ascertain its particular producing cause, which are frequently very difficult matters to accomplish. Indeed, the difficulty in *diagnosis* commences, as it were, with the presence of the icterus. Still, attempts, by the light of what knowledge we have, should always be made. A yellowishness of the conjunctiva, without an icteric hue of the skin at the same time, can not be considered as indicative of jaundice. *Chlorosis* may give a slight greenish hue to the skin, but the conjunctiva presents a pearly or bluish lustre; the same occurs with malignant affections in which the skin has a sallow earthy appearance; the yellow tinge of the conjunctiva is not present in pyæmia unless jaundice co-exists.

If the patient has been free from any symptoms of hepatic disorder, and the jaundice is preceded by some powerful mental emotion, we may, as a general rule, safely attribute it to this cause. In all cases, the urinary analysis, heretofore referred to, will determine whether the icteric symptom is due to suppression of the biliary secretion, or to an impediment to its flow into the intestine—but it will not inform us what has occasioned the one or the other of these conditions. We should therefore, beside acquiring a detailed history of the case and an accurate knowledge of all the phenomena attending it, very carefully examine the various organs of the body, to determine the existence of one or more of the lesions with which jaundice may exist as a symptom, as,—waxy liver, acute yellow atrophy which is associated with cerebral disturbances, cancer, fatty liver, cirrhosis, acute hepatitis, disease of the bileducts, obstruction from gall-stones, disease of the heart, or of other organs that may induce hepatic disorder, pyæmia, or, the presence of poisonous substances in the blood, etc.

The *prognosis* of jaundice rests wholly upon its cause. Simple, uncomplicated jaundice is usually curable. The less serious the attendant phenomena, the more favorable is the prognosis; it is

also favorable when resulting from moral or mental causes; likewise when the stools assume a more natural appearance, with a gradual disappearance of the icteric tint of the skin and of the accompanying symptoms,—though it must be remembered that the discoloration of the skin may continue for some time after the impediment to the flow of bile has been removed, and the urine no longer gives indications of its presence. The jaundice during pregnancy, generally disappears after delivery. When the jaundice is complicated with structural lesions it is very apt to prove fatal; also when it is due to a suppression or defection in the secretion of bile. An obstinate, long-continued jaundice, is generally due to structural lesion, and is unfavorable, though recoveries sometimes occur; yet, in the course of my practice, I have met with three cases in which the patients, having been previously in apparent good health, were suddenly attacked with jaundice, which proved fatal in one case in five days from the first manifestation of the disease, and in the other two, in seven days,—in each, the stools were pale, hard, devoid of odor, and very scanty, and in one case there was a constant intractable epistaxis until a short time previous to death. If the jaundice accompanies pneumonia, peritonitis, pyæmia or other blood affections, it is apt to prove fatal. The presence of cerebral symptoms is an indication of danger. Severe pain in the hepatic or epigastric region, rapid pulse, great debility and emaciation, a dark or livid color of the skin, obstinate paleness of the stools, chilliness, œdema of the extremities, wakefulness, depression, melancholy, and hiccough, are unfavorable symptoms. When the skin is deeply discolored, as in *green* or *black* jaundice, a fatal result most generally ensues.

There are no *pathological appearances* peculiar to jaundice. The icteric hue may be found coloring all the internal tissues, especially the cellular, adipose, and serous. Sometimes there will be no evidences of disease sufficient to account for the jaundice or its fatality. In other instances, various structural changes will be observed in the liver, gall-bladder, biliary ducts, portal vein, hepatic veins, stomach, heart, kidneys, etc., some of which changes, are referred to under their respective heads in this book.

The *treatment* of jaundice is based upon its cause; but we are not always able to satisfactorily ascertain this, hence the means employed, are, to a great extent, empirical. When the cause is known, our object should be to remove it, and then the jaundice will disappear; but, unfortunately, the peculiar structural lesions upon which the jaundice depends, are frequently of such a nature as to render all therapeutical measures unavailable, except as far

as palliation of urgent symptoms is concerned. There is "one principle to be borne steadily in mind in all cases, whatever their cause, and that is to promote in every way the functions of those organs by which compensatory elimination of bile is effected." (*S. H. Ward.*)

When the jaundice results from inflammation of the liver, or of the gallducts, as manifested by a sense of fullness, with pain and tenderness in the hepatic region, extending as far as the epigastrium, and which is augmented upon pressure, a redness of the tongue, frequent pulse, and other indications of febrile action, leeches or cups should be applied over the affected parts, followed by hot fomentations of Lobelia, Hops, Stramonium, etc., an occasional Hot Air Bath, frequent bathings of the surface, and nauseating doses of Bloodroot and Ipecacuanha. A gentle diaphoresis should be constantly maintained. The bowels should be kept free by Podophyllin and Bitartrate of Potassa, or, what will be found better in many cases, a mixture of Compound Powder of Jalap and Bitartrate of Potassa. Proper attention should be paid to the kidneys, keeping up their action by means of saline diuretics, or, cooling vegetable diuretics. The diet must be moderate and light. After the more active symptoms have disappeared, small doses of a mixture of Podophyllin, Leptandrin, Sulphate of Quinia, and soluble Hydrastin, should be given three or four times a day, for several days subsequently. Of course, the more severe the symptoms, the more energetically must the above measures be employed.

In those cases where the patient having been previously in a state of health, is attacked with jaundice, and no other symptoms can be detected except drowsiness, languor, constipation, derangement of the appetite, and extreme sensitiveness; and the person is able to be about, one of the following preparations will be found of much efficacy, conjoined with laxative doses of Podophyllin and Leptandrin, or, of the Compound Pills, or Compound Powder of Leptandrin: 1. Take of Golden Seal, Barberry, each, one ounce; Sheep Laurel, Bloodroot, each, two drachms; Cider one pint and a half; mix. The dose is a tablespoonful three or four times a day. 2. Take of Wild Cherry Bark, Prickly-ash Bark, Bloodroot, Golden Seal, Sheep Laurel Leaves, each, in powder, one ounce; Cider five pints; mix, and infuse for several hours. The dose is the same as the preceding.

In some cases, I have substituted Whisky or Spirits for the Cider, and with good effect, though I prefer the latter when a good article can be had. In a similar way, various combinations may

be formed into a tincture or infusion, of, Horse-radish, Bayberry Bark, Bitter Root, Yellow Walnut Bark, White Poplar Bark, etc.

If there is pain, tenderness, and enlargement of the liver, in connection with the above form of the disease, stimulating liniments in which Oil of Turpentine enters as an ingredient, or, the Croton Oil Liniment, or, the Compound Tar Plaster should be applied over the hepatic region.—Excessive drowsiness, and other cerebral symptoms, must be combated by active purgatives and diuretics, together with energetic counter-irritating measures to the scalp, neck, and along the spinal column. Saline purgatives and diuretics are generally to be preferred in these cases.

When the jaundice is known to be the result of powerful mental emotion, torpor of the liver, or, when it is of a simple, uncomplicated character, but very obstinate to treatment, emetics will prove serviceable, which may be repeated daily, or every other day.—When the jaundice is due to excessive secretion of bile, as may be known by the alvine evacuations being colored with bile, or by bilious diarrhea, and, sometimes, vomiting of a dark bilious matter, and usually more or less febrile action, Oil of Turpentine will be found of much service, to be given in drachm doses every two or three hours, in conjunction with Spirit of Nitrous Ether to prevent strangury, and produce perspiration. With this, may also be used Turpentine Liniments to the side, and, if there is considerable gastric irritability, sinapisms should be applied over the epigastric region. Turpentine has also been found useful in jaundice due to biliary calculi; two parts of Oil of Turpentine mixed with three parts of Sulphuric Ether, and taken in half fluidrachm or fluidrachm doses every morning. As turpentine is apt to occasion nausea, vomiting, and pain, some caution should be used in its administration. The means recommended for gall-stones, are, however, to be preferred.

Other agents have been recommended in jaundice, that have frequently proved of considerable benefit, as for instance: Take of clean hard-wood Soot one ounce, Salt, Black Pepper, each, half an ounce, White or albumen of six Eggs; mix. The dose is half a tablespoonful every morning; the patient drinking freely of an infusion of Wild Cherry during the day. Bernard has shown that albumen becomes assimilable only through the medium of the function of the liver, and it may be that it acts as an excitant of this organ, or as a superior cholagogue, hence the efficacy of the white of egg in jaundice, associated with, or due to a torpid condition of the liver.—“In jaundice with obstruction of the biliary ducts, we should make early use of Nitric Acid or Nitro-

hydrochloric Acid, which should be greatly diluted with water, in order to have the remedy more quickly assimilated, and to produce more certain effects. A watery solution of Nitrous Acid is easily made, and may be drank as a pleasant lemonade; it is less apt to produce griping than the nitric or nitro-hydrochloric acids, beside which, it not only destroys and lixiviates the deposits of cholorchrome and other amido-acids, but it also tones the digestive organs, and acts antiseptically. Nevertheless, a remedy to stay the abnormal action of the liver cells we are yet in want of. Creosote is beneficial. In all cases where the disorder of the liver proceeds from the intestinal canal particularly, Creosote, Charcoal, astringents like Gallic Acid, and preparations of Iron, particularly the Tincture of the Sesquichloride given together with some Nitric Acid, are highly beneficial." (*Thudicum.*) Bathing with dilute Nitro-hydrochloric Acid in the hepatic region will also be of service.

Prepared Beef's-gall has also been of considerable advantage in many cases of jaundice depending upon obstructed flow of bile, but in order to be of efficacy it must not be administered for an hour or two after a meal, so as not to interfere with the action of the gastric juice; then it may pass into the duodenum and act upon the chyme, at which period alone will this remedy be useful, by rendering the chyme fit for assimilation.—In jaundice from suppression, Benzoic Acid has been recommended.—When the jaundice is idiopathic, or, is due to, or associated with, dyspepsia or chronic gastric irritation, crystalized Nitrate of Silver in doses of three-quarters to one grain, given on an empty stomach, and repeated twice a day, has been highly recommended; it is said to give immediate relief, and to effect a cure in ten or twelve days. If constipation be present, the agent may be combined with some laxative.

The diet in jaundice should be plain and unirritating, but nutritious and of easy digestion, avoiding fats and articles consisting of starch; meats, vegetables, fruit, and raw eggs are the best. Good Cider may be drank several times a day; it forms a grateful draught, as well as a useful medicine. Stewed Barberries, or Barberry preserves may also be advantageously used; probably the efficacy of these acid articles is due to the malic acid they contain. A tendency to mental or physical inactivity should be resisted by the patient; moderate exercise should be taken, when there are no symptoms of irritation or inflammation; and all harsh and debilitating measures must be carefully avoided. The bowels, kidneys, and skin must be attended to during the whole course of the disease.

ABNORMAL CONDITIONS OF THE BILE.

The bile is an exceedingly complex fluid, and, as has been already stated, performs a two-fold office, viz., that of an excretory and that of a secretory fluid. The former office consists chiefly in conveying cholesterine, an excrementitious substance, from the blood, which is passed from the body in the form of stercorine, a substance nearly identical with the cholesterine; it is also very likely that the biliary salts, as the chlorides, carbonates, phosphates, etc., are recrementitious. The latter office consists in carrying on the hepatic secretions, as the glycocholate and tauro-cholate of soda, etc., which do not pre-exist in the blood, and are not discharged from the body, being probably absorbed, or employed in some way, to aid in some of the nutritive processes. Prof. Flint's experiments appear to place these views of the offices of the bile and of the functions of the liver, beyond a doubt.

In the time of Hippocrates and Galen, we find that the bile, or the liver, was supposed to be concerned in the production of animal heat as well as in the processes of assimilation and nutrition, views which correspond with those of Flint and Bernard of the present age.—Bernard supposed that sugar was formed in the liver, but more recent investigations have led to the belief that this organ only forms a substance, more especially designed for the production of fat, that may, however, be readily changed into sugar. These opinions, together with others, which it is unnecessary to repeat here, tend to demonstrate the two-fold function of the liver, and of its peculiar fluid, the bile.

It must, therefore, be readily perceived that any great disorder in the hepatic function, diminishing or increasing the quantity of the bile, or altering its quality, must necessarily occasion much disturbance in the general system, from a deficiency in either the excretory or secretory elements of the bile, or in both, as well as from a retention of those substances in the blood from which these excrementitious or secretory elements are derived. Still it must be borne in mind, that many maladies may and do exist, with which the liver has but little if anything to do, except perhaps secondarily. And it has in past years been too much the case that medical men have jumped at conclusions, and attributed certain disorders to the liver, or to the bile, without seeming to be aware that the stomach and intestinal canal are much more readily exposed to disease, entering them in various forms by the mouth, and which gastro-intestinal maladies are the originators of the hepatic derangements, aided

sometimes by neglect of the surface, exposures to sudden changes, sedentary habits, etc.

The conditions of the bile, connected with functional disorder of the liver, may be as follows: 1. *Excessive Secretion of Bile*, which may be the result of high living, irritating articles of diet, stimulating or fermented drinks, and other causes that may give rise to gastro-intestinal irritation and hepatic congestion. It is more especially apt to occur during hot seasons. There is generally more or less fullness, pain and tenderness in the region of the liver, and frequently pain in the right shoulder, some febrile reaction, a general feeling of indisposition, dryness and sallowness of the skin, foul tongue, scanty and turbid urine, perhaps regurgitation of bile from the duodenum vomited up from the stomach, and almost invariably a diarrhea, in which the stools are of a yellowish-brown or green color, and contain bile, usually of an acrid, irritating quality, and which is accompanied with tenderness of the abdomen, and griping pains, and sometimes soreness and irritation at the anus.

The *treatment* consists in removing morbid accumulations from the intestines by a purgative dose of the Compound Powder of Jalap, which also exerts a derivative influence upon the liver. Should the diarrhea still continue, astringents may be administered, in conjunction with opiates, when pain or griping is present. In some instances, after the purgative, the Compound Powder of Rhubarb and Potassa, will be of service, to which one-third or one-fourth part of Tincture of Prickly-ash Berries may be added. Considerable gastro-intestinal irritability remaining after the action of the purgative, with diarrhea and pain in the hepatic region, may often be overcome by a mixture of Subnitrate of Bismuth, Geraniin, and Opium; together with hot fomentations over the painful regions. When there is heat and dryness of the skin, perspiration must be produced by bathings of the surface, and the employment of the Compound Tincture of Virginia Snakeroot. In malarial countries, the addition of Sulphate of Quinia to the articles used will be of service; and in anemic cases, the Tincture of Sesquichloride of Iron, or Solution of Perchloride of Iron may be administered with advantage, in conjunction with the other remedies. I have frequently derived much benefit, when pain, or diarrhea is present, from the following preparation: Take of Sulphate of Quinia ten grains, Sulphate of Morphia three grains, Elixir Vitriol one fluidrachm; mix, dissolve the salts, and add to the solution, Essence of Cinnamon two fluidounces. The dose is thirty or forty drops in a tablespoonful of water, to be repeated every two, three, or four hours.

To prevent a return of the disease, which may occur frequently and ultimately occasion some structural lesion, the patient should avoid all the exciting causes, and strictly conform to the sanative principles of hygiene, as, attention to the skin, stomach, bowels, and kidneys; respiration of pure air; exercise; nourishing, digestible, and unirritating food, etc.

2. *Deficient Secretion of Bile*, not due to structural hepatic lesion, is most generally dependent upon a torpid or inactive state of the liver, and is the premonitory indication of some more serious hepatic disorder, which, however, may be avoided by proper management. It may be the result of a sedentary life, of insufficient, or, innutritious food, of chronic hyperemia of the liver, of dyspepsia, and not unfrequently occurs after the use of active purgative medicines. Any cause that will produce exhaustion or depression of the nervous system, may give rise to inactivity of the liver; it may also accompany certain conditions of the system, as, anemia, chlorosis, cancer, scrofula, etc. The *symptoms* are, an irregular or constipated condition of the bowels, light-colored stools, high-colored urine depositing a sediment, impaired appetite, with more or less indigestion, flatulency, drowsiness, frontal headache, depression of spirits, peevishness or irritability; sallowness of the skin, heavily-coated tongue, disagreeable and bitter taste in the mouth in the morning, frequently nausea, and, generally, more or less gastric acidity. There is a general feeling of indolence, or both mental and physical inactivity. Occasionally diarrhea may be present.

This functional disorder is best *treated* by regularity in diet, using nutritious and easily digestible articles, moderate exercise, regularity in the sleeping hours, frequent bathings of the skin, and regularity of the bowels by means of some cholagogue medicines. Thus, the Compound Powder of Charcoal, or, the Powder of Rhubarb and Potassa, heretofore named, may be used in sufficient doses, repeated three times a day, to produce one, but not to exceed two evacuations daily; these preparations will be of service in cases attended with gastro-intestinal acidity. In other cases the following may be used: Take of Podophyllin two grains, Leptandrin sixteen grains, White Sugar three drachms; mix, triturate thoroughly together, and divide into sixteen powders, of which one is the dose, to be repeated three times a day. Or, the Compound Pill of Leptandrin, Compound Cathartic Pill, or Compound Pill of Dandelion, may be used, one or two per day, as required, to keep up a soluble condition of the bowels. In anemic cases,

with feeble digestion and want of appetite, the following pills will prove serviceable: Take Citrate of Iron and Strychnia forty grains, Podophyllin seven grains, Leptandrin forty grains, Alcoholic Extract of Aletris forty grains; mix, and divide into forty pills, of which the dose is one, two, or three, daily, according to the effect upon the bowels. The action of the remedies employed may generally be facilitated by the daily application of rubefacient liniments over the hepatic region, and along the spinal column between the shoulder-blades. In long-standing cases, or where this biliary deficiency has frequently occurred, a prolonged course of treatment will always be required, in order to produce permanent benefit.

3. *Unhealthy states of the Bile.* The bile may be said to be in an unhealthy condition when it is deficient in either its excretory or secretory elements, or, in both at the same time, and these conditions may exist whether the bile be in excess or scanty. This state of the bile may be due to some faulty condition of the blood, which does not furnish the required amount of excretory or secretory elements to the liver, or, it may be due to structural disease of this organ itself; occasionally, it may arise from hepatic functional disorder, connected with nervous depression, or, nervous overexcitement of the organ.

We have no means by which we may positively determine these states of the bile, and, therefore, will have to rely principally upon the symptoms. Thus, when there is no hepatic structural lesion, and the skin is sallow; the mental faculties depressed, enfeebled, or deranged; with or without tenderness in the hepatic and duodenal regions; the appetite impaired; the stools lighter-colored than natural, or, perhaps, clay-colored, whether looseness or constipation be present, and furnishing little or no stercorine; the urine scanty, and high-colored from the presence of bile pigment; a sense of languor, indolence, and indifference; and a great tendency to drowsiness; we have every reason to believe that the excretory function of the liver is faulty and does not purify the blood of those excrementitious substances that are designed to form the excretory biliary elements.

On the other hand, if it be the secretory elements of the bile that are at fault, the skin will be more or less sallow and dry; the head will feel heavy, or there may be headache, but no particular torpidity or enfeeblement of the mental faculties; pain or tenderness may or may not exist in the hepatic region; the appetite is variable;

digestion slow ; usually, habitual constipation, but no great decolorization of the stools, which may be of natural color, or darker than ordinarily ; the urine paler than usual or natural, in usual amount, and giving no indications of the presence of bile pigment ; and the strength fails gradually, with emaciation and anemia from imperfect digestion and nutrition.—If both the excretory and secretory biliary elements are at fault, there will be more or less of a mixture of the two sets of symptoms just named, and which will render the diagnosis still more difficult.

When the morbid condition of the bile consists in an excess or deficiency of only one or two of its elements, as, of its water, its mucus, its coloring matter, its phosphoric acid, its soda, lime, or magnesia, etc., or, in the presence of some foreign body, as, a free acid, urea, etc., we have no means of determining this condition during life, and the symptoms accompanying it will be in accordance with the morbid alteration of the bile, but which it is impossible for us to diagnose. This state of the bile may be due to functional or structural disease of the liver, or, of some other organ intimately associated with it, as, the lungs, heart, stomach, or kidneys.

When we meet with a case of one of these morbid states of the bile, and upon a careful examination find it to depend upon organic lesion of the liver, or other organ, the *treatment* will be that recommended for such lesion.—If no such lesion be found, and the symptoms indicate a deficiency in the excretory biliary elements, the agents to be employed will consist chiefly of alterative tonics, diuretics, and cholagogues. Sulphate of Quinia, Xanthoxylin, Alcoholic Extract of Black Cohosh, Compound Syrup of Partridgeberry, Hydrastin, Hydrochlorate of Ammonia, Creosote, etc., are among the alterative tonics. As diuretics, we may employ the Compound Infusion of Parsley, Compound Infusion of Trailing Arbutus, Pipsissewa, Juniper Berries, Water-melon Seeds, Cleavers, Eryngium, Liatris, Acetate of Potassa, Oil of Turpentine, etc.; and, as cholagogues, laxative doses of Podophyllin, Leptandrin, Oleoresin of Iris, etc. A very excellent cholagogue pill, useful in many hepatic derangements, is composed of Podophyllin five grains, Leptandrin twenty grains, Ipecacuanha five grains, Extract of Hyoscyamus thirty grains; mix, divide into twenty pills, and give two or three pills per day, in doses of one pill at a time, so as to keep up a laxative effect. Among persons very susceptible to the action of podophyllin, the quantity may be diminished to two or three grains, if necessary.

Again, if the faulty condition of the bile be due to a deficiency of its secretory elements, tonics will be required, as, Alcoholic Extract of Nux Vomica, Strychnia, Citrate of Iron and Strychnia,

Elixir of Cinchona and Iron, Hydrastis, Salicin, Columbo, Alcoholic Extract of Aletris, Quassia, Helonias, Chelone, Barberry, Nitrohydrochloric Acid, etc.; likewise alteratives, as, Compound Syrup of Stillingia, Yellow Dock, Scrophularia, Celastrus, Sassafras, Iodides and Bromides of Potassium, or of Ammonium, Iodide of Iron, Phosphate of Iron, etc.; and cholagogues, as, Leptandrin, Sanguinarin, Taraxacum, Albumen, Soda, etc.; and if laxatives are required, Podophyllin, Oleo-resin of Iris, etc.—When both the secretory and excretory biliary elements are at fault, it will require a proper combination of these two therapeutical measures.

If only one or two elements of the bile are deficient, or in excess, which, as already stated, is of very difficult determination, we can only treat the case upon general principles, being governed by the symptoms present, and the peculiar condition of the patient. And, in such cases, as with many others of an obscure character, great judgment, caution and skill are required, on the part of the practitioner.—In the above cases it is almost impossible to satisfactorily lay down any specific rule of treatment, for the conditions present, of the liver, the bile, the blood, the nervous system, etc., are found to vary so much in different patients, that the measures to be employed can only be mentioned in general terms—and which, indeed, is the case with the treatment of all chronic maladies, though many are, in this respect, much better understood than others. It is principally in the more obscure affections in which the knowledge, judgment, and skill of the practitioner are especially displayed.

In all these unhealthy conditions of the bile, we must be very careful not to fatigue, depress, or enfeeble the system; treating urgent symptoms, when present, by the means heretofore named for them, when occurring in this class of diseases. Moderate exercise in the open air should be taken daily, if the weather will allow; the skin should be bathed daily; the food should be light, nutritious, and easy of digestion; the apartments be kept comfortably cool, and well ventilated, for respiration of pure, healthy air, is a means of the greatest importance; and all high living, alcoholic or fermented drinks; exposures to great heat, cold, or moisture, sedentary habits, and excesses of all kinds, should be studiously avoided.

The *Gall-bladder* and *Ducts* are liable to several abnormal conditions, as, Accumulation of Bile in them, Distension of the Gall-bladder, or Cancer, etc., the diagnosis of which is by no means positive, and, indeed, in nearly every instance, only an approximation to the actual condition of the parts can be had. Besides

which, abnormal states of these organs have been found after death among persons who, during life, presented no symptoms indicating the existence of such states. Another difficulty in the investigation of chronic affections of the gall-bladder and ducts, is, that these affections are ordinarily associated with either functional or organic lesions of the liver, rendering the diagnosis still more obscure, and, consequently, permitting us to advise only palliative treatment, or therapeutical measures in accordance with the general principles of practice.—There is, however, one affection with which medical men are more conversant, and upon which I will bestow a brief consideration, and that is

Biliary Calculi or Gall-stones. Gall-stones are ordinarily formed in the gall-bladder, and occasionally in branches of the hepatic duct. The gall-bladder may be filled with these calculi without there being any indications of their presence, but when they move along the duct, their passage more commonly occasions considerable pain. Not unfrequently they become arrested in their passage, and continue permanently lodged unless set free by ulceration. It is rarely the case that gall-stones are found in persons who have passed middle life, and they occur more generally among persons of sedentary pursuits, of indolent habits, or who have much mental anxiety or trouble. Fat persons and high livers are quite subject to them; and the use of fermented strong drinks, or lime-water, also appears to favor their formation.

The *cause* of gall-stones appears to be an unhealthy state of the bile, or its decomposition, and which may possibly be due to blood disease, hepatic disease, innutrition, or, perhaps, “some putrid ferment generated in, and absorbed from, the intestinal canals.” This change in the composition of the bile must precede the separation of the substances forming the calculi; the same as alkaline urine must precede the deposition of phosphatic crystals in the urinary bladder. But we are still in the dark as to a knowledge of the cause of the decomposition.

Gall-stones vary in size from that of a small pea to that of a hen’s egg, are round or oval, with rough surfaces, frequently polygonal with smooth, roundish facets, are of a yellowish-brown color, or variegated greenish and brownish, are usually lighter than water, and burn readily with a yellowish flame, leaving only a very small quantity of ash. They consist chiefly of cholesterine in layers, with patches or layers of bilifulvine and biliverdine (coloring matter) in various proportions and shades, small masses of stellate crystals

of bistearate of lime, and a minute quantity of phosphate of lime mixed with shrivelled cylindrical epithelial cells; upon cutting into the concretions they are usually found to contain a brown, pulpy, exceedingly fragile, granular, and non-crystalline matter, consisting, when carefully washed, of threadlike, cylindrical fibres, of different lengths, variously branched, and which are supposed to be casts of the biliary ducts; and the substance holding them together, instead of being inspissated mucus or bile, is cholic or choloidic acid, or both. (*Thudicum*.) Sometimes, no tangible nucleus can be detected in the calculus, in which case it is of a pure pearl-white color, consisting throughout of cholesterine, which is almost invariably precipitated from bile in a crystalline form. Converging rays from the center of the calculus to its circumference are formed by the crystallization of the cholesterine, but when these are colored by bile pigment, an appearance of distinct concentric layers is usually presented. Tauro-cholic acid is the solvent of cholesterine, and to its decomposition in the bile may probably be attributed the deposition of the excrementitious element.

Occasionally gall-stones have been found, consisting chiefly of bile pigment, mucus, and some calcareous salts; or, of stearate of lime; or, of phosphate or carbonate of lime; and having nuclei of coagulated blood, lime, or mucus, and often an appreciable amount of copper; in rare instances, uric acid has been found in gall-stones.

It is very probable, therefore, that the first step in the formation of gall-stones is the presence of a small substance of some kind, even of crystals of cholesterine itself, to form a nucleus, around which the cholesterine is deposited from the morbidly altered bile, as the second step.

When calculi are in the gall-bladder there may be no *symptoms* whatever of uneasiness or pain; or there may be pain experienced in the epigastrium darting toward the right side and to the back, with more or less gastro-intestinal disorder, and, perhaps, a slight yellow tinge of the skin. But when the stone commences to move, there are almost always some well-marked symptoms during its passage along the ducts. Very suddenly the patient is attacked with excruciating pain in the epigastric region and in the right side, which, after a longer or shorter period, subsides, and after a certain interval of rest, is renewed with as much severity as before. The sufferings are often so intense that patients will writhe on the floor in the greatest agony. Pressure upon the epigastrium usually affords a degree of relief, but not complete. In connection with the pain there is distressing nausea and vomiting, which is frequently so excessive and severe as to bring up large quantities of gastric acid, and, occasionally, even

some bile,—great exhaustion, cold extremities, a cold perspiration over the whole body, and spasmodic contractions of the abdominal muscles. The pulse remains unaffected, or becomes slower or weaker than natural. The pain is complained of as being spasmodic, and it is often attended with a “sense of constriction around the inferior part of the chest, as if a cord were tied tightly around it, and which is a very distinctive symptom of sudden stoppage of the common gall-duct.” (*Budd.*) Jaundice is frequently present, but not always, and may be the result of a partial or complete obstruction of the common duct. As soon as the stone has passed through the duct, and escapes into the duodenum, a relief from all these symptoms occurs suddenly, and the patient remains free from suffering until another one commences to move along the duct, when similar symptoms are renewed.—Sometimes there will be no pain present, but rigors and other symptoms, greatly resembling those peculiar to chronic intermittent fever, and which are due to calculi in the hepatic duct or ducts.

The severity and duration of these symptoms vary according to the number, form, and size of the concretions, and the condition of the ducts. The longer the calculus is in passing, the more severe is the pain, and the greater the liability to inflammation of the ducts; and not unfrequently an enlargement of the liver from retention of bile, or a fullness of the right side from distended gall-bladder, or a throbbing sensation, may be detected.—If the stools be carefully examined among patients subject to the affection under consideration, it is often the case that one or more gall-stones will be found.

Ulceration of the stomach may excite a local *peritonitis*, the symptoms of which will greatly resemble those of the passage of a gall-stone,—but the tenderness from the very first, its augmentation on pressure, the acceleration of the pulse, and other symptoms of inflammatory action, will distinguish the peritonitis. *Flatulence* likewise may produce a severe pain in the right side, but it is never so severe as in gall-stones, nor is it attended with the symptoms of exhaustion, spasmodic action of the abdominal muscles, etc., it may come on suddenly, though more commonly gradually, is often preceded by dyspeptic symptoms, and, in some cases, is attended with a lancinating or keen-cutting pain whenever a mouthful of food is received into the stomach,—it is also apt to be shifting.

The *prognosis* of gall-stones is usually favorable, though persons who have been once attacked are always liable to subsequent attacks at longer or shorter intervals. A long retention of the stone in the common duct may prove fatal, either from the excessive pain and vomiting induced, or, from a permanent closure of the duct, with

jaundice. Rupture of the gall-bladder, or of the duct behind, is followed by speedy death, but it is of rare occurrence. Inflammation or ulceration of the gall-bladder or duct may prove fatal. A very large calculus having passed into the intestines may in its progress through the bowels give rise to slight colicky pains and tenesmus, or, it may obstruct the bowels at some point, and give rise to constipation, or even fatal ileus.

The *treatment* of gall-stones consists chiefly in relieving the pain and spasm during their passage. For this purpose a fomentation of Stramonium Leaves and Lobelia, as hot as can be borne, should be applied over the the painful region, and be frequently renewed. Internally, Opium, or Extract of Belladonna, in substance, and not in tincture, should be given, being very cautious in their administration, lest, after the cessation of pain, they may give rise to dangerous symptoms of narcotism. I advise these agents in substance, because of the great irritability of the stomach, that almost always rejects any fluids received into it. Frequently, the gastric irritability may be lessened by the exhibition of officinal Hydrocyanic Acid. Ether and Chloroform have also been employed with benefit, as well as Oil of Turpentine; and it must be observed that these three agents are solvents of cholesterine, and may possibly act by being conveyed through the circulation to the suffering organ; but we have no positive proof that such is really the fact. A combination of three parts of Ether with two of Oil of Turpentine, and given in doses of from half a fluidrachm to a fluidrachm, once or twice a day, has been found of considerable service, although it is not so much employed now as in past years. I have often derived benefit from the administration of the Compound Tincture of Lobelia and Capsicum by mouth, or, if the gastric irritation will not allow the stomach to retain it, by injection into the rectum. Tincture of Gelsemium internally, in doses to relax the system, aided by anodyne and relaxing cataplasms, will also prove useful.

Dr. Prout recommends large draughts of hot water, to every pint of which one or two drachms of Bicarbonate of Soda has been added,—to be used in conjunction with Opium. He thinks the alkali relieves the distressing gastric symptoms by neutralizing the acid present, while the hot water acts like a fomentation to the seat of the pain.—The Spirit Vapor Bath will also prove serviceable in those cases where it can be employed. As to emetics, which have been frequently advised, I am decidedly opposed to them; if nauseants can be retained upon the stomach long enough to produce complete relaxation of the system, and relief from pain, that is all we

can desire for the time being, and the subsequent production of emesis is superfluous and unnecessary.

After the cessation of pain, and when we have reason to infer that the calculus has passed into the duodenum, we should hasten its evacuation from the intestines, as well as the discharge of the accumulated and irritating bile, by a purgative dose of the Compound Powder of Jalap and Senna, aided by copious injections of warm water.

Having thus disposed of the calculus, and of the symptoms occasioned by its movement through the duct, the next object will be to prevent these concretions from again forming, and this can only be effected by the employment of those measures that will give health and energy to the blood, nerves, and liver, in order to the production of healthy bile. For this purpose, regularity of the kidneys and bowels, normal action of the skin, good plain, digestible diet, not too rich or gross, avoidance of all alcoholic, vinous, and fermented liquors, and plenty of exercise in as pure an atmosphere as can be had, are very important measures. To influence the action of the liver, albumen, Leptandrin, Hydrochlorate of Ammonia, Nitro-hydrochloric Acid, and other cholagogues may be administered, if necessary. And if any hepatic, gastro-intestinal, constitutional, or other disease be present, it must be met by the appropriate treatment. The use of mineral waters containing large proportions of carbonate of soda, will also be of benefit.—In many instances of jaundice, cider that has not yet undergone alcoholic fermentation, has proved of great benefit, and its efficacy may, probably, depend upon its malic acid effecting some healthy change in the bile; it may, therefore, be worthy a trial in the treatment of gall-stones.

It has also been proposed to make use of internal remedies for the purpose of dissolving any calculi that may still remain in the gall-bladder. Chloroform, Ether, Turpentine, salts of Soda, and Soda-soap, are all solvents of cholesterine, and have been recommended for the object proposed. Ether and Turpentine, as mentioned above, has been administered with this view. Also Chloroform one part, Alcohol eight parts, Syrup fifty-five parts; mix,—to be given in such doses, that half a fluidrachm of the chloroform shall be taken daily; or, some medicated wine may be used instead of the syrup. But it is very much to be doubted whether agents administered by mouth can produce any more solvent effect upon biliary than upon urinary calculi, when once formed; besides, it is impossible to positively determine either the presence of calculi in the gall-bladder, or their solution in the living body by the means named.

DISEASES OF THE SPLEEN.

Although the anatomical structure of the spleen has been minutely investigated, yet of its functions and its diseases we know but little. In its structure it is very similar to that of the lymphatic glands, and indeed is found only among those animals that are red-blooded and possess a distinct lymphatic system. Its functions are supposed to be,—to separate the coloring matter from the blood of the portal circulation, preparing this fluid for the action of the liver,—to remove excess of watery fluid from the newly-absorbed chyle,—to generate white globules, that always exist in large number in the splenic vein,—and to serve as a diverticulum, protecting neighboring organs from having their vessels over distended with blood. As giving some support to these views it may be stated that it is by no means uncommon to find affections of the lymphatic glands associated with abnormal states of the spleen, either as a cause or an effect,—that when the spleen has been removed from animals, the lymphatic glands assume a vicarious activity, and but little, if any, colorless bile is to be found in the gall-bladder,—and that enlargement, or other abnormal condition of the spleen is almost invariably present in leucocythemia, anemia, inflammation of the lymphatic vessels, chlorosis, scurvy, etc.

From the intimate relations existing between the spleen and the lymphatic system,—between it and the liver and lungs in the process of hematosiis, as well as from its sympathies with other organs, it may be at once seen, how readily this organ may be influenced to take on abnormal action, and how difficult it must be to determine whether its pathological phenomena are those of a primary or secondary affection. And, indeed, it is frequently the case, that an extensive organic lesion of the spleen exists without the manifestation of any symptoms positively and satisfactorily indicating their splenic origin. “We know that this organ is often involved in blood diseases, that especially in fevers it becomes almost disintegrated, and that in pyemia it is the seat of secondary deposits, capillary phlebitis, and suppuration; but we know nothing of the indications which mark these conditions, as they are wholly obscured by the more general symptoms of disease.” (*Barclay*).—It is extremely rare to find affections of the spleen present, unless accompanied with some marked malady of one or more other organs; beside which, with the exception of considerable splenic enlargement, it is very difficult, if not frequently impossible, to

satisfactorily diagnose the presence or nature of diseased conditions of the spleen.

According to Heinrich, there exists a strong tendency to splenic diseases in certain families, especially among persons of certain temperaments, as those who are lymphatic, and disposed to solitude, melancholy, and extreme sensitiveness. Females are especially subject to them, from the splenic tumefaction occasioned by menstrual disorder. Children are more liable to tuberculous affections of the spleen, while chronic enlargement of this organ is ordinarily met with only in adult life. Softening, atrophy, hardening, and cartilaginous degeneration, very rarely occur in the young, but are quite common during middle age and subsequently.

Splenic diseases may be the result of mechanical injuries, as falls or blows; of depressing mental emotions; of suddenly suppressed habitual discharges; of excessive exercise or labor, which produce distention and irritation of the splenic structure; of an excessive use of alcoholic drinks; of the employment of the water of swampy lands as a common drink; and of the use of food containing considerable hydrogen and carbon, as, the fat vegetable oils, saccharine and amylaceous substances, etc. Constant sedentary position of the body, excessive heat and moisture combined, especially in swampy regions, and on low grounds subject to inundations, are also named as causes of splenic maladies. Distension and softening of the organ are also said to result from the abuse of narcotics, and, especially, hydrocyanic acid. Enlargement and softening are a common consequence of intermittent fevers, typhus, exanthema, scurvy, and pyemia. "In the history of its enlargement, this will sometimes be found as a sequel of intermittent fever, commonly known as 'ague cake.' Very often no precursory phenomena are discovered, and its cause is quite unknown; occasionally it is associated with enlargement of the liver, and probably then both are lardaceous. It is intimately connected with an anæmic state of the blood; and as its functions in reference to the elaboration of this fluid become better understood, we shall probably obtain more direct indications of the changes which it undergoes in disease; at present we can only affirm that there seems to be some close relation between one of the forms of enlargement and the condition of leucocythemia. In consequence of this circumstance it may be also associated with general dropsy; with ascites it would seem to be connected only through the medium of concomitant disease of the liver." (*Barclay*.)

Chronic Splenitis is a somewhat obscure disease, and is usually associated with or succeeds some malarial fever, or some gastric, or hepatic affection. It may also follow acute splenitis; and is occasionally complicated with abdominal dropsy, or hemorrhages. There is generally more or less of a low febrile condition present, with a sense of fullness in the splenic region, and a deep-seated, dull pain or tenderness that is augmented by deep pressure. Sometimes a periodically recurring lancinating pain will occur. The skin is usually dry, countenance sallow, pulse quick and small, tongue somewhat coated, perhaps nausea, and the stools dark and fetid. Resolution, suppuration, or degeneration are its usual terminations.

If the painful and tumefied organ loses its tenseness, and imparts a soft, yielding sensation at certain points, when palpated, while at the same time rigors and hectic fever manifest themselves, *suppuration* has occurred; and, at a more advanced period, fluctuation may be more or less distinctly recognized. The purulent matter may be discharged through the bowels, or be coughed or vomited up, according to the point at which the abscess breaks and the adhesions it may form with the neighboring organs. Recoveries may sometimes occur.

If we can detect a spongy condition of the spleen with an indistinct undefinable margin, and but little if any pain with or without pressure,—if the features present dark spots, the gums become dark colored, spongy, and bleed easily, with hemorrhages from other parts, dropsical effusions, bloated face, small and compressible pulse, protuberant abdomen, cold extremities, fetid breath, quick breathing, emaciation and debility, *softening* of the spleen has taken place. In these cases, almost invariably the skin presents more or less the appearance of purpura hemorrhagica. The blood in this degeneration of the spleen is dark, thin, and does not readily coagulate.

It may be proper to observe that in all cases of hemorrhage from the stomach or bowels, in anemia, chlorosis, anasarca, ascites, and chronic liver diseases, it will be well for the practitioner to carefully examine the region of the spleen in order to detect any abnormal condition of this organ, which will be frequently ascertained to co-exist with these maladies, and a knowledge of which may lead to more efficacious measures.

The proper tissue of the organ is the part attacked, involving its nutrient vessels, its internal fibrous elastic coat, and sometimes even its external peritoneal covering. The organ is found more or less turgid after death, exhibiting variegated tints of blue and

red upon its surface. The internal structure is generally more or less softened.

But the abnormal condition more commonly met with is *Chronic Enlargement of the Spleen*, which may be owing to fibrous infiltration, hyperemia with structural alteration, hypertrophy, waxy degeneration, malignant growths, etc.; lesions that present no characteristic symptoms to enable us to form a correct diagnosis of them.—In an examination of the spleen, when enlarged, the patient should lie on his right side, and the examination should always be made before a meal, as the sounds elicited by percussion vary greatly according to the degree of fullness of the stomach. In health, the spleen never projects below the false ribs even during a deep inspiration, and while the splenic tumor is concealed beneath the false ribs, we must be careful to avoid falling into error. A constant dullness of sound over the left hypochondrium in the region of the spleen is a presumptive evidence of splenic enlargement, when in addition, a sense of weight and tenderness is complained of in this region, when the false ribs project more than natural and are somewhat immovable, and the patient is in the habit of selecting a position that will afford more or less relaxation of the walls of the abdomen. As soon as the enlarged organ projects beneath the false ribs, its margin may be detected by careful palpation, and percussion will readily detect dullness in the protruding portion, as well as sonorousness around its margin. The organ presents a firmness and fleshy hardness to the touch, is rather inelastic, and has usually an oblong form. If no dullness can be detected, we may infer that the spleen is not enlarged. It must be recollected that the spleen may become so enormously enlarged as to extend superiorly even as far as on a level with the third or fourth rib, inferiorly, into the lowermost part of the left iliac region, and laterally in front, even beyond the right side of the median line; though such excessive dimensions are not very frequently met with. Therefore, in making the examination we must be careful to distinguish splenic disease from pleuritic effusion, tubercular deposit in the inferior lobe of the left lung, disease of the stomach, of the left lobe of the liver, of the colon, or of the ovary, also from ascites, and disease of the left kidney; but should these maladies co-exist with the splenic affection, then the symptoms must be investigated in detail. In connection with these physical signs we must assist ourselves in forming the diagnosis, by the history of the case, and the accompanying morbid phenomena.

The *symptoms* usually present in cases of enlarged spleen, and more especially when this is due to malarial influence, are, a sense of weight and fullness in the left hypochondrium, rarely any pain or excessive tenderness; the skin will present a peculiar, pale, dusky or light-mahogany color; the conjunctiva have a dull bluish or greenish tint, and the eyeballs appear more or less sunken; the tongue and lips are pale, the papillæ of the former being small and whitish,—frequently the tongue will be coated white, and occasionally its body will be redder than natural; the gums shrunken and sallow; appetite variable; digestion imperfect with emaciation, and protrusion of the abdomen; bowels variable, with a lighter or darker color of the stools than natural; urine also variable, but commonly pale, abundant, and of low specific gravity, containing albumen if dropsy be present; debility; periodic or constant pain in the head, back, and limbs; occasional chilliness; dejection of spirits; restless nights and unpleasant dreams; palpitations; difficult breathing, especially upon exercise; coldness and numbness of the extremities; and the pulse usually quick, small, and easily compressible. If a drop or two of the blood of the patient be examined under the microscope, it will be found deficient in fibrin and red corpuscles, with, in many instances, an increase of white corpuscles.

These symptoms it must be observed are more or less gradually developed, and all of them may not be present in any one case, though several will almost invariably be met with, and as the disease progresses, they become more severe, the patient becomes mentally and physically indolent, peevish or hypochondriacal, with, perhaps, a dry cough, dyspnoea, attacks of hiccough, ascites, or renal disease, increased emaciation and debility, hemorrhages, hectic fever, or delirium, coma, and death.

The *prognosis* of chronic splenic disease depends entirely upon the character and duration of the disease as well as of the cachectic symptoms present, the co-existence of lesions of other organs, and the age of the patient. Enlargement due to malarial causes when of recent date and occurring in persons not over thirty-five years of age, is mostly curable; but if the enlargement existed previous to the attack of malarial disease, recovery is very doubtful. The older the patient, the longer the disease has existed; and, the more prominent the accompanying cachexia, the less favorable will be the prognosis. Waxy degeneration, malignant growths, (atrophy), the existence of dropsy, of hepatic or renal disease, etc., are almost always unfavorable.

The *pathological appearances* will be in accordance with the

character of the lesion. In hypertrophy the spleen will present a thickening of its cellular tissue, have somewhat the dark color and firmness of muscular tissues, and be of increased weight. Sometimes the hypertrophy may be accompanied by no change in the structure of the organ, which will present the same characters as are observed in its healthy state. In enlargement from malaria, pus may be found in the structure of the organ, or, cartilaginous or ossific deposits in its fibrous coat, adhesions between its peritoneal covering and neighboring parts, etc.; but, when the enlargement or tumefaction has not affected the splenic tissue, but is owing to congestion, the spleen may present a normal appearance after death. Frequently it is soft, and flexible, like a coagulum of blood inclosed in a thin, more or less tough, membrane. And again, especially when the enlargement is oblong, the organ will be found much firmer than natural, and its margins thin and notched. Waxy degeneration, malignant tumors, etc., when present, will be known by their peculiar characteristic appearances, and the co-existence of lesions of other organs may always be ascertained.

The *treatment* of chronic maladies of the spleen must be entirely upon general principles, keeping up a moderate stimulation of all the excretory organs, with alteratives, tonics, chalybeates, etc., to meet the indications, viz., to improve the portal circulation by removing all impediments; to overcome the periodicity of irritative action when present, and to restore the blood to a normal condition. In cases of anemia, chlorosis, leucocythemia, and other cachexia associated with splenic disease, I have derived great benefit from the preparation containing Glycerin and soluble Pyrophosphate of Iron, referred to on page 774. When there is much debility or nervous depression, I employ, in addition, pills composed of Bromide of Potassium, and Xanthoxylin, Strychnia, (or Citrate of Iron and Strychnia) and Alcoholic Extract of Black Cohosh, in various proportions. And in all cases of enlargement, I have found considerable advantage to follow puncturing the skin over the region of the enlarged organ, daily or every other day, by means of the Dermabiotokon,* and then rubbing in over the punctured surface, an ointment composed of Iodide of Ammonium one drachm, Hydrochlorate of Ammonia one scruple, good prepared Lard one ounce; mix. I prefer this to the Compound Tar Plaster in these affections.

In enlargement following malarial fevers, Sulphate of Quinia

* This instrument can be had of Messrs. Wade & Ford, surgical instrument makers, New York City.

has been found a very valuable remedy for the restoration of the general health; it may be given in quantities varying from twelve to fifty grains during the twenty-four hours,—suspending its use if it creates a sense of uneasiness, debility, or appears to arrest the secretions. I generally prefer giving it in doses of two grains every two or three hours, instead of the larger doses advised. If a chloro-anemic condition be present, with indications of dropsy, it may be combined with the Sulphate of Manganese, so that three or four grains of this salt may be taken daily. A combination of one part of Sulphate of Quinia with three parts of Phosphate of Iron, and given in syrup, has also proved efficacious. If, after the exhibition of Quinia, the urine becomes hot or acrid, the medicine is probably passing away through the kidneys, and must be diminished in its doses, in order to have it exert any influence on the local malady.—If symptoms of purpura manifest themselves, Hydrochloric Acid, or Nitro-hydrochloric Acid will be found useful, in conjunction with the Tincture of Chloride of Iron; or, the Elixir of Cinchona and Iron, because, where debility exists with this condition, Cinchona will be found to answer a much better purpose than the salts of quinia.—If much flatulence be present, saline purgatives as well as drastics must be avoided, lest hemorrhage result,—in such cases, Castor Oil with Oil of Turpentine, etc., may be used. (*See Flatulence and Tympanites*).—Obstinate constipation is by no means unfrequent in chronic affections of the spleen, and the employment of cathartics generally augments the constipation, so that the patient gradually requires larger doses to produce a cathartic effect. Catharsis is by no means desired, except occasionally—regular daily evacuations, as near healthy as possible, in quantity, are all that is necessary, and may be procured by mild cholagogue laxatives combined with Strychnia, or Alcoholic Extract of Nux Vomica, as, Podophyllin, Oleo-resin of Iris, Alcoholic Extract of Bitter Root, Xanthoxylin, etc.

Among the other agents that have proved serviceable in this disease, are, 1. Milk of Sulphur, Precipitated Carbonate of Iron, each, five to ten grains; mix for a dose, to be repeated three or four times a day. In some instances, Sulphate of Quinia two grains may be added to each dose. 2. The inner bark of White Ash (*Fraxinus acuminata*), boiled in White Wine, and taken in wineglassful doses, three or four times a day, has been advised as a remedy for “agne cake.” 3. The Citrate of Quinia and Iron, or Citrate of Quinia, Iron, and Strychnia.

Every means should be taken to invigorate the system; avoiding ardent spirits, and any kind of stimulant, as a general rule, as

well as all the circumstances and causes that may produce or keep up the malady; being temperate in food, drink, and exercise, and doing nothing that will enfeeble or irritate the nervous system. In some instances, currents of electro-magnetism passed through the enlarged spleen, once or twice a day, and persisted in for a long time, will be found very useful. If possible, the patient should change his residence to a place where he will not be subject to malarial influences.—Any co-existing disease of other organs must be met by appropriate measures, properly conjoined with those desired for the splenic affection.

CHRONIC DISEASES OF THE GENITO-URINARY SYSTEM.

URINE AND ITS CONSTITUENTS.

BEFORE treating upon chronic diseases of the Genito-urinary System, I will at first make a few brief statements relative to the more important normal and abnormal constituents of the urine, as well as to some of the general characteristics of this fluid. (*See* pages 87 to 124.)

Healthy urine is of a light-amber color, transparent, acid, reddening litmus paper, and of a violet-like odor; in the course of twenty-four hours, an average quantity of 35 ounces is passed, though this may vary from 20 to 50 ounces, it is of the temperature 92° to 100° F., when passed, of specific gravity 1.010 to 1.030, and contains 800 or 1000 grains of solid matter in solution, as,—chloride of sodium 100 to 300 grains,—400 to 600 grains of urea,—5 to 10 grains of uric acid,—3 to $6\frac{1}{2}$ grains of creatine,—5 to 10 grains of creatinine,—57 grains of mixed sulphates,—and from 10 to 30 grains of mucus, besides alkaline and earthy phosphates, coloring matter, etc. Among the alkaline and earthy salts, the acids and bases are present in about the following proportions: From 90 to 125 grains of chlorine—from 25 to 40 grains of sulphuric acid—from 45 to 50 grains of phosphoric acid—from 20 to 30 grains of free acid—from 26 to 110 grains of potash—from 75 to 200 grains of soda—from 2 to 7 grains of lime—from 2 to 5 grains of magnesia—from 5 to 13 grains of ammonia, etc.—The specific gravity of the urine may, for all practical purposes, be determined by a good urinometer.

A visible deposit in urine when passed, or shortly after, is abnormal; if the microscope enables us to detect yellowish epithelial cells in the urinary deposit, we should test for bile-pigment; if pus, or casts are detected we should test for albumen.—The most

important *normal* constituents of the urine, in its pathological relations are the following :

1. *Urea* is a nitrogenous compound, derived from the disintegration of some of the nitrogenized tissues, and, probably, also from imperfectly assimilated food rich in nitrogen ; it is not formed in the kidneys, but is merely excreted from the blood by these organs. A large proportion of the urea passed by the kidneys, exists previously in the form of uric acid. The elimination of urea is *increased* by water, salt, tea and coffee without milk or sugar, gelatine, animal soups, eggs, milk, jellies, and nitrogenized diet generally, cubebs, cantharides, and atropia ; liquor potassa, and bicarbonate of potash increase both uric acid and urea, and, with phosphate of soda, lessen the quantity in the system by hastening its (urea) elimination from the body. Its elimination is *diminished* by sugar, starch, fat, cream, tapioca, sago, arrow-root, cod liver oil, alcoholic drinks, beer, tea or coffee with cream and sugar, and non-nitrogenized diet generally, digitalis, benzoic acid, citrate of iron and quinia, acetate and phosphate of soda, colchicum, etc.; acetate of potassa, colchicum, quinia, and cod liver oil diminish both uric acid and urea in the urine, and arrests its (urea) formation in the system.

Urea may be known to be *in excess*, when the urine has the specific gravity of 1.020 to 1.030, has a strong urinous odor, and when upon the addition of an equal bulk of nitric acid to it, it forms flat, shining, rhomboidal plates of nitrate of urea, without requiring any concentration of the urine previously, by evaporation. Urea is *deficient* in quantity when the urine is of specific gravity 1.001 to 1.008, is in increased quantity, and when, upon the addition of an equal bulk of nitric acid to it, after it has been evaporated to a mucilaginous consistence, crystals of nitrate of urea form slowly, or in a small quantity. (See page 108.)

2. *Uric Acid* is another normal nitrogenous and excrementitious constituent of the urine, being derived from the disintegration of some of the nitrogenized tissues, and, probably, from the mal-assimilation of nitrogenous articles of food ; it is eliminated by the skin and lungs, as well as by the kidneys. (It may be proper to state here that the recent experiments of Perls, Oppler, and Zalesky, tend strongly toward proving that urea and uric acid are not separated from the blood by the kidneys, but are produced in the kidneys, from creatine, creatinine, etc.; and when they are detected in the blood it is because they have been absorbed from the urinary organs.) Uric acid is *increased* in the urine by animal diet, by alcoholic drinks, beer, liquor potassa, bicarbonate of potash,

suppression of perspiration, etc.; and we also find an increase of urinary uric acid in several cutaneous affections, as, eczema, psoriasis, pemphigus, etc. It is diminished by atropia, cod liver oil, quinia, tea, coffee, acetate of potash, colchicum, digitalis, etc.

To detect uric acid in healthy urine, some nitric or hydrochloric acid must be added to the urine, which, decomposing the soluble urates in which it exists in the urine, sets free the uric acid, which falls in crystals. Uric acid in excess, the urine yielding crystals of the free acid scattered among an amorphous deposit of urates, is more frequently met with in chronic than in acute diseases. Uric acid is met with in more or less diminished amount in diabetes, chlorosis, anemia, hysteria, and the advanced periods of Bright's disease. In the commencing stage of an attack of gout it is diminished in the urine, but increased in the blood. The excess or diminution of uric acid must be determined not by its ready precipitation, but by its actual amount.—When treating cases of uric acid deposit, it is not necessary to render the urine more than neutral, for, if we make it alkaline, phosphates will be developed.—In these cases the uric acid may be rendered soluble, or be retained in a soluble state while in the bladder, by carbonate of soda, bicarbonate of potash, and carbonate of lithia, but carbonate of ammonia should not be used, as it forms less soluble salts than either of the others.—Nitro-muriatic acid is considered an oxidizing agent, supplying oxygen to the system; it acts upon uric acid, converting it into carbonic acid and urea, the last products of oxidation,—and if this conversion is not effected by the action of oxygen, oxalate of lime or sugar may result as the consequence of the imperfect oxidation of the uric acid and urates. (*See page 110.*)

3. *Urates*, which consist principally of urate of soda with smaller proportions of urates of lime, ammonia, and magnesia, are redissolved when the urine is heated, become again deposited as the fluid cools, are immediately dissolved by liquor potassa or ammonia, and deposit uric acid on the addition of nitric acid. They present an amorphous appearance under the microscope, are usually of a grayish, pink, red, orange, or brown color, according to the amount and kind of coloring matter (urohæmatin) present in the urine. Their presence may be due to cold, overexertion, excess in eating or drinking, hard study, sudden mental emotions, and sudden change in the manner of living; but in these cases their presence is only temporary. Urates in urine, or indeed deposits of any kind, are always indicative of either an ephemeral, or else a more serious derangement of the system, and their presence should never be disregarded. When the urates appear suddenly in the course of febrile or inflam-

matory diseases, it is indicative of a crisis, most generally for the better. When pink deposits occur every now and then, in the urine, without any acute disease being present, and any other attributable cause being absent, it indicates, as a general rule, some chronic disease of the spleen, liver, or heart, etc., with a tendency to gravel, and which should be treated by alkaline tonics. Urine containing urates is always acid, and, in chronic diseases, especially, crystals of free uric acid will be found among the amorphous urates, after the liquid has stood a short time, particularly in cancer of the liver, and other affections of this organ. When the urates are accompanied by the phosphates, the urine may be neutral or but faintly acid, depending upon the amount of phosphates present. (See page 111.)

4. *Phosphates*, which consist of amorphous phosphate of lime, crystals of phosphate of lime, and crystals of phosphate of ammonia and magnesia. These are derived partly from the food, and partly from the oxidation of the phosphorus in the nervous structures, etc. Phosphate of lime is not only met with in an amorphous state, but also occurs in crystals of various sizes, small and needle-like, or thick and wedge-shaped, or in more or less perfect rosettes, or penniform, stellar, etc.; and they occur much more frequently in the urine than the amorphous phosphates, or the triple ammonio-magnesian phosphatic crystals. Urine containing crystals of phosphate of lime is voided in large quantity, with frequent calls to pass it, and more or less uneasiness and smarting being occasioned by its passage, at the neck of the bladder and along the course of the urethra; it is usually pale, occasionally high-colored, is below the average quantity passed in twenty-four hours, is feebly acid when first voided, but speedily becomes alkaline, and contains an excess of urea and animal matter. These calcareous phosphatic deposits are of much greater pathological importance than those of the ammonio-magnesian phosphate, and generally appear with patients who present marked symptoms of nervous exhaustion.

Phosphates are usually present in cases where there exists much nervous or cerebral excitement; the urine containing them is usually neutral or alkaline, and when heated the phosphates are not dissolved. The phosphate of lime is not so readily dissolved as the phosphate of magnesia, hence, in acid urine the former may be precipitated, while the latter remains in solution. The phosphatic deposit in urine is dissolved by acetic, nitric, or hydrochloric acids, but not by liquor potassa, ammonia, or the alkaline carbonates. Ammonia, which, it must be recollected, is not a normal constituent of urine, when added to this fluid, causes a deposit of penniform

or stellar crystals, or crystals of the triple phosphate. (*See* page 114.)

Among the important *abnormal* constituents of the urine, are :

1. *Blood*. (*See* page 118.)

2. *Casts*, especially in albuminous urine. (*See* page 119.)

The epithelial cells lining the walls of the renal uriniferous tubes never appear in the urine but under the influence of disease; they differ in appearance, according to their location. The individual cells of the convoluted tubes are spherical; sometimes appearing oval, and by apposition become somewhat hexagonal,—they have but one nucleus, and are slightly granular.—The epithelial cells of the straight tubes are larger, less granular, contain a single nucleus, and are the last to exhibit any character of degeneration.—The epithelium of the calyces, pelves of the kidneys, and ureters, are more or less ovoid when isolated, are often seen in groups of two or three, when they are somewhat pyriform, are larger than those of the straight tubes, somewhat resemble the tessellated or pavement variety, and are never seen in a state of health; they are often met with in abundance during an attack of uric acid gravel, and, when irritation is present, give place to exudation and inflammation-corpuscles, and ultimately to pus-cells.—The epithelium of the bladder, urethra, and female vagina is of the scaly or squamous variety, and is always seen in healthy urine, either isolated or cohering; it is frequently present in abundance in albuminous and purulent urine.—Pus, mucus, or, as they are sometimes called, exudation-corpuscles, are usually present in the urine, during gonorrhea, leucorrhea, and stricture of the male urethra; and not unfrequently in cases of nocturnal emissions. Although not indicative of renal disease, these corpuscles may co-exist with it.—For the examination of renal casts under the microscope, a power of 200 or 250 diameters is sufficient; nothing can be gained by using any higher powers.—A full account of the renal casts, and the diseases of which they are manifestations, will be found in “Johnson on Diseases of the Kidney,” and “Basham on Dropsy connected with Diseases of the Kidneys.”

3. *Bile*. (*See* pages 121 and 799.)

4. *Pus*. (*See* page 121.)

5. *Albumen* may be detected in urine when this fluid contains pus or blood, or after an attack of scarlatina, diphtheria, during chlorosis, pregnancy, liver disease, etc., without being indicative of any serious lesion of the kidneys. It may also be found in the urine during leucorrhea, at the menstrual period, in hysteria, in spermatorrhea, and in prostaticorrhea, without being necessarily an unfavor-

able manifestation. Indeed any temporary irritation or hyperemia of the kidneys may cause the urine to become more or less albuminous. It is only when it is constantly found in the urine, associated with casts, and with symptoms of failing health, that, as a general rule, its presence in this fluid denotes danger. However, in all cases in which albumen is detected in urine, this fluid should be subjected to repeated microscopic examination, for the purpose of detecting pus, blood-corpuscles, epithelial deposits, renal-casts, etc., and thus enabling us to form a correct diagnosis. When the circulation of blood in the kidneys is impeded by structural disease, so that the albumen of the serum of this fluid transudes through the renal capillary vessels, the prognosis is almost always unfavorable.

In examining for albumen where there is much phosphoric acid in the urine, (in which acid, albumen is very soluble,) we should first precipitate the phosphoric acid by adding a few drops of solution of chloride of lime, and then a little ammonia; let it stand for twenty-four hours, filter to remove the soluble phosphates, and then test with heat and nitric acid.

A very minute quantity of albumen in urine may be detected by the following means: Into a clean test-tube put half a fluidrachm of *fuming* nitric acid; carefully incline the tube, and let the same quantity of the suspected urine trickle down *very slowly* to the acid, over the surface of which the urine will float without the slightest admixture. If albumen be present, a milk-white, sharply-defined, tolerably tenacious film will form at the exact point of junction of the two fluids. If the amount of albumen be extremely minute, this film may be so thin as to become visible only by reflected light when the test-tube is inclined. When very thin, the albuminous film will be dissolved in the course of a few hours; otherwise it increases in breadth, diminishes in density, becomes yellow or yellowish-green at its under surface, and deposits at the bottom of the acid in the tube, minute coagula.—If a ruby or violet ring is developed, at the part in immediate contact with the acid, uroxanthine is present—and, if in addition to a red or violet hue, a green-colored ring is formed, bile is also present.—If the urine presents a granular-like, turbid appearance throughout, urates, uric acid, or epithelia are present, and the turbidity will disappear on the application of heat. (A. Clark.)

When it is desired to estimate the exact quantity of albumen in the urine, we first acidulate a given portion with acetic acid, heat it in a water-bath to the boiling point, collect the precipitate on a weighed filter, well wash it, dry it, and then weigh it,—from the weight found in this given portion of urine, that of the whole quan-

tity passed in twenty-four hours may be determined. As earthy salts are generally present with the albumen, we may burn the filter and albumen, weigh the ashes which remain (of the earthy salts), and deduct this weight from the previously determined weight of the dried albuminous precipitate.

A new substance, allied to albumen, the *hydrated deutoxide of albumen*, has been found in the urine of a patient laboring under *molli-ties ossium*; it is not coagulable by heat or nitric acid, until after the urine has been heated and then allowed to cool. (*See* page 120.)

6. *Oxalate of Lime* is a very common abnormal urinary deposit, occurring in the urine either in the form of octohedral crystals, or of spherical or oval masses, termed, from their resemblance to dumb-bells, "dumb-bell crystals." The octohedral crystals do not appear to be due to any peculiar diathesis or habit of body, are rarely observed in the urine until some time after it has been voided, are generally due to some defect in the processes connected with oxidation, and occasionally they result from some change in the urates of urine that has been allowed to stand for some time. Their presence becomes an important symptom, only when associated with severe local or constitutional manifestations of the existence of disease, being frequently observed in the urine of persons apparently in good health. When oxalates and urates co-exist in the urine, the latter may prevent the former from being discovered; in such case, the addition of a little liquor potassa will dissolve the opaque urates, and the oxalates being no longer obscured by them, may be readily seen.

Oxalic deposits are considered to be emanations from uric acid, in which this acid is imperfectly organized into carbonic acid and urea. Nitro-hydrochloric acid in doses of twenty drops, repeated three or four times a day, in some bitter tonic infusion, is the common remedy; this acid is an oxidizing agent, supplying oxygen to the system, which acts upon uric acid converting it into carbonic acid and urea,—if the uric acid is not converted by the action of oxygen into these last products of oxidation, oxalate of lime or sugar may result as a consequence of the imperfect oxidation of the uric acid and urates. Nitrate of Ammonium in doses of twenty grains three times a day, has also been found efficacious in many instances.

Dumb-bell crystals are never formed in the urine after it has been voided; they are always present when the urine containing them is first passed, and are very probably formed in the secreting tubes of the kidneys, being sometimes observed in the renal-casts. They often form the nuclei of uric acid, and oxalate of lime cal-

culi, and are likewise apt to cause hematuria. Their presence is of much importance clinically. To get rid of them the patient should frequently drink large quantities of fluid, as, a solution of Bitartrate of Potash, or other alkaline fluids; the general health, and especially the digestive organs must be attended to; with Iron, Quinia, or other tonics according to the patient's condition, and especially good air, exercise, but not to fatigue, and a proper and well-regulated nutritious diet. Oxide of Silver in grain doses every six hours, for three or four days, after which, in half grain doses three times a day, has been found very efficacious when dumb-bells are present in the urine, in conjunction with a pill three times a day, composed of Alcoholic Extract of Aletris, Extract of Gentian, Capsicum, each, one grain, Colombo a sufficient quantity. When both dumb-bells and crystals are present alternate the treatment, every four or eight days, for each. The surface of the body must also be especially attended to in these cases. (See page 123.)

7. *Grape Sugar.* (See page 122.) There are several methods of detecting sugar in urine, some of which are given in the sixth edition of my American Dispensatory, page 821. The determination of sugar in urine, as well as its quantity, is most easily and expeditiously effected by means of a polarizing apparatus, as, Mitterlich's.—The following process, being a modification of Fehling's test by Dr. Pavy, will be found useful in practice: Dissolve neutral Tartrate of Potash thirty-two grains, and Caustic Potash (*potassa fusa*) sixty-four grains in distilled Water half a fluidounce. Also dissolve Sulphate of Copper sixteen grains in distilled Water half a fluidounce. Mix these two solutions together. It is better always to prepare this test shortly before using it. One hundred minims of this test solution are decolorized by half a grain of sugar.

Under ordinary circumstances the urine requires no preparation for the application of this test. But if albumen be present, the urine must first be boiled and then filtered, in order to get rid of the albumen. Or, boil a small quantity of the urine with crystals of Sulphate of Soda, enough to insure a total separation of all that is coagulable, and then filter; the presence of the Sulphate of Soda does not in the least interfere with the application of the test solution.—If traces of sugar only exist in the urine, this fluid must first be concentrated by evaporation, and then treated with acetate of lead to remove coloring matter, urates, and phosphates—after which, filter.

To use the above copper-test solution, dilute the diabetic urine with four times its bulk of distilled water, and then from a small

pipette, graduated into one hundred minims, let it slowly drop into a small porcelain capsule containing one hundred minims of the blue-test solution and a piece of caustic potassa about double the size of a pea, and which liquid must be made to boil gently over a spirit-lamp all the time of the operation. As soon as the blue color has disappeared, and a pure orange or orange-red color is produced, read off, on the pipette, the number of minims of diluted urine required to effect the decolorization.

Table showing the quantity of Sugar per fluidounce, for from 15 to 100 minims, required to decolorize 100 minims of the blue copper-test solution. (Pavy.)

The number of minims required will give the amount of sugar per ounce, as in the foregoing Table; but as the urine is diluted, and only represents the fifth part of an ounce, the amount given in

the Table must be multiplied by five, to get the amount of sugar in the fluidounce of urine. Thus, if 28 minims of diluted urine be required to effect the decolorization, this, according to the Table, would give 8.57 grains of sugar to the fluidounce,—but, as the urine is diluted, this is only for the one-fifth of an ounce, and must be multiplied by 5=42.85 grains in an undiluted ounce of urine. Three gallons of urine per day = 384 fluidounces = 16454.40 grains of sugar.

8. *Inosite*, or muscle sugar, is generally found in the flesh of muscle; though it has been found in the urine in Bright's disease, and diabetes. It forms in cauliflower-like crystals, is soluble in water, but not in ether or alcohol, melts at 410° F., loses its water of crystallization in the air, when fused it forms into needles on being quickly cooled, but forms into a horny mass when slowly cooled, and it does not produce alcohol when yeast is added to it.

Urine containing it should be concentrated to one-fourth its volume; a little of this should be placed on platinum foil, and a drop or two of nitric acid be added, and the whole be evaporated to dryness. Moisten the residue with a little ammonia and a solution of chloride of calcium, and again carefully evaporate to dryness; if a grain of inosite be present, a lively rose-red color appears. The true sugars do not give this reaction.—Neutral acetate of lead does not throw down a precipitate with a solution of inosite; but basic acetate of lead produces in it, when warmed, a transparent jelly, which becomes white in the course of a few minutes, and assumes the exact appearance of paste. (*Neubauer and Vogel.*)

KIDNEY DISEASES.

Diseases of the Kidneys are frequently very insidious, coming on very gradually, and manifesting no appreciable symptoms of their presence until they have assumed a formidable character. Simple functional renal derangement is no evidence of disease of these organs, as the color, quantity, quality, and specific gravity of the urine are greatly influenced by changes of temperature, active or sedentary habits, mental emotions, and certain articles of diet or drink, as well as by a number of drugs. It is only by a microscopical and chemical examination of the urine that we become enabled, even at a very early stage of renal disease, to detect its existence. The microscope, by revealing to us the presence of casts, epithelia, blood, pus, etc., informs us not only of the presence of disease, but often of the particular portion of the kidney in which it is located; while chemistry makes known to us the existence of a more or less

serious abnormal condition of the kidneys, by its detection of albumen, etc. And, to verify the presence of a serious disease, these examinations should be frequently instituted. The symptoms usually present in chronic affections of the kidneys, but which are not always positive indications, are,—pains in the region of the loins and groin; weakness in the small of the back; numbness of the thigh on the side with the affected kidney; partial impotency; irregular urination; high-colored, scalding urine, depositing a sediment; sometimes white or milky urine; weakness of the lower limbs; sometimes a desire to void urine very often; bloody urine; pains in the testicles shooting into the loins; gravel; stone; suppression of urine; dropsical swellings; pain and burning in the testicles; swelling of the testicles; irritability of the bladder; mucous, and sometimes seminal discharges ooze from the urethra.

Those commonly complained of in affections of the *bladder*, are,—irritability of bladder; incompetency to retain more than a small quantity of urine, and for a short time only; pain or dullness in the region of the bladder, extending to the back, thighs, etc.; urine hot and scalding; depositing a sediment; sometimes bloody urine; appetite diminishes; depression of spirits; urine passes by drops; irregularity in quantity, quality, and the intervals of voiding urine; strangury; paralysis of the bladder; partial impotency; dull, disagreeable pain in the testicles; irritation of urethra; mucous and sometimes seminal discharges ooze from the urethra.—Yet, it must be recollected, that many of these symptoms may be present as the result of functional or organic lesion of other organs than the kidneys or bladder; and that to designate them satisfactorily is a very difficult, if not an impossible task, unless other aids and diagnostic means be employed.

BRIGHT'S DISEASE. (*Morbus Brightii.*)

Albuminaria, or Bright's Disease of the Kidney, so called after Dr. Richard Bright, who first described it, is a malady in which albumen is detected in the urine, and is frequently a cause of dropsy. It may exist in the acute form, or in the chronic; it is with the latter form only, which is much more frequently observed than the acute, that we have to deal here. Of late years the unity of the disease has been denied, and efforts have been made, based upon careful microscopical, chemical, and pathological investigations, to prove that in reality the disease consists of several renal maladies which agree in the one symptom of a more or less albuminous condition of the urine, and which view has been strongly maintained by Dr. George

Johnson, and others. And from the facts which have been made known by Dr. Johnson especially, and corroborated by other observers, there is no doubt but that the affection termed Bright's Disease, comprises various morbid conditions of the kidneys, essentially different from each other in their origin, their progress, and often in their results. It must, however, be stated that the dissimilar appearances observed in the renal-casts, and the varied conditions detected in the diseased kidneys, are considered by many excellent investigators to be different stages of the same disease, instead of different maladies. I will presently refer to these conditions under the names given to them by Dr. Johnson, to whom I am greatly indebted in the following description of the history and symptoms of this disease. But first, a few words as to the *causes* of kidney disease. In general terms, it may be said that any cause that will give rise to a more or less permanent congestion of the kidney, will induce either a temporary albuminaria, or a true Bright's disease. Excluding causes of local origin, Dr. Johnson observes: "It will be found that all the causes of renal disease have this common feature—that *they tend to produce a morbid condition of the blood*, either by introducing some poison from without, or by interfering with the elimination of certain noxious matters developed within the body, by so far reducing the quantity of nutritive food that it is insufficient for supplying the waste of the tissues and for enabling the blood to maintain its healthy composition, or, lastly, by some exhausting and depressing agency, which lowers the vital energy and diminishes the power which the healthy body possesses of resisting and overcoming injurious influences, whether originating within or without."

Exposures to cold and wet, suppression of perspiration, the intemperate use of alcoholic drinks, want of cleanliness, deficiency of nutritious diet, dyspepsia, cardiac, pulmonary, or hepatic disease, certain poisons in the system, as, of scarlet fever, of measles, of erysipelas, of cholera, of diphtheria, etc., in conjunction with sedentary habits, mental depression, bad air, etc., may each occasion albuminous urine, and eventually lead to true Bright's disease. A strumous habit of body appears to be a strong predisposing cause; and chronic renal maladies frequently follow gout, rheumatism, carbuncles, masturbation, constant presence of oxalate of lime crystals in the urine, renal calculi, improper use of diuretics, blows upon the loins, saccharine urine, etc. In many instances, the chronic form of Bright's disease is the result of a previous acute attack; and it is often developed slowly and insidiously without any known attributable cause.

The only positive *symptom* of this disease is the presence of renal-casts and the persistency of albumen in the urine; but with this, certain secondary or indirect symptoms are observed, which, however, vary considerably in different persons, and are not characteristic. There may be derangements of digestion; obscure pains or uneasiness in the loins; occasional attacks of nausea and vomiting; sense of weakness in the back; paroxysms of dyspnœa occurring more or less frequently, independent of any bronchial or pulmonary affection, and generally attended with palpitation of the heart; pains in the limbs and loins which are considered rheumatic; pulse frequently small and compressible; heart's sounds distant and feeble; debility; gradual loss of flesh; irregularity of the bowels; anemia; a red, brown, or dingy urine, containing casts and albumen; œdema of the face and other parts of the system, which gradually extends; firm pressure over the kidneys causes more or less tenderness or pain; the skin becomes harsh and dry, not perspiring even under exercise; drowsiness is a common symptom; and, not unfrequently, apoplexy, or convulsions. These symptoms may not become fully developed for several years, being very obscure at first, and the disease may even prove fatal without the patient having experienced any extraordinary symptoms.—In some cases, especially among those whose system is enfeebled by want, exposures, intemperance, or disease, (scrofula, syphilis), the commencing symptoms observed, will be a frequent desire to urinate, flatulency, occasional attacks of diarrhea, dropsical swellings of the face and extremities, paleness, and increasing debility.

The urine is sometimes abundant, but ordinarily more scanty than in health, is acid in its reaction, generally of low specific gravity, and containing a diminished amount of urea, uric acid, pigment, and other urinary solids.—The pale, bloodless countenance, the dropsical condition of the cellular tissue, and the persistent albuminous urine, are certain indications of Bright's disease; though, it must be borne in mind, that a temporary absence of albumen in the urine is by no means uncommon.

As the disease progresses the symptoms more or less gradually become more severe and well marked; the breathing often becomes of a moist, wheezing character; a pearly mucus composed of compound granule cells, is frequently expectorated, (abortive epithelial cells); drowsiness increases; apoplexy, or coma ensues; and death; and before death the albumen may have disappeared from the urine.

In the *differential diagnosis* we must remember that epithelial-casts with well-developed renal epithelial cells, or with blood

globules, in the albuminous urine; pain in the renal region and along the course of the ureters; more or less frequent paroxysms of dyspnoea; quick, full, and hard pulse; febrile thirst; harsh and dry skin; and rapidly-developed dropsical swellings are indicative of *acute morbus Brightii*.

Bright's disease may be distinguished from *acute inflammation of the kidneys*, in which there is more soreness and pain in the lumbar region, more especially on the side of the inflamed kidney, with a retraction of the testicle of the affected side, and no albumen in the urine.

From *simple albuminaria*, which occurs temporarily in the course of some acute affections, or which may be due to pregnancy, or to cardiac or other disease, and in which the urine contains but a small amount of albumen, and no renal casts nor epithelial cells.—Bearing in mind, however, that epilepsy, apoplexy, convulsions, and coma, may be due to Bright's disease, or to another cause, namely, uræmia,—and which will require the microscope to correctly determine.

From *suppurative nephritis*, which is usually confined to one kidney, is attended with considerable pain, and, perhaps, also a well-marked enlargement in the renal region, irregular or periodical febrile symptoms, rigors, throbbing in the part affected, etc. Both blood and pus may be found in the urine, and perhaps a few renal casts with pus-globules attached.—In both *purulent urine* and *hematuria*, albumen will be found in the urine, but in small quantity, or proportioned to the quantity of pus or blood present. Both pus and blood may exist in the urine in Bright's disease, but the albumen will be in much larger amount.

From *anemia*, not associated with renal disease, in which dropsy is seldom present or not to any great extent, and no albumen nor casts are present in the urine.—When excessive discharges give rise to anemia, it is by no means uncommon to find the urine albuminous, and dropsy present,—but, upon the cessation of the discharges (hemorrhage, etc.), and as the patient recovers, the albumen will gradually disappear, no casts will be observed, and the dropsy, if due to this cause only, will also pass away.

From *chronic rheumatism*; from *chronic bronchitis*, which is frequently associated with Bright's disease; from *chronic dropsy*, not due to renal disease; and from *gastro-intestinal affections*, which may accompany the kidney malady,—solely by an examination of the urine, which will contain no albumen or casts, if Bright's disease be absent; or, should albumen be present, it will be only temporarily.

From *cancer of the kidney*, in which there is no dropsy or but slight, (but this may also be the case with true Bright's disease); and a small amount of albumen in the urine, with considerable blood, which occurs at frequent intervals. This periodical hematuria is a very important symptom, if not pathognomonic, of renal cancer.—From *tubercle of the kidney*, by the presence of tubercles in other organs, and the appearance in the urine of the degenerated cheesy-like tuberculous matters. Both of these affections are, however, very rare.

I will now briefly describe the several forms of renal disease which, according to many eminent authors, are included in the term Bright's disease.

1. *Chronic Desquamative Nephritis*, (Johnson), *Chronic Albuminous Nephritis*, (Basham). *Gouty Kidney*.—This may follow acute desquamative nephritis, or it may be manifested independent of any previous acute attack, coming on very insidiously, and often terminating in sudden death without the manifestation of any peculiar or troublesome symptoms. It may be due to gout, syphilis, scrofula, or other taint, want of exercise, abuse of liquors especially, mental depression, or whatever tends to lessen the physical or moral activity of the system, and cause an abnormal condition of the blood.

The usual premonitory symptoms are, according to Johnson, a gradual loss of strength with more or less emaciation, which latter is sometimes concealed by the anasarcaous swelling of the body; a harsh, dry state of the skin, with defective perspiration; skin and lips pallid, or sallow, or pallor blended with a dusky hue; loss of appetite, though this is often variable; thirst; constant flatulence; perhaps gastric pain, pyrosis, and vomiting; headache, or heaviness of the head; a tendency to drowsiness; dimness of vision; and frequent attacks of epistaxis, or else amenorrhea or menorrhagia in the female. After a shorter or longer period dropsy may occur, though the disease often proves fatal without any dropsy whatever; a slight puffiness of the face, and in the eyelids is frequently observed, especially on rising in the morning; the urine, from its irritating properties, is frequently voided during the day, and the patient is compelled to get up once or oftener during the night, to urinate,—this symptom is frequently one of the earliest ones observed, and should always lead to an investigation of the urine.

This fluid will be found, at first, more acid than usual, of the

natural sherry tint, and occasionally deeply colored with urates, containing no albumen, but an amorphous granular material, and cylindrical granular-casts, covered with granules and entire or disintegrating epithelial cells, detached from the basement membrane of the uriniferous convoluted tubes. As the disease progresses in the second stage, the urine becomes paler and scanty, at first temporarily albuminous, the urinary solids become lessened, and the granular-casts become more numerous, being sometimes obscured by uric acid or urate of ammonia, (soda?). In the last stage of the disease, the urine becomes paler and permanently albuminous, and its sediment contains larger granular-casts, which from their appearance are called "large waxy-casts," with well-defined, sharp outlines, about $\frac{1}{500}$ of an inch in diameter or nearly equal to that of the renal convoluted tubes, and loaded more or less with resplendent granules, or aggregated masses of nuclei. Blood is seldom present in the urine in chronic desquamative nephritis; but an extensive destruction of cell-structure is going on, frequently beyond the power of subsequent reproduction.

The secondary diseases induced by this form of renal lesion are, dropsy, especially anasarca,—but dropsy is less frequently a consequence of this form of kidney disease, than of many of the other forms associated with albuminous urine.* Dyspepsia; chronic vomiting after meals; diarrhea; pulmonary disease, especially dyspnea with wheezing and cough, or chronic bronchitis with a copious secretion; inflammation of the serous membranes; *obstinate* chronic rheumatism, more commonly seated in the muscles than in the joints; coma, and convulsions; diseases of the heart, especially hypertrophy with or without valvular disease; and hepatic disease, especially cirrhosis. When even one of these complications exist, the case is beyond remedial aid, though relief may sometimes be given.

The *pathological appearances* vary according to the advanced condition of the disease. At first, there is scarcely any change in the external appearance of the kidney, the only evidence of disease being in unnatural opacity of the convoluted tubes, due to their being filled with epithelial cells, either entire or in a disintegrated condition. In a further advanced stage, the kidney becomes diminished in weight and size; its cortical substance becomes thinner and atrophied, and the bases of the medullary

* Dr. Basham states—"The atrophied kidney, then, though it gives rise to albuminous urine, never produces renal dropsy, nor any of the symptoms characteristic of Bright's disease of the kidney." And again, "In fatal cases the cause of death may most frequently be traced to symptoms of uremic poisoning, referable to the influence of the retained urea on the nervous centers."

cones gradually approach the capsular surface of the kidney. One of the surest external signs that the kidney has not undergone much structural change, is, the distinctness and natural appearance of the lobular divisions on the capsular surface; but as the atrophy of the organ progresses, these markings become more and more completely obliterated. The basement membrane of the renal tubes having been denuded of their epithelial cells, the reproduction of these cells becomes wholly arrested, and the tubes become atrophied, and may contain a few broken and scattered particles of epithelium, an unorganized fibrinous or albuminous material, oil, or serum. These secondary deposits in the tubes are generally observed at an advanced stage of the disease, the fibrinous, or albuminous material forming the large waxy-casts. In some cases, a layer of very delicate, transparent, nucleated cells takes the place of the epithelial lining removed from the tubes, and the tubes remain of their normal size, or become more or less dilated, and appearing as if they were in detached, circular, or oval cyst-like portions. These cysts usually contain a yellowish or dark-brown albuminous liquid; sometimes fatty matter, cholesterine, etc.*

The kidney gradually loses its vascularity, and becomes atrophied so far as to reduce its weight and size to one-fourth of its natural standard, but retains its smoothness until at an advanced stage, when it becomes corrugated, hard, and whitish, with occasional patches of vascular engorgement. The medullary cones become contracted, indistinct, and finally obliterated. The outward aspect of the kidney in true desquamation, and in disintegration of the epithelium, without desquamation, is the same. In those cases where the unorganized waxy material is abundantly deposited in the tubes at an early period of the disease, the size and bulk of the kidney may be very little below the average, and the cortex will be firm, yellowish-white, and of waxy aspect in proportion to the amount of this secondary deposit present. Both kidneys are always attacked, but in one the disease may have progressed more rapidly than in the other.

* According to more recent researches it would appear that the course and structure of the uriniferous tubes are more complicated than has been heretofore imagined, and which, if found correct, must tend considerably to lessen confidence in the accuracy of the above microscopical investigations. Henle, Ludwig and Zawarykin, Roth, Schweigger-Seidel, and other German investigators, have all been making independent researches upon the renal tubes, and thus far with about the same results as to the chief points. The question is, however, still undergoing investigation, not being fully decided, but enough has been elicited to prove that our previous views of these canals will have to be greatly changed.

The Malpighian capillaries and the arteries have their coats remarkably thickened, while the walls of the intertubular capillaries and of the emulgent vein present no appearance of hypertrophy or thickening.—Both layers of fibres in the muscular walls of the renal arteries become hypertrophied without change of structure, and the thickening is proportionally greater in the smaller afferent arteries of the Malpighian bodies; the hypertrophied arteries are also more tortuous than when these vessels are in a healthy condition, owing probably to the obstructed state of the circulation which attends extensive disorganization of the secreting tissues. The canal of these vessels remains pervious.

Besides the opacity and thickening of the capillary walls, the Malpighian capillaries undergo further changes. Their canals are normal in calibre, or but slightly narrowed; the thickened vessels become crowded together and less distinct than natural, presenting smooth surfaces free from deposit, or roughened by an indistinctly granular material; the entire Malpighian body is not sensibly enlarged, but the tuft presents a peculiar, whitish appearance. In the last stage of the disease, after the atrophy of the renal tubes, the Malpighian bodies become bloodless, atrophied, and the capsule shrivelled,—the decayed vessels sometimes containing a few oil globules.—The intertubular capillaries probably become atrophied, as they can not be readily seen; and a similar gradual wasting and obliteration of the minute veins likewise takes place; the larger branches become shrunk, contracted, and often contain firm coagula of blood, adhering more or less closely to their walls.

In the *diagnosis* of this affection, we must bear in mind that in the acute form of the disease the urine contains entire renal epithelial cells, while in the chronic form they are mostly disintegrated; and that while blood-corpuscles are common in the urine of acute nephritis, they are rarely seen in chronic desquamative nephritis, though this last may follow acute nephritis, in which case the blood-corpuscles gradually disappear. Albumen, disintegrated epithelium, hyaline, and large granular-casts, and large waxy-casts, are peculiar to the urine of this form of Bright's disease. The granular-casts first appear, becoming more abundant as the disease advances,—the albumen appears at a later period—both become more abundant during the middle period of the disease,—and then gradually diminish, the large waxy-casts replacing the granular.

The *prognosis* is favorable in proportion as the disease is at an early stage, its progress slow, and its secondary consequences few and unimportant; it is also more favorable when in addition, the

constitution is vigorous, and not debilitated nor tainted by disease. When the granular-casts become daily more transparent, and the epithelial cells more perfect and less abundant, the case is highly favorable. When dropsy is present, or pulmonary, cardiac, or hepatic diseases, severe gastro-enteritic symptoms, the chances of recovery are much diminished. A scrofulous disposition, or syphilitic taint is unfavorable. Scanty urine, with a diminution of its albumen and granular-casts, is indicative of a fatal termination, which is generally preceded by drowsiness, and coma, or convulsions. Previous acute nephritis, hereditary gout, intemperance, lack of nutrition, a rapid progress of the renal disease, and the appearance of the waxy-casts, are all unfavorable symptoms. Pus in the urine, or ischuria with a tendency of the urine to putridity, are also serious indications. One thing, however, should always be borne in mind, that even in incurable cases, life may be prolonged for a considerable period by judicious management. The disease is most commonly fatal by uræmic poisoning, coma, or convulsions.

In the *treatment* of this, as well as of other forms of Bright's disease, it must be recollected that, as Dr. George Johnson remarks, "it is not precisely a disease *in* the kidney, but a constitutional disease manifesting itself *at* the kidney," which we have to contend with, or, as Dr. W. R. Basham observes, "we must look to the kidneys rather as the organs which more plainly reveal to us the nature and peculiarity of the constitutional disorder, than as the *fons et origo mali*."

In the first place, all causes that may produce or perpetuate the disease, must be absolutely avoided, or, if the patient can not escape from them, he should be fortified against their influences. All bad habits must be corrected. The diet should be plain, in moderate quantity, and of easy digestion, avoiding pies, pastry, spices, rich or greasy dishes, articles that disagree with the stomach, or occasion flatulence, constipation, or other gastro-intestinal disorder. Meats, fish, or poultry may be used once a day if there are no secondary feverish, or inflammatory symptoms to contra-indicate their use; or twice a day, if the patient is weak and illy nourished, and not of too sedentary habits. Indeed, when there is an enormous drain of albumen from the system, highly albuminous food is proper, as, uncooked eggs, oysters, milk, juicy and rare-cooked beef, custards, calf's-foot jelly, etc. On the other hand, fat, butter, saccharine and amylaceous substances are improper articles, and should be dispensed with altogether. All liquors, alcoholic, vinous, or fermented, must positively be prohibited; yet pure wine is sometimes useful, as a tonic, in the early stage; and where the patient has been long ad-

dicted to the excessive use of alcoholic drinks, it may be prudent not to withdraw them suddenly or entirely.

The surface of the body should be kept warm, by wearing flannel next the skin throughout the year; and exposures to cold, damp, and sudden changes of temperature must be avoided. Moderate exercise in pleasant weather should be insisted upon, when there is no contra-indicating secondary disease present, as, walking, horse-back riding, or in an open vehicle,—avoiding fatigue, overexercise, jolting or sudden jerks, straining, etc. “When the disease has not advanced so far as to require rest and careful nursing at home, it will often become the duty of the practitioner to urge upon a patient the necessity for making a great immediate sacrifice by the temporary abandonment of home and his calling, with the hope of ultimately recovering his lost health and strength.” Sailing, and especially at sea, is very useful; as well as change of scenery, etc., by travel on land,—but the sudden jerks given by railroad cars on starting, and frequently on stopping, are apt to exert an injurious effect upon the kidneys in all forms of Bright’s disease. Long journeys by sea or land, and especially when these lead to sudden changes of temperature, are not advisable, especially in the advanced stage of renal disease. Cheerfulness of mind is a powerful auxiliary to successful treatment.

The skin must be carefully attended to by bathing the whole surface daily, or every other day, with a warm alkaline water, drying with friction to cause a gentle glow; and, every week or two, according to the strength of the patient, a Spirit Vapor Bath may be taken. If the patient can not take a spirit vapor bath, a warm bath may be substituted for it, repeating it every four, six, or eight days. If necessary, diaphoretics or diaphoretic infusions may be used at the time of taking a vapor bath, to aid in the promotion of diaphoresis. The Citrate of Ammonia, in an effervescent form, is recommended by Dr. Johnson, as a mild, pleasant, and efficient diaphoretic. When feverish symptoms or pulmonary congestion is present, a combination of Tinctures of Gelsemium and Aconite will be useful.

If the patient be of a scrofulous habit, or is gouty, or has a syphilitic taint, the proper remedial treatment must be pursued to remove them, or to overcome their influences as much as possible, by the means heretofore named for these maladies. Indeed, one chief object of treatment in all cases should be to purify the blood, and strengthen the nervous system.

Counter-irritants or revulsive means over the region of the kidneys and in the neighborhood of the loins, will be found very use-

ful, but we must be careful not to use agents that may exhaust or debilitate; as, for instance, Croton Oil Liniment, Compound Tar Plaster, setons, etc.; and we must be careful not to employ articles that may irritate or overstimulate the unhealthy kidneys, as, preparations containing Cantharides, Turpentine, etc. Dry cupping, firing, rubefacient liniments, sinapisms, and frictions are the proper means to employ, together with stimulating applications to the feet and legs. A combination, heretofore referred to on page 464, composed of Chloroform, Benzine, and Alcohol, will prove a useful counter-irritant to be applied over the lumbar region. I have, heretofore, employed the Compound Tar Plaster, intermittingly, but have of late years found the other means above named much more beneficial and less debilitating.

As internal remedies, we place our principal reliance upon tonics and alteratives. The preparation composed of Soluble Pyrophosphate of Iron, Blue Flag, Black Cohosh, etc., (*see* page 774), will be found very valuable. In some cases a mixture of Solution of Bromide of Potassium, or of Ammonium (thirty-two grains to a fluidounce), twelve parts, and Solution of Perchloride of Iron one part, will prove useful, in doses of a fluidrachm repeated three or four times a day. Where there is great want of nervous power, an appropriate quantity of a Solution of Citrate of Iron and Strychnia may be substituted for the perchloride of iron solution. It must not be forgotten, however, that iron is contra-indicated whenever signs of cerebral disturbance are present; in such cases I have derived benefit from a pill of Manganese (Oxide or Sulphate) one grain, Aletridin two grains,—mix for a dose, and repeat it two or three times a day,—the same time giving one or two active cathartics to relieve the head symptoms.—The Tincture of Chloride of Iron will frequently be found a very efficacious agent, acting as a tonic, restoring coloring matter to the blood, giving tone to the digestive organs, influencing the capillary vessels to healthy action, and acting as an astringent to check the drain of albumen from the kidneys. It may be given in combination with Tincture of Digitalis, Tincture of Kalmia, Infusion of Lycopus, Infusion of Rudbeckia Laciniata, Infusion of Eupatorium Purpureum, or Infusion of Epigaea Repens, etc. Infusion of Asarum Canadense has been found efficacious in albuminous urine; also Infusion of Ampelopsis Quinquefolia.

Dr. Basham speaks highly of the following mixture: Take of Solution of Acetate of Ammonia one fluidrachm, Dilute Acetic Acid twenty minims; mix, and then add Tincture of Chloride of Iron ten minims, Water one fluidounce; mix for a draught, to be

repeated three times a day. As soon as the urine contains an excess of uric acid, the acetic acid and acetate of ammonia solution must be discontinued.—Lactate of Iron, Ammonio-tartrate of Iron, Ammonio-citrate of Iron, Malate of Iron, and Iodide of Iron, have all been found serviceable in this disease; substituting one chalybeate for some others, when these disturb digestion, or occasion headache.

When there is a deficient action of the kidneys, they may be gently urged by mild diuretics, as, an infusion of equal parts of Queen of the Meadow and Peach Leaves; an infusion of *Rudbeckia Laciniata*; or, an infusion of Parsley Root, etc. But one of the best agents I have met with to promote diuresis is Chloride of Gold and Soda in solution, either with or without the addition of the Hydrochlorate of Ammonia. Great care is necessary, however, never to irritate or overexcite the kidneys. It is generally much better to eliminate excess of fluid, when present, through the skin and bowels, than through the kidneys.

For the purpose of diminishing the amount of albumen passed by the urine, various agents have been advised, as, Iodide of Potassium, Nitric Acid, Tannic Acid, and Gallic Acid, and there is no doubt but that they have sometimes proved efficacious. I have, however, found more benefit from Alum than from any other article; it should only be used when the amount of albumen in the urine is considerable.

Unless dropsy be present, or symptoms of cerebral disorder, purgatives must not be employed. But the bowels must be kept regular, so as to have one alvine evacuation daily; if this does not occur naturally, it may be effected by small doses of Podophyllin and Leptandrin, or, of Oleo-resin of Blue Fag and Leptandrin, or, of Bitartrate of Potassa,—and, in many instances, the White Liquid Physic will be of service.

Among the most frequent and most distressing secondary consequences of disease of the kidneys, are *dropsical effusions*. These are to be combated by hydragogue cathartics, as, *Elaterium* in conjunction with Jalap and Bitartrate of Potassa, which I prefer to any other combination. In some cases, Tincture of *Elaterium* may be given in some Elixir of Cinchona and Iron, so as to produce the desired hydragogue effect. The cathartic should be repeated according to circumstances, every one, two, or three days, being careful to omit its use if more than a temporary debility follows its action. In all instances, when not contra-indicated, I administer in conjunction with the hydragogue, the Compound Infusion of Parsley, giving it not only during the presence of the dropsical effusion, but persisting in its use for some time after the effusion has disappeared.

While using these active measures, the patient's strength must be supported by nutritious diet, and mild stimulants. (*See Treatment of Dropsy*, pages 474 to 490.)

However, there may be instances in which hydragogues are contra-indicated, as, when they produce a persistent debility and exhaustion, or, when an exhausting diarrhea is present. In these cases, we must rely entirely on warm baths or the spirit vapor bath, aided by diaphoretics internally, as well as diuretics. Though, it must be recollected that the want of urinary flow is not owing to a torpid condition of the kidneys, but to their structural disorganization, and hence, diuretics must always prove injurious to these organs. And this will be more especially the case in long-standing and advanced states of the disease, in which nearly the greater portion of the renal organs is deprived of the power of exerting its natural excretory function, from structural degeneration. Still, it becomes necessary that diuresis must be produced, to relieve urgent and dangerous symptoms, even at the risk of increasing the renal disease, and we should select the least stimulating diuretics, as, Queen of the Meadow; Trailing Arbutus; Rudbeckia Laciniata; Compound Infusion of Trailing Arbutus, without the liquor; Horseradish; Spruce-beer, etc. And the diuretic effects of these infusions may be greatly promoted by administering, in addition, the Chloride of Gold and Soda, and applying counter-irritants over the renal region.—If these means fail in evacuating the dropsical effusions, and the tension of the integuments threatens erythema and gangrene, it has been recommended to make a few punctures in the integuments with a needle, or to make incisions into the sub-cutaneous tissue of the legs. Being careful to check any subsequent attack of erysipelatous inflammation by keeping the incised or punctured parts enveloped in hot, moist flannels. Sometimes, when the effusion is in the abdomen, it may be necessary to use the trocar. Not unfrequently it happens, that after the fluid has been discharged by these operations, the kidneys begin to secrete more copiously.

Gastro-intestinal derangements occurring as secondary consequences will be very much lessened by a strict attention to the rules for diet, above referred to. Acidity, persistent nausea and vomiting, and excessive diarrhea, should be treated as already named on pages 741, 747, 757, and 775. In diarrhea, astringents are generally of most efficacy; opiates must not be administered when there are any signs of cerebral disorder. Nausea and vomiting may often be relieved by applications of chloroform over the epigastric region; but if the vomiting be of uremic origin, as known by the watery character of the fluid ejected, and its ammoniacal odor, or, if acid, by

the evolution of ammonia on the addition of caustic potassa to it, it will be very obstinate, and is best combated by allowing ice to melt in the mouth, and administering creosote, or morphia.

Uremic symptoms may be present, as, twitchings and convulsions of the voluntary muscles, headache, drowsiness, dilated or semi-dilated pupils, deadly paleness of countenance, stertorous, but easy breathing, vomiting, diarrhea, dimness of vision, and coma. The attack may consist of one or more convulsive paroxysms, which will be of the epileptic type, and which usually leave the patient deeply comatose. The first attack may prove fatal, or several attacks may occur at various intervals before death takes place. A slight drowsiness occurring in this form of Bright's disease, and persisting for a day or two, is a premonitory symptom that should not be overlooked, but should decide us to immediate and energetic measures. These symptoms must be met by active catharsis and profuse diaphoresis, with cold applications to the head, and hot ones to the inferior extremities; which treatment must be pursued energetically. Cupping on the loins will relieve the kidneys, and be found a very beneficial measure, frequently affording immediate relief. Not more than eight or ten fluidounces should be taken from an adult, and two or three fluidounces from a child three or four years old. It is better to repeat the cupping than to take too large a quantity of blood at once. To counteract the depressing effects of uremic poisoning, Dr. Johnson recommends stimulants, as, ammonia, wine, or brandy.—Frerichs advises chlorine internally, either inhaled in the state of vapor, or, taken dissolved in water; also, sponging the surface with vinegar, giving enemata of vinegar, and administering vegetable acids by mouth. He thinks that these acids, meeting with the poison in the system (carbonate of ammonia), neutralize the free ammonia and reduce it to a state of innocuous combination; this course has not been fully tested.

Any *pulmonary, hepatic, or cardiac* complications must be met by the treatment heretofore named for them as primary affections, being careful, however, to avoid all active depletive or exhausting measures, and, remembering, that as they are secondary consequences, we must not neglect the primary disease. Cirrhosis of the liver is a frequent complication of renal disease.—*Chronic rheumatism*, as a consequence of renal disease, will disappear upon the removal of the primary affection. The pains may be relieved by warm baths, and anodyne liniments.

laceous, or Amyloid Degeneration of the Kidneys. Two forms of waxy kidney are now distinguished by pathologists, the acute and chronic. The disease comes on insidiously, and most commonly in patients greatly enfeebled by some previous wasting malady. It usually co-exists with tubercle of the lungs, caries, syphilis, emphysema, cancer, and abscesses, and may be produced by causes similar to those giving rise to the other forms of Bright's disease. The malady is intimately associated with other pathological conditions, as, non-desquamative disease of the kidney, fatty degeneration of the kidney, etc.—Waxy-casts are often observed in acute and chronic desquamative nephritis as the result of the last remains of secretory power, separating materials from the blood but not organizing them into cells; a true chronic waxy degeneration may occur, however, without being preceded by, or associated with, true desquamation.

The *symptoms*, excepting urinary inspection, are not of a positive character. The patient is usually pale and cachectic, or sallow and emaciated. In the greater number of cases dropsy is present, being either general and abundant, or slight and partial. Symptoms of uremia are seldom observed. At first, the urine may or may not be abundant and only slightly albuminous, but as the disease progresses, it becomes scanty, of high specific gravity, and exceedingly albuminous; some rare cases have been observed in which the urine continued entirely free from albumen. The urine is commonly pale, or of a light sherry-wine color, and gives but a scanty deposit. Upon examining the deposit under the microscope, it will be found to consist principally of large tube-casts of a waxy or hyaline appearance, around which may frequently be observed small cells, either separate or aggregated, and somewhat resembling those of pus. Johnson suggests that these small cells may be "abortive epithelial germs." These tube-casts do not give a violet color with iodine and sulphuric acid; but corpora amylacea, when present, do yield this color when acted on by the chemical agents just named. No cysts are to be seen in the deposit, and but few if any renal epithelial-casts.

In the *diagnosis* of waxy kidney, it must be borne in mind that large waxy-casts are observed in almost all forms of kidney disease; in the present affection, we only observe the immense amount of the waxy material itself; the character of the "casts" themselves, not being diagnostic. This takes the place of the epithelial lining of the tubes, the casts themselves having the full diameter of the renal tubes, and being entirely filled with the waxy material, which gradually suspends the secretory functions of the

tubes, impairs their nutrition, and finally destroys the renal functions entirely, unless benefited by appropriate treatment.—In addition to the waxy material passed by urine, enlarged (lardaceous) liver and spleen will be found to co-exist with the renal malady, as well as one of the wasting diseases of which the kidney affection is so frequently a complication, as, tubercular phthisis, caries, long-standing abscesses, constitutional syphilis, etc.

As there are many points of agreement and alliance between this form of kidney degeneration and the two forms next described, the *prognosis* and *treatment* will be considered together.

The *post-mortem appearances* of waxy kidney, are, usually an enlargement of the organ, though occasionally it may be diminished in size; externally it is smooth, or occasionally slightly roughened; the capsule is easily peeled off, and on section, the cortex is bloodless, of a yellowish or pale waxy-white color, smooth, shining, and with a few arborescent vessels on its surface. “The cortical part is slightly striated, the intervals of the striæ having a glistening appearance of a spermacetic brightness rendered more shining and resplendent under water.” The bright glancing points which dot the smooth-cut surface of the kidney are the changed Malpighian bodies. The cones are unnaturally red and distinct. In the less severe cases, the microscope will be required in order to clearly make out these changes.

Under the microscope, the Malpighian bodies, being the parts earliest attacked, appear as shining particles with thickened capsules; and the waxy material will be found infiltrated into their vascular tufts. In the advanced stages of the disease, the blood-vessels of the cortex, of the pyramids, etc., will be found to have undergone a similar change. The epithelial cells of the uriniferous tubes are usually withered, often containing fatty particles; the tubes themselves are more or less filled with the waxy material, which may sometimes be pressed out in the form of hyaline-casts. The stroma of the kidney though enlarged is not lardaceous.—In nearly all cases enlargement of the liver and spleen, one or both, of a lardaceous nature, will be found to co-exist.

3. *Chronic Non-Desquamative Disease of the Kidney.* (Johnson.) Non-desquamative renal disease occurs in both an acute and a chronic form. The absence of desquamation is the characteristic feature of the disease; in some cases the urine contains neither renal epithelium nor any form of tube-casts; and the *diagnosis* during life must be based partly upon positive, and partly upon

negative evidence. The positive includes a scanty secretion of highly albuminous urine, clear, of natural color or somewhat paler, and giving only a very slight deposit, consisting of pavement epithelium from the bladder, and, occasionally, more or less small waxy-casts; the urine is usually acid, of varying specific gravity, and seldom up to the normal standard. The negative evidence is derived from the absence of renal epithelium, tube-casts, and indeed of any sediment, other than that just referred to, in the urine. According to Johnson, the appearance of the small waxy-casts indicates that the tubes in which they have been moulded still retain their epithelial lining, and are, therefore, considered by him as favorable signs; he also considers the appearance of blood-casts in the urine as of favorable import. The large waxy-casts are formed in tubes wholly deprived, or nearly so, of the epithelial cells lining their internal walls, and are not observed in the present disease.

The *symptoms* are usually serious in consequence of the impoverished state of the blood from the copious drain of its albumen, and of its becoming poisoned by retained excrementitious elements. Dropsy is present, which in the advanced stage of the disease becomes excessive, and intractable to treatment, together with symptoms of congestion and inflammation of the lungs, or of the serous membranes, dyspnoea, great debility, coma, convulsions, etc. Urine, same as named in the preceding paragraph. Benefit may arise from treatment in the early stage of this renal affection, and of the existence of which a microscopical and chemical examination will afford us correct indications; in the advanced stages, a cure is out of the question.

The *post-mortem appearances* are, an increase in the size and weight of the kidneys, which are firmer and much denser than natural. Each kidney may weigh even as high as from six to ten ounces, varying however according to the extent and duration of the disease. In very rare cases, the kidneys are considerably diminished both in size and weight. The cortical substance loses the color due to its vascularity and is found of a wax-like pallor, or yellowish pale, while the medullary cones retain their vascularity, and have a pale-pinkish color. In the advanced stage, the lobular markings become less and less distinct, and finally, only a few small, isolated, vascular patches can be seen over the capsular surface. Occasionally, hemorrhagic spots may be observed scattered over the surface, or in the cortical substance. The capsule is readily detached, leaving a smooth, ungranulated surface, the only inequalities being slight bulgings of the cortical substance, at

points corresponding with the parts where the original lobar divisions were located.

Under the microscope, the convoluted tubes are more opaque than usual, presenting a coarse, opaque granular appearance of their epithelial lining, occasionally of a brownish-yellow color. The epithelial cells appear to contain an unusual amount of solid matter, and the central axis of the tubes is lighter than the margins, presenting a free canal unoccupied with desquamated epithelium, but sometimes filled with the white coagulable material of which the small waxy-casts are formed. Rarely, hemorrhagic spots are noticed in the cortical substance, and some of the tubes may even be filled with blood. The straight tubes of the medullary cones usually present no important structural change.

The Malpighian capillaries pass gradually through a series of changes, from simple congestion without thickening, to a thickening of their walls and opacity, when they resemble firm, whitish, waxy coils,—acetic acid added to them renders these vessels transparent, and shows a single row of blood-corpuscles within them; in some of the Malpighian tufts, however, no blood-vessels will be seen, the circulation having entirely ceased in them, and the capsule and tuft sometimes become shrunk and atrophied, with, perhaps, oil globules deposited within and upon the vessels. The muscular coats of the arteries are often hypertrophied, but less constantly than with chronic desquamative nephritis; this hypertrophy appears to bear a direct proportion to the duration of the disease, and an inverse proportion to the general enlargement of the kidney. A large proportion of the intertubular capillaries are obliterated and atrophied.

4. *Fatty Degeneration of the Kidney.* (Johnson.) Fatty degeneration of the renal organs may co-exist with the maladies, heretofore considered, of these organs, or it may exist as a consequence of them, more especially of the non-desquamative form, or, it may be present as an independent lesion.

Two forms of fatty kidney have been met with, in which the general *symptoms* are somewhat similar to those already named in the preceding forms; indeed, I have observed a few cases in which the patients continued in apparent health, until a few weeks before death. The differential diagnosis between these two forms, are as follows:

a. The *smooth, white, or mottled, and enlarged kidney*, comes on, generally, as a consequence of acute Bright's disease, often sud-

denly, and developing itself rapidly; more commonly, its cause can be determined, as, previous acute disease of the kidney, repeated pregnancies, phthisis, etc. Dropsy is always present before the disease proves fatal; the face is pale and puffy, and the surface of the body smooth, white, and glossy. There is also a much greater tendency to secondary inflammations, and to uremic symptoms, and a less disposition to valvular disease of the heart, and hypertrophy of the left ventricle, than in the other form of the disease. The urine is in less quantity than natural, highly albuminous, and having a specific gravity deviating but little from the standard of health, rarely below 1.015, and from this to 1.030. It is voided of natural color, and deposits a slight cloudy sediment, which contains some epithelial elements, and small waxy-casts, entangling scattered oil globules and oil in cells. From time to time blood will be usually observed in the urine, especially in the earlier stage of the disease. Sometimes no oil will be present. The disease is of shorter duration than the subsequent variety, being less than six months; occasionally, it may be protracted for several years.

The *post-mortem appearances* are an increase in the size and weight of the kidney; in a few cases, especially those in which the patient survives for a sufficiently long period of time, it becomes diminished in size. The surface of the organ is smooth, and the capsule is thin, and easily peeled off. The cortical substance is either uniformly pale, or mottled by red vascular patches, and in some cases hemorrhagic spots will be found scattered over it. The medullary cones retain their normal color and vascularity; the consistence of the kidney is softer than natural, with frequently an œdematous feel and aspect—Under the microscope, the convoluted tubes are found distended and filled with oil globules of a larger size than in the form next described; some of the tubes may be ruptured. When blood has been effused into the convoluted tubes, hemorrhagic spots may be observed. The epithelial cells only are filled with oil, there being none in the intertubular tissue, and rarely any in the Malpighian bodies, or in the tubes of the medullary cones. The epithelial cells are usually disintegrated and atrophied, and can not be seen at all in some of the tubes, which are then occupied by their oily contents. The Malpighian capillaries are opaque and thickened. Much more fatty matter exists in this form of the disease, than in the one next described. This is considered by many as the true Bright's disease.

b. The *granular, brownish or red, and contracted kidney* is rarely met with in its early stage; it usually comes on very gradually and insidiously, often without any definite exciting cause, and frequently makes great progress before the urine affords any indications of the existence of renal disease. It may run a latent course for months and years, and is more usually observed among persons further advanced in years, than those laboring under the preceding form. Its victims are generally very cachectic, with a pale, anemic appearance of the surface, not so white as in the variety just described, and often with sallow and pinched features. Dropsy is generally absent, or if present, amounts to only a puffiness under the eyes, or a slight œdema of the ankles and legs. The œdema of the eyelids should be particularly noted by the practitioner at an early period, it extends to the face, and then to the extremities, being accompanied eventually with an obstinate dryness of the skin, pains in the lumbar region, febrile action, diarrhea, debility, and vomiting. Hypertrophy of the heart is frequent, as well as epistaxis. The urine is copious, three or four pints in twenty-four hours, of low specific gravity, sometimes as low as 1,010 or 1.005, but containing comparatively only a slight amount of albumen, or, in rare instances, it may be temporarily absent. A scantiness or suppression of the urine is indicative of a rapidly fatal termination. The deposit in the urine is very slight, consisting of hyaline and granular-casts, with minute quantity of epithelium, not often fatty; sometimes, there will be no deposit at all. Blood is rarely observed.

The *post-mortem appearances* are, considerable diminution in the size of the kidney, and a reduction of its weight some two or three ounces; roughness of its surface from numerous straw-colored elevations or prominences, termed “granulations.” The capsule is opaque, thickened, and usually so adherent to the subjacent surface, that it can not be detached without tearing the glandular structure; sometimes, it may be peeled off, leaving the subjacent surface apparently smooth. In certain places the capsule sinks into the cortical substance, irregularly dividing the kidney, and giving to it a strikingly lobular aspect. The cortical substance is greatly atrophied, forming a thin rim around the bases of the medullary cones, not exceeding a line in thickness; the cones are atrophied to a much smaller extent. The whole kidney is tough and resistant, of a coarse granular texture, and of a red or brownish color. The yellowish-white opaque “granulations” observed in the kidney, vary in number, and are found, on a microscopical and chemical examination, to be composed almost entirely of fatty mat-

ter. It is seldom the case that a granular kidney in its early stage is observed; it is then of its normal size, and presents a thickening of the capsule and slight granulation of the surface of the organ.—Under the microscope, the secreting tissue is found to have undergone extensive degeneration; the Malpighian bodies are dwindled to half their size, and are abnormally packed together. Their vascular tufts are contained in a fibrous and granular envelop, and, sometimes, they are so crowded at the bottom of their capsules as to form an imporous knot. The renal tubes are variously altered and in various degrees, and frequently there are no traces of them. They may be deprived of epithelium and appear like mere tubular filaments, or may contain glassy fibrinous cylinders, or, be loaded with disintegrated epithelium, in both of which oil may frequently be observed, but in much less quantity than in the preceding form of the disease. Some tubes of normal character may also be observed. Minute cysts may likewise be seen in the tubes and in the cones, being often elongated when in the latter.

The varieties of disease just described under the names of waxy degeneration, non-desquamative disease, and fatty degeneration, are so closely connected with each other, that although as isolated conditions they may require a separate description, yet their *prognosis* may be considered under one head. In a certain sense, one form of disease may be considered as a sequence or later stage of another, though each form sometimes exists independent of the other; but their causes are about the same.

In forming our prognosis of these affections we should not rely alone upon the chemical and microscopic characters of the urine, but should carefully consider all the circumstances of the case, as to the patient's constitution, predispositions, manner of living, previous exposures and diseases, causes of the renal disease, etc., as well as his actual mental and physical condition. There are certain circumstances that not only develop the disease with many persons, but, when present, render the prognosis unfavorable, as, a scrofulous tendency, exhausting diseases, profuse and debilitating discharges, want of nutritive diet, unhealthy diet, intemperance, protracted chronic disease, previous renal disorder, syphilitic or other taints of the system, etc. The presence of symptoms of uremic poisoning, of phthisis, caries, enlarged liver or spleen, hypertrophy of the left ventricle, or dropsical effusions, confirm the seriousness of the case.

The presence of small waxy-casts in the urine are more favorable than that of the large casts, as, the former indicate the existence of

epithelial lining upon the walls of the renal tubes, and the latter, an absence or destruction of this epithelium. Small waxy-casts are, however, more favorable in the acute forms than in the chronic; when there is a long-continued deposit of waxy-casts in the latter forms, it tends to the disorganization and atrophy of the tubes. Large waxy-casts indicate embarrassed circulation, impeded renal secretory functions, and degeneration of the renal gland-cells.—Frequently, unless a most careful examination be made, the waxy-casts may, from their sparseness, escape detection.

A scanty urine of low specific gravity, and highly albuminous, is unfavorable, more especially when the albumen is persistent and there is an obstinate dryness of the skin; if, under such circumstances, blood appears in the urine, it is rather favorable, as indicating an early stage of the disease, though this must not be too confidently relied upon, because blood may occasionally be present in the latest stages. The more persistent the presence of albumen in the urine, the more unfavorable is it.—When, with the continued albuminous condition of the urine, numerous oily-casts and cells are also present, the urine being nearly of natural color, and depositing only a slight cloudy sediment, a fatal result will inevitably occur. A temporary presence of albumen, or of a few oily-casts, are, not necessarily unfavorable, as these may often be observed during convalescence.

An absence, or a gradual disappearance of the above-named general and local signs, may be considered favorable; though, generally, the prospects of a patient laboring under a chronic Bright's disease are exceedingly gloomy. In some instances, especially in the granular contracted kidney, by a proper course of treatment, hygienical and therapeutical, life has been prolonged for a number of years; in others, death occurs in a very short time after the first recognition of the symptoms. Pneumonia, pericarditis, ischuria, or uncontrollable vomiting and diarrhea are indications of speedy death.

The *treatment* required for these several forms of Bright's disease, both hygienical and therapeutical, as well as for their secondary consequences, differs in no respect from that named for Chronic Desquamative Disease, on page 873.

SUPPURATION IN THE KIDNEY.

There are several affections of the kidneys, in which pus may be found in the urine; but the mere fact of its presence in this fluid, does not determine its source nor the nature of the particular renal

malady giving rise to it,—this must be had principally from the other symptoms.

Pus may, however, be detected in the urine when the kidneys are healthy, and, consequently, it is always highly necessary to ascertain its source, in order to be positive that the renal organs are not implicated. If it be derived from the *urethra*, (gonorrhea), a drop or two may be squeezed from the meatus urinarius, beside which, the history of the case, and a careful exploration of the canal will solve the matter; when the *urethra* is the source, the pus is usually in small amount, and does not affect the general properties of the urine.

If it be derived from the *vagina*, (leucorrhea), the history of the case, an examination of this canal, the additional presence in the urine of vaginal or pavement epithelium, and the discharge occurring as well when no urine is passed, as when it is, will determine this source.

If it be derived from the *bladder*, (cystitis, stone, enlarged prostate, stricture), it is of more serious import, and may be known by the history of the case, the frequent calls to urinate, the alkaline and ammoniacal state of the urine, and the rapid formation of the pus into a viscid mass. In less severe cases urination may be less frequent, and the urine remain acid.

If it be derived from an *abscess* that has discharged into the urinary passages, (perineal, perivesical, perirenal), it is more difficult to determine, and we have to rely more on the history of the case and the peculiar symptoms present. Generally, the rupture of the abscess is followed by a large quantity of pus in the urine.—Its derivation from the *kidney*, will be presently considered under the description of the several affections of this organ in which the presence of pus in the urine forms a symptom.

When pus exists in urine, it renders this fluid milky and opaque when passed, and subsequently forms a yellowish-white deposit. If the urine be acid, the pus globules are discrete and the deposit loose; if it be alkaline, the pus forms a viscid glairy mass, which may be drawn out into long tough strings. Liquor potassa or liquor ammonia always gives this latter character to pus.—Under the microscope, pus-globules are observed to be spherical and about a third larger than a red blood globule, yellowish, opaque, and granular; a drop of acetic acid added to the drop of urine under examination causes the granules to disappear, the pus-globule becomes more transparent, and exhibits a nucleus with two, three, or four nucleoli. An excess of the acid causes the cell wall and its contents, with the exception of the nuclei, to disappear altogether. As pus contains albumen,

more or less of this latter substance will be found in purulent urine, but always in proportion to the amount of pus present. If there exists a much larger amount of albumen than can be accounted for by the quantity of pus present, the detection of renal tube-casts in the freshly-voided urine will aid in solving any doubts.—The renal lesions giving rise to purulent urine, are the following:

1. *Suppuration from Morbid Conditions of the Blood*, etc. According to Johnson, certain depraved conditions of the blood may gradually modify the renal secreting or epithelial cells, by the passage through them of materials different from those which they naturally secrete, so that ultimately these cells become converted into pus. The *symptoms*, in nearly every respect, are the same as those of Bright's disease, with the addition of purulent tube-casts in the urine; and, in the later stages, a quantity of free and scattered pus-corpuscles. Johnson describes three cases of this kind, one associated with boils and carbuncles; another with erysipelas of the face, legs, and scrotum; and the third with gout and intemperance. I am much inclined to doubt whether the conditions stated by Dr. Johnson can be considered true cases of what he terms "suppurative nephritis," inasmuch as the *post-mortem examination* revealed the presence of Bright's disease of the kidney, and the *treatment* pursued was similar to that advised for this last-named disease. Besides which it must be recollected that the renal epithelial cells sometimes greatly resemble pus-corpuscles, with nuclei and nucleoli, especially when these cells are generated with rapidity.—While, again, it is by no means uncommon for the bladder, in nearly every form of renal disease, from irritation arising from contact with unhealthy urine, to shed more or less of its epithelium together with a number of scattered or irregular clusters of pus-corpuscles, which are *never moulded in tubes*, like the renal purulent-casts.—And even when the kidneys are healthy, pus-corpuscles may be observed in the urine, in connection with phosphatic deposits, being derived from the bladder irritated by an alkaline urine.

However, should Dr. Johnson's view of the matter prove to be correct, it may be proper to state that, when a highly albuminous urine, with tube-casts and pus-corpuscles, is present, indicating the co-existence of Bright's disease and renal abscess, (a very rare complication), and a further evidence of the depraved condition of the blood is manifested by the presence of boils, carbuncles, etc., on parts of the external surface of the body, but little hope can be entertained of recovery, and the *prognosis* must necessarily be unfavorable; more especially when we find an increased manifestation of pus-corpuscles, and a disappearance of the renal epithelium.

Tonics, stimulants and alteratives are required only after all inflammatory symptoms have been subdued.

2. *Suppuration from Mechanical Injury or External Violence, etc.* Severe blows or fall on the loins may occasionally give rise to phlegmonous inflammation of the kidney of the injured side, followed by an abscess. The *symptoms* are, more or less severe pain in the affected kidney, febrile reaction, hematuria recurring at shorter or longer intervals, followed by the pain becoming duller, and successive attacks (sometimes regular) of rigors. If the accumulation of pus be quite considerable, a fluctuating tumor may be detected in the region of the affected kidney. As no purulent tube-casts will be observed in the urine, except, perhaps, at the very commencement of the suppurative process, the *diagnosis* must be based upon the character and location of the symptoms, and the previous history of the case. In standing cases, hectic symptoms are apt to be present. Instead of bursting into the infundibula, the abscess may open into the intestines, and the pus be discharged with the stools.

These cases are attended with considerable risk, but the *prognosis* will be principally based upon the severity of the injury and of the subsequent symptoms, together with the condition of the patient's health, constitution, and resisting power. If the suppurative process can be prevented, a careful watchfulness for a long time, and a close adherence to hygienic measures continued for several years, will remove any further tendency to disease, and the patient be thus relieved from any further apprehension of danger.—When a renal abscess opens into the pelvis of the organ, the pus passing through the ureters, it is more favorable than when it discharges through other parts. If the patient is not carried off by the severity of the first symptoms, nor by the exhaustion consequent upon a suppurative drain, the cavity of the abscess contracts, being partially filled with adipose tissue, or other matters, and the kidney becomes inactive; while the other kidney increases in size, and, in a great degree, assumes a functional activity compensating for the want of action in the contracted and inactive organ.

The *treatment* consists, at first, in preventing the occurrence of suppurative inflammation; the patient should keep quiet in bed for several days,—his diet should be low, avoiding even the mildest stimulants; cups or leeches, followed by Stramonium fomentations should be applied to the loins over the painful part; the bowels should be kept open by laxative enema, or doses of Castor Oil;

and inflammatory action be kept down as much as possible by Tinctures of Gelseminum, Aconite, Veratrum, etc.

If, notwithstanding the continued and energetic employment of these means, suppuration occurs, we must then change our treatment, encouraging the pus to the surface by means of warm cataplasms; and if the abscess points externally, it should be discharged by an artificial opening made at the proper period, in order to prevent it from forming communications with the peritoneum or thorax. At the same time, during the whole of the suppurative period the strength of the patient must be sustained by a non-stimulating nutritious diet, tonics, iron, mineral acids, alteratives, etc., to suit the particular exigencies of the case.

Should we succeed in checking or preventing suppurative inflammation, the patient must be informed that all danger is not yet over, as the kidney will suffer for months or years from the injury, and, by imprudence on his part, ultimately suffer from suppuration. He should use all the necessary hygienic measures to protect himself from sudden changes of temperature, dampness, over-exertion, fatigue, etc.; should avoid rich and stimulating articles of food or drink; and whenever any unpleasant sensations are felt in the renal region, he should apply counter-irritants over the affected parts, as, sinapisms, Compound Tar Plaster, Croton Oil Liniment, etc.

b. The lodgment of a *calculus* in the substance of the kidney may also give rise to inflammation terminating in an abscess; so also may suppuration of the lower urinary passages, the inflammatory action extending by sympathetic action, or by continuity of tissue to the kidney.

Uric acid, and oxalate of lime calculi, are among those more frequently met with in the kidneys, the continued presence of which may disorganize the greater part of the glandular tissue, and convert the kidney into a suppurating cavity, which may discharge either through an orifice in the loins, into the intestines, into the abdominal cavity, into the thorax, or through the ureter into the bladder. The early *symptoms* are those common to renal calculi; in the suppurative stage, the urine will present pus-corpuscles, as in the preceding variety, and similar symptoms will be present.

The *prognosis*, as well as the *treatment*, are also similar during the suppurative stage. And after recovery the kidney becomes converted into a membranous cyst inclosing the offending concre-

tion. In the early stages, before suppuration occurs, the treatment will be that usually employed for Renal Calculus.

c. When the abscess is due to *disease of the lower urinary passages*, it is frequently of difficult diagnosis, requiring the most careful investigation; and not unfrequently its presence may not be suspected until a post-mortem examination reveals its existence. A *retention of urine* is frequently due to stricture of the urethra, and sometimes to enlargement of the prostate gland, in which the walls of the bladder and ureters become thickened, and that part of the urethra behind the obstruction, as well as the ureters, pelvis, infundibula, and calyces of the kidney, become dilated, in proportion to the duration and degree of the impediment, and pus is often secreted, to a greater or less extent, from the inflamed mucous membranes of these several parts. And the kidneys may eventually become involved, as already explained.

d. *Embolism* of the arteries of the kidney occasionally gives rise to renal suppuration. The plugs or emboli that lodge in these blood-vessels are yellow fibrinous formations, that are carried away by the current of the arterial circulation from their original seats in the aortic and mitral valves, and become lodged in the renal vessels, or in those of other organs. These fibrinous vegetations frequently exist in rheumatic endocarditis, being loosely located in the valves; and sometimes they are encountered in atheromatous erosions of the valves and aorta. Occasionally, part of the fibrous lining of an aneurism may be detached, and swept away by the circulation, to be lodged in the cerebral, renal, or other arteries.

It is only when a large artery is entirely obstructed by these emboli, and which do not become removed, that suppuration and serious results are to be apprehended; this is by no means easy of diagnosis, though it may be suspected in those cases, where a more serious primary disorder exists, (of the heart), and when there occurs a sudden hyperemia of the kidney, accompanied with an intense pain in the loin, shooting down the course of the ureter. Usually, however, the effects of renal embolism pass off without being noticed by the patient.

e. *Pyemia* in other parts of the body, as from chronic suppurations, carbuncles, gangrenous maladies, or after surgical opera-

tions, etc., sometimes produces secondary or metastatic abscesses in the kidneys, as well as in the lungs, liver, and other organs. There are no positive symptoms whereby we can determine the existence of these multiple abscesses during life, though we may suspect their presence, when, with unmistakable pyemia, the urine contains considerable albumen, with, perhaps, a little pus, but no tube-casts, and pressure upon the region of the kidneys occasions more or less pain. The *prognosis* and *treatment* in emboli, and in secondary abscess, is based entirely upon the much more serious primary lesion.

3. *Pyelitis*, or Inflammation of the Mucous Membrane of the Renal Pelvis and Calyces, may exist either in the acute or in the chronic form, and may attack only one kidney or both.

The *causes* of pyelitis are various, and the inflammation is intimately associated with its cause; in some instances, the inflammation itself is the most important feature of the attack, while in others, it is of much less importance than the more serious primary disease. The following conditions may give rise to pyelitis:

a. In both the acute and chronic forms of Bright's disease, and in diabetes, pyelitis, in a greater or less degree, is often present.

b. It may arise from exposures to cold, sudden changes of temperature, or dampness.

c. From an improper use of stimulating diuretics, as, cantharides, turpentine, etc.

d. From mechanical irritation resulting from the presence of a foreign body in the renal pelvis, or infundibula, as, calculi, clots of blood, tuberculous deposits, hydatids, or other parasites.

e. The worst forms of pyelitis arise from an inflammation of the bladder extending upward into the kidney,—the cystitis being produced either by a urethral stricture, a prostatic enlargement, a urinary calculus, a fungous, a tuberculous disease of the bladder, or a sudden suppression of the discharge in catarrh of the bladder or in gonorrhea, by an improper employment of astringent injections,

f. A sudden stagnation of the urine in the renal pelvis and infundibula, from an obstruction in the ureter, together with a decomposition of the urea into carbonate of ammonia. If no decomposition of the urine occurs, there is generally only dilatation, (hydronephrosis.)

g. Pyelitis is sometimes complicated with certain general diseases, as, eruptive fevers, scorbutus, diphtheria, pyemia, carbuncle, cholera, etc.

h. Cases may be occasionally met with in which there is no known cause for the pyelitis.

The *symptoms* of pyelitis are always associated with those of its exciting cause, and which are referred to under their appropriate headings. The more immediate symptoms of the inflammation itself, are, an aching pain over one or both kidneys, which is aggravated on pressure; a sense of weakness in the back; and, not unfrequently, attacks of nephritic colic. But these symptoms bear no proportion to the actual amount of structural lesion in the kidneys, and it is by no means rare for alarming symptoms of uremic poisoning, quickly followed by fatal typhoid collapse, to be the first indication of serious renal disease. The calls to urinate are often more frequent than natural, and, during an attack of nephritic colic, they are constant and painful. The bowels may be obstinately constipated, from compression of the colon by the tumor, or, there may be an intractable diarrhea resulting from inflammatory adhesions between the dilated kidney and the colon. Rigors are usually present when there is tumor, coming on regularly every evening; and, in the latter stages, hectic symptoms will be present.

The urine, however, affords the most reliable indications. In the first stage of pyelitis, this fluid is usually acid, and contains more or less blood, sometimes in very minute quantity, together with mucus, and the irregular, fusiform, caudate, trigonal, elongated, and rudely circular epithelial cells from the renal pelvis and infundibula, and but a small amount of albumen in proportion to the mixed blood and pus present.—As the disease advances, these epithelial cells disappear, and in their place is more or less pus; and eventually the urine loses its acidity, and becomes ammoniacal from decomposition of the urine and the pus. Tube-casts or purulent-casts are not found in the urine, or, at least their presence is extremely rare, and which is due to the fact that the destruction of the tubes commences in the anterior parts and advances backward into those more deeply situated.

The presence of pus in the urine is constant and regular, when the uriniferous canals are free; but, as often happens, should a calculus, a clot of blood, or other foreign body or debris, obstruct the ureter, the purulent flow will be temporarily arrested, and then, should but one kidney be affected, the urine will again assume and retain its transparent and normal characters, until the obstruction is removed, and the pus reappears. “A decidedly low specific gravity of the urine, with a scanty secretion, would be suspicious symptoms; and especially so when they are associated with any

indications of uremic poisoning, such as, drowsiness, headache, vomiting, and a brown, dry tongue, with an excess of urea in the blood." (*Johnson.*)

At an advanced period of pyelitis, a tumor may be observed in the loin, or in the space between the crest of the ilium and the false ribs. It may be so large as to extend across the median line, but more generally it only occasions a fullness in the part. It is usually painful and tender on pressure, dull on percussion, except where it is crossed by the colon, and is the seat of fluctuation, frequently obscure.

The *diagnosis* of pyelitis without tumor, or in its first stage, is made out by the presence of the epithelial cells of the renal pelvis and calyces, in the urine, with more or less blood or pus, and the pain in the loin being aggravated by pressure. In the advanced stages, the diagnosis may be greatly assisted, by observing the presence of a large amount of pus in the urine, say two or four ounces per twenty-four hours, the urine being slightly ammoniacal, the loins painful on pressure, the apparent disproportion existing between the debility and other symptoms, and the urethral or vesical lesion, and the previous existence for several years of urethral stricture, vesical disease, etc., or of attacks of nephritic colic.

In pyelitis with tumor (pyonephrosis), there is an enlargement of a fluctuating character in the flank of the affected side; a large amount of pus is discharged with the urine, which may vary in quantity from time to time,—the tumor or fullness increases and becomes more or less painful as the pus diminishes in the urine, and this fluid becomes more transparent accordingly; and when the purulent discharge becomes large, or is re-established after a temporary arrest, the tumor becomes rapidly lessened in size, with less pain and a more purulent condition of the urine. When both kidneys are affected, a temporary or permanent obstruction of one ureter may lessen, but will not entirely remove, the amount of pus in the urine.—Ultimately the sac may burst, and discharge its contents, the symptoms varying according to the direction this may take; or, more frequently, there will be no rupture, the patient dying from the exhaustion consequent upon the purulent drain on the system. Again, the discharge may gradually diminish, until it ceases entirely, the sac contracting and drying up, and the patient recovers, the urinary function being performed by the opposite healthy kidney.

The *prognosis* is much more favorable when the pyelitis is confined to one kidney, as recovery, with or without destruction of

this kidney, may occur; when both kidneys are diseased (double pyelitis), with purulent discharge, the chances of recovery are doubtful.—Much, however, will depend upon the character of the original exciting cause of the disease. If it be the result of urethral stricture of long standing, enlarged prostate, obstinate disease of the bladder, or cancerous or tuberculous disease of the kidney, the case is hopeless. The removal of retention of urine by a cure of urethral stricture, may at an early period, be followed by favorable results; and, in cases, depending upon renal calculus, or hydatids, or which follow pregnancy, recoveries sometimes occur.

When the pyelitis is secondary to other diseases, as, zymotic fevers, diabetes, Bright's disease, etc., the prognosis must be based upon the character of the primary disease; in acute disease, it usually disappears with the recovery from the primary affection; in Bright's disease, etc., the pyelitis is a secondary consideration, being overshadowed by the gravity of the primary malady.

If the pus be discharged externally, the patient may die from exhaustion, though recoveries often occur, even in the most unpromising cases; but if the sac ruptures into the thoracic or peritoneal cavities, or into the intestine, a fatal result will take place more or less speedily. If symptoms of uremic poisoning manifest themselves, the prognosis is decidedly unfavorable.

The *post-mortem appearances* in *acute* pyelitis are, a vivid red injection of the mucous membrane; and sometimes, minute dots of ecchymosis may be observed on its surface, or, effused blood. The mucous membrane may be thickened, friable, and softened; its epithelium more or less freely shed, and, at a later period, pus is formed. Occasionally, ulceration may be present, or, the mucous surface may be lined with false membranes, that may become detached during life and block up the ureters.

In *chronic* pyelitis the mucous lining membrane is thickened and presents a dead-white, gray, or slate color; it may not be at all injected, or else be traversed by dilated veins. There is dilatation of the pelvis and infundibula, which, as it proceeds, encroaches more and more on the substance of the gland, flattening or obliterating the papillæ, then the pyramids, and at last the cortex, and the kidney is wholly sacculated, and transformed into a multilocular pouch filled with pus. Sometimes, the surface of the pelvis is covered, more or less, with small vesicles resembling sudamina. Ulceration of the mucous membrane may be present, especially when renal calculus is the exciting cause of the disease, and even perforation, with purulent discharge into the surrounding tissues or cavities.—In the interior of the pelvis, according to the cause

of the inflammation and the character of the urine, may be found calculi, calcareous crusts, blood, tubercle, cancerous material, pus, uric acid, urates, phosphates, and other foreign substances. Sometimes, the kidney will be found reduced to a mere shrivelled pouch.

When the ureter has been blocked up by thickened pus, a calculus, a clot of blood, etc., preventing the free discharge of urine and pus, these fluids accumulate behind the obstacle, and dilate the organ forming an abscess-like cavity (pyonephrosis) which frequently may be felt as a tumor in the loin. And the matter thus inclosed may eventually discharge itself through the loin, under Poupart's ligament, into the peritoneum, duodenum, thoracic cavity, etc.—Most generally, chronic inflammation of the bladder will be present, with dilated, thickened, suppurating ureters. And, sometimes, the renal substance itself will become involved forming a chronic Bright's disease, with the usual changes in the urine, dropsy, etc.

The *treatment* consists, firstly, in removing the primary lesion or the exciting cause of the pyelitis, as, urethral stricture, diabetes, scorbutus, etc., by the appropriate means for such maladies—several of which are treated upon in this work; and, secondly, to diminish or arrest the discharge of pus, and give support to the patient.

In acute pyelitis, with pain in the loins, painful and bloody urination, febrile symptoms, etc., cupping should be practiced over the painful parts, followed by warm baths, and hot Stramonium and Lobelia poultices over the renal region. Internally, Tincture of Gelsemium, of Veratrum, or of Aconite should be administered, with the free use of warm diluents; and if much pain and suffering remain, opiates or other anodynes may be required. Should the loss of blood by the urine become threatening, astringents and styptics internally will be demanded.

In chronic pyelitis, to lessen the purulent discharge, astringents will be required, as Tannin, Geraniin, Marsh Rosemary, Oil of Erigeron, Alum Root, Alum, and mineral acids. In some cases, the Tincture of Chloride of Iron has proved decidedly beneficial. In the advanced chronic stage, when stimulants to the affected mucous membrane are required, balsamic and terebinthine substances, as, Queen of the Meadow, Oil of Golden Rod, Oil of Juniper Berries, etc. will be found useful.

To sustain the strength of the system in the chronic stage, and also aid in lessening the discharge of pus, Elixir of Cinchona and Iron; the preparation on page 774, containing the soluble Pyrophosphate of Iron; Sulphate of Quinia; or, a Solution of Bro-

mide of Potassium (thirty-two grains to the fluidounce), one fluidrachm, Solution of Perchloride of Iron five minims; mix for a dose, to be repeated three times daily, etc.,—may be administered, in conjunction with nourishing diet, pure air, and, if possible, sea-bathing.

We should be very careful not to attempt artificial evacuation of the sac through the integuments, unless there be decided indications of pointing, or, when the sac becomes so greatly distended that its internal rupture might lead to a speedy fatal result. The opening should then be made in the lumbar region, where the sac is most prominent, and where there is the least danger of wounding the peritoneum.

As the several renal, urethral, and other affections that may occasion suppuration have been referred to in the preceeding remarks, the more important ones will now be taken up and considered separately, along with other maladies of the kidneys, bladder, urethra, etc.

HYDRONEPHROSIS.

This malady consists in an atrophy or complete absorption of the substance of the kidney, so that the organ forms a cavity or sac, of which the fibrous capsule of the kidney forms the envelope or walls. This condition may exist with or without the presence of pus from the living membrane; when pus is present, it is termed pyonephrosis. Hydronephrosis has been described by authors under the names of “hydro-renal distension,” and “dropsy of the kidney.” It may occur in either sex, at any period of life, and even during intra-uterine existence; and it may affect either one or both kidneys.

The *cause* of hydronephrosis is an obstruction to the passage of the urine from the kidney to the bladder, in consequence of which this fluid accumulates behind the obstacle, gradually dilating the parts in which it is retained, and causing absorption of tissue by its compression. The obstacle may be due to a congenital malformation of the urethra, the ureter, the kidneys, or the renal artery, or, it may arise from the presence of a calculus, or other foreign body, in the ureter or other parts, occurring during life. It may also be produced, but generally in a minor degree, by compression of the ureters during pregnancy, by an ovarian enlargement, or by a cancerous or other pelvic growth. Congenital hydronephrosis is apt to be accompanied with malformations in other parts.

The *symptoms* of hydronephrosis vary according to its cause and the size of the sac or tumor. If but one kidney be affected, and

the cavity be small, there may be no symptoms whatever to indicate the lesion, or to shorten the duration of life. The healthy kidney enlarges, and compensates, by an increase of its secretory function, for the absence of this function in the opposite one.

When the hydronephrotic tumor becomes very large, it will be found located in the flank, from which point, according to its size, it may extend posteriorly to the lumbar vertebræ, superiorly into the hypochondrium, inferiorly into the iliac region, and anteriorly to the umbilicus; and as it encroaches upon these several regions, the small intestines, are forced to one side, and the tumor may be mistaken for some other malady, especially when its anterior projection is large and well marked. The colon generally remains in front of the enlargement. The tumor has a soft, undulating, and sometimes lobulated, feel, with more or less marked fluctuation, and is occasionally tender on pressure, but more generally there is no pain, the only annoyance being its size. And, should there at any time, from a dislodgement of the obstruction, be a sudden and copious flow of urine, the tumor will diminish in size or disappear altogether.

The bowels are usually irregular, being more commonly disposed to constipation. The urine is generally normal, occasionally containing a small quantity of pus. Should the obstacle be an impacted calculus, there will be symptoms of nephritic colic, with vomiting, retraction of the testicle, painful micturition, and the urine may contain blood. When both kidneys are affected, uremic symptoms may present themselves.

If the obstruction becomes dislodged, so that the fluid may be discharged, and the kidney has not become wholly obliterated, it may regain its functions, at least in part, provided there be no subsequent impediment with re-accumulation of fluid. If, however, the renal secreting tissue has, from long-continued pressure, been wholly or nearly absorbed, it will collapse into an empty pouch, after the fluid has been discharged. In these cases, the patient may live to old age, more especially if the healthy kidney remains free from any disease that will interfere with its function, or, death may result at any period from other diseases. Death from spontaneous rupture of the sac is rare; yet it may happen when the tumor is large, from pressure upon the thoracic organs, from exhausting suppuration or peritonitis following tapping, from compression of the digestive organs, from dysenteric diarrhea, and, in double hydronephrosis, from suppression of urine with uremic symptoms.

The *diagnosis* depends upon the detection of a fluctuating swelling in the renal region, without any symptoms of suppuration, and the diminution or disappearance of the swelling when an abundant

flow of urine occurs suddenly; in the absence of these symptoms the diagnosis is difficult. Hydronephrosis may be determined from an *ovarian cyst*, by the colon remaining in front of the tumor, and by percussion over the affected lumbar region yielding no intestinal resonance.

From *ascites* which yields a dullness on percussion, in *both* flanks; but when the hydronephrosis is double, dullness is also observed in both flanks,—yet by changing the patient's position, the fluid in ascites will be found to have changed its level; while in hydronephrosis the dullness is stationary no matter what posture may be assumed by the patient.

A *hydatid cyst* is rarely double, and its discrimination from hydronephrosis is difficult, if not impossible, unless some of the hydatid vesicles be found in the urine. The commemorative symptoms may afford some aid.

Circumscribed renal abscess has a more acute course, with pain and symptoms of suppuration. The same may be said of *perinephritic abscess*.

Pyonephrosis affects the system more severely, pus in quantity occurs at some time in the urine, with recurring attacks of rigors.

The *prognosis* is more favorable when but one kidney suffers, than when both are affected; though, a double hydronephrosis does not necessarily imply a speedy death, as, a patient may exist for years before the atrophy of the renal tissue becomes so great, or the uremic symptoms from suppression so severe, as to prove fatal.

The *post-mortem appearances* are, a more or less complete obliteration of the renal secreting tissue, with more or less distension of the kidney, the pelvis, and the ureter. The renal sac may be composed of one single cavity, or it may be divided into two or more chambers, separated from each other by strong membranous septa. When the renal tissue has not become wholly absorbed, the effects of the urinary compression may be noticed in the flattened and more or less atrophied condition of the papillæ, the pyramidal bodies, and the gradually diminished cortical tissue. If one kidney only is obliterated, the other will, if healthy, be found more or less enlarged.

The fluid contained in the hydronephrotic cysts is generally urine, more watery than natural, more or less albuminous, and variously colored by blood, pus, and epithelium; urea, uric acid, and other urinary deposits may also be present. In rare cases, the cysts have contained a gelatinous substance resembling colloid matter. In one case thirty gallons of fluid were removed from the cyst; and in another, sixty pounds,—but these cases of enormous distension are not common.

The *treatment* consists in endeavoring to remove the obstruction, or, if this can not be done, to favor the flow of urine past the impediment. For this purpose, the renal tumor should be carefully shampooed and manipulated in every direction, applying some oil or ointment to the surface to prevent irritation or abrasion; and repeating these operations every day or two, and continuing it until the swelling subsides immediately after the sudden evacuation of a large amount of urine. If but one kidney be affected, and, from the presence of nephritic colic, etc., we believe the obstacle to be an impacted calculus, means should be employed to prevent a similar attack on the opposite side, by measures adapted to overcome the peculiar calculous character of the urine. Much animal diet should be avoided in these latter cases, and the urine should be kept well diluted by the free and systematic use of fluids, especially decoctions or infusions of agents that will exert a sanative influence upon the condition of the urine. (*See Gravel.*)

In the case of failure by these means, we are not justified in any more severe measures, until the size of the tumor becomes so enormous, as to threaten danger from its compression upon vital parts, or by obstructing circulation, etc., when we may discharge more or less of the fluid by tapping, bearing in mind, however, the serious consequences that may follow this operation, heretofore referred to. The point preferred for the introduction of the trocar, is in front, near the anterior extremities of the two last (floating) ribs, directing its point somewhat forward,—thus avoiding any danger of wounding the kidney, the peritoneum, or, the intestines. An exploring trocar should first be passed, to ascertain whether any fluid be present. If no untoward symptoms follow the operation, life may thus be prolonged for some time.

TUBERCULAR OR SCROFULOUS DISEASE OF THE KIDNEY.

Tubercular deposits in the kidney are occasionally met with, more especially among tuberculous children, and, heretofore, according to statistics by Rilliet and Barthez, in the proportion of about one in seven, or, about one in twenty-one among tuberculous adults. In the Pathological Institution of Prague, it was found to occur in the proportion of about one in nineteen, including children and adults. Rayer believes the disease to be more common during middle life, than in childhood or old age. The affection may be *primary*, and located principally in the kidney and its appendages; or, as is more frequently the case, it may be *secondary*, or associated with and dependent upon a general tuberculous disposition. The

disease is almost invariably met with in persons disposed to scrofula or tubercle, but its direct exciting *cause* is not satisfactorily known, though cold, and renal inflammation have been named as among these causes. Both kidneys are more apt to be implicated; and one case has been recorded in which the tumor formed by the disease, occupied the whole side of the abdomen,—but this can only happen when there is an obstruction in one or both ureters. The disease may terminate fatally in a few months, or, not until two or three years have passed.

It is very difficult, if not impossible, to positively detect renal tuberculous disease during life, and more especially when it is present in the secondary form; in most cases, the *symptoms* observed are those of chronic pyelitis, and which are often complicated with those of chronic cystitis. More commonly, when symptoms are observed, dull pain or tenderness in the lumbar region of one or both sides is complained of, the urine being turbid and often containing some blood; as the disease progresses, emaciation and hectic symptoms manifest themselves, the same as when other organs suffer from tubercle. If the disease be associated with a general tuberculous disposition, evidences of this tendency, will sooner or later be observed, by symptoms of tubercle in the lungs, intestines, or other organs. If the bladder becomes involved in the affection, there will be pain and tenderness in the region of this organ, with frequent and painful micturition, and other symptoms of chronic cystitis. When, from any cause, as for instance, an obstructed ureter, the urine accumulates in the pelvis and calyces, the kidney becomes dilated, forming a more or less painful multilocular sac or tumor, which may frequently be detected by palpation and percussion of the abdomen, and of the flank; as soon as the obstacle in the ureter becomes removed, the urine suddenly flows freely, the tumor diminishes, and is less painful. The tuberculous matter may be discharged through the ureter into the bladder, or, it may likewise form a communication with the rectum, vagina, peritoneal sac, or with the external surface in the lumbar region.

The primary form of the disease can only be suspected, after the tuberculous deposits have softened, when an abundance of pus-corpuscles will be found in the urine, mixed with a quantity of amorphous granular organic matter insoluble in acetic acid, broken masses of softened tubercle, shreds of connective tissue and meshes of elastic fibres, and sometimes blood. If the bladder be involved, shreds of mucous membrane will also be observed, with epithelium from the bladder, ureter, pelvis, etc. The albuminous condition

of the urine, which fluid is more commonly of a feebly acid reaction, is proportioned to the amount of pus present. Tube-casts are rarely found in the urine. In severe cases, the urine is scanty, of a brown or smoky color, and its sediment reddish-brown. The above symptoms, conjoined with a distinctly marked tuberculous diathesis afford pretty conclusive evidence of secondary renal tuberculous degeneration; but, if this diathesis be absent, we can only suspect the existence of the primary form of the disease.

The *prognosis* is unfavorable,—and much more so, when the already serious renal malady is associated with tuberculous disease in other organs. When but one kidney is affected, and especially in the primary form of the disease, the renal appendages not being involved, recovery may possibly occur. If both kidneys are involved, death may ensue from uremic poisoning, but at all events, recovery can not take place. Generally, in the primary form, the exhaustion consequent upon the abundant suppuration is the immediate cause of death.

The *pathological appearances* are, tubercles in some portion of the kidney, or throughout its entire tissues, varying from a very minute size to that of a cherry, or, they may coalesce, and form large crude tubercular masses, composed of amorphous, finely granular matter. Fragments of uriniferous tubes may also be observed in the midst of this matter, and the neighboring tubes will present more or less unhealthy appearances under the microscope. Subsequently these firm tubercles soften, and form larger or smaller abscesses in various parts of the organ, which may sometimes coalesce and form one large cavity. The granular-tuberculous softened material rarely contains any well-defined pus-corpuscles. Not only may a less or greater part of the kidney be destroyed by the disease, but the pelvis, infundibula, ureter, bladder, prostate, and other parts may also be found more or less involved in the general renal degeneration. The kidney retains its normal size, or may even be contracted, unless there be an impediment to the free passage of the urine, pus, and tubercular debris.

The *treatment* is the same as that ordinarily pursued for tubercle in other organs. (*See Scrofula, Tubercular Meningitis, White Swelling, Consumption, etc.*) Every means should be pursued to strengthen and nourish the system by nutritive diet, a moderate allowance of stimulants, and a general attention to hygienic measures. Of course, we must be governed by the influence that all these means exert upon the patient, avoiding whatever appears to be useless, injurious, or debilitating. Tincture of Chloride of Iron in doses of fifteen or twenty drops, three times a day, will often

lessen the abundant secretion of pus. Severe pain in the renal region may be mitigated by warm anodyne fomentations over the renal region, warm bath, and opiates; and other urgent symptoms must be promptly met with appropriate treatment.

CANCER OF THE KIDNEY.

Cancer of the Kidney is likewise a disease not frequently encountered. It may be *primary*, confined to the kidney; or, as more frequently observed, it may be *secondary*, or associated with cancer in other parts. The most usual variety of cancer met with in the kidney, is the encephaloid (*fungus hæmatodes*); scirrhus is very rarely observed, as well as colloid and epithelioma. The disease, the same as with most other forms of renal degeneration, generally begins in the cortical substance,—subsequently involving the medullary cones, and, perhaps, the walls of the pelvis, and the ureters. The disease sometimes assumes the nodular form, at others, the infiltrated; the former is more apt to produce irregularity in the shape and position of the affected organ than the latter. No period of life is exempt from the disease, though aged persons are the most liable to it; it has also been stated that children under four years of age are greatly liable to it. The disease may terminate fatally in a few weeks or months, or it may continue three or four years before death ensues. The *cause* of cancer is not yet known.

The *symptoms* of cancer of the kidney are rarely observable until the disease is somewhat advanced. More or less deep-seated severe pain is experienced in the hypochondrium and loin, frequently on both sides, shooting along the course of the ureter to the inside of the thigh, and without any retraction of the testicle; yet frequently pain is absent for a long period even after the tumor is observed. As the disease advances derangement of the digestive organs ensues, as, nausea, vomiting, anorexia, and flatulency. The skin assumes the pale-yellow tint peculiar to the cancerous cachexia, emaciation rapidly occurs, with debility, and frequently an œdematous condition of the legs, which may ultimately become general. There may be an obstinate diarrhea, or constipation, or, these may alternate. Death may occur from exhaustion, from uremia owing to obstruction of the ureters by coagulated blood, or, from a sudden bursting of the tumor.

Renal cancer, however, may be more readily detected at an advanced stage, by the presence of a tumor in the abdomen, and blood in the urine. The tumor will first be observed in the anterior

lumbar region, between the borders of the crista ili and the ribs; as it increases in size it advances forward toward the umbilicus, upward into the hypochondriac region, and downward into the iliac and inguinal regions, occasionally occupying the whole abdomen. The colon, as in most renal tumors, lies in front of it; and percussion over the tumor elicits dullness, except over the colon,—unless this intestine be flattened between the tumor and the abdominal wall. Palpation detects a soft, smooth, or irregularly-lobulated surface, with rounded obtuse margins, the lobulations being of unequal hardness and sometimes yielding a deceptive sense of fluctuation.

Hematuria is another important symptom, though, it must be remembered that a renal calculus may occasion it; and again, that cancer may exist without any blood being discharged, until near the fatal termination, even though a tumor has been known to exist for a long time. The hematuria usually manifests itself without any apparent cause, is moderate or profuse, and comes on frequently, at irregular intervals. When excessive, the usual constitutional symptoms of loss of blood are observed. Coagula are often formed in the ureters and in the bladder, causing much irritability and suffering. Albumen is always present in proportion to the amount of blood in the urine; and epithelium from the ureter and renal pelvis will not unfrequently be observed along with the blood. If portions of the encephaloid pulp be detected, the diagnosis would then be positive. The hemorrhage, presence of tumor, and other symptoms, together with the general history and condition of the patient, must all be carefully considered. Cancer in some other organ will materially aid us in our diagnosis.

From the difficulty of positive *diagnosis* in renal cancer, it has been frequently confounded with other enlargements, as, of the liver, spleen, ovary, and uterus, also with ascites, aortic abscess, renal hydatids, hydronephrosis, etc.—In the determination of cancer, we must at first be fully assured that renal calculus does not exist, nor urethral stricture, nor prostatic enlargement, and that the lungs are wholly free from tuberculous disease. These having been satisfactorily determined, then, in addition to what has already been stated, we will derive valuable aid from a knowledge of the following points:

Renal cancer, when the tumor is on the right side, may be distinguished from *enlarged liver*, by its seldom rising as high in the chest as the latter does, and by the possibility in many cases of tracing its upper borders below the costal margins, also by the well-defined lower edge of the liver being readily detected. A moderate-size renal tumor will almost always be found located in a plane below

the liver. Hepatic tumors rarely have any intestine in front of them, and always yield a dullness over their entire surface when percussed; a renal tumor has the ascending colon in front of it, passing from below upward, and obliquely from right to left, and over this intestine percussion will elicit a more or less clear tympanitic sound,—flatus may also be detected passing along the gut. When there exists a morbid adhesion between the renal and hepatic tumors, or, when the right lobe of the liver becomes displaced by the advancing renal tumor, the diagnosis becomes more difficult. But the position of the colon in front of the tumor, the detection of the thin margin of the liver as it lies applied to the wall of the abdomen, and the fact that an enlarged liver frequently rises very high in the chest, may aid us materially.

In cancer, there is a peculiar leaden or sallow appearance of the skin; in liver disease, the skin has more of a yellowish hue, the conjunctiva is yellowish, and bile may frequently be detected in the urine. If *ascites* be present, it is still further indicative of hepatic disease. In ascites, both flanks are dull on percussion; in renal tumor, one is dull, and the other resonant, unless the tumor occupies the entire abdomen.

An *enlargement of the spleen* extends more forward and upward into the chest, in proportion to its backward direction, than a renal tumor; the descending colon in front of the splenic tumor is absent; its borders are rigid, thin, and not rounded; it is very movable; its direction is downward and inward to the epigastrium and umbilicus, and not toward the iliac fossa. A leucocythematous condition of the blood may be observed under the microscope; or, there may have previously existed intermittent or remittent fever, or, an impediment to the circulation in the heart, lungs, or liver.

An *ovarian tumor* begins in the iliac fossa, and ascends, while a renal tumor commences in the flank, between the crest of the ilium and ribs, and descends. In ovarian tumor there is no bowel in front of it; it is movable; can generally be detected by examination per rectum; an examination per vaginum will manifest its connection with the uterus; it yields a dullness in front with a resonance on either side of it, or in the lumbar region at the point where dullness exists when the tumor is renal,—and this sign will also serve to determine *uterine enlargements* from renal.

Acephalocyst hydatids in the kidney, can only be positively known by the presence of some of the hydatids in the urine. The hydatid tumor yields a *frémissement*, a vibration or trembling, when palpated or percussed, and, not unfrequently, there is a discharge from the urethra, of a greenish, pus-like fluid.

Having determined the renal character of the tumor, the next thing will be to ascertain its malignant or non-malignant nature. The symptoms of renal cancer, made known above, will aid in determining the former, taken in connection with an absence of those indicating kidney enlargement from other causes.

The *prognosis* of cancer of the kidney is always unfavorable, the disease generally proving fatal in from two to ten months. Where there is much severe pain and profuse hemorrhage, it runs its course rapidly.

The *post-mortem appearances* show that, as in most other forms of renal degeneration, the cortical substance is the first attacked, and then the pyramids, etc. There may be an extensive tumor, with more or less irregularity in the shape of the kidney, or this organ may not have undergone much change in its form or size; the tumor will generally be found to have contracted adhesions with neighboring tissues, and, according to its size, to have displaced other of the abdominal organs. The disease may be confined to only parts of the kidney, or the whole of this organ may be involved, having its form and structure completely destroyed. The cancerous parts of the organ will be found to vary greatly in consistence and vascularity, being hard at first, then soft, or about as hard as human brain, smooth or more commonly irregularly lobulated, and cavities will often be found containing cancerous detritus and fluid or clotted blood. The tunica propria is usually thickened, and the lymphatic glands, blood-vessels, etc., of the kidney will be found to have suffered more or less from the disease. In most cases, the ureter will be found permanently obstructed from compression of the tumor, from an extension of the malignant tumor into it, or from the presence of impacted coagula of blood. More commonly but one kidney is affected, especially the right.

The *treatment* consists in sustaining the patient's strength, and relieving urgent symptoms. Good nutritious food, easy of digestion, with tonics, especially preparations of iron, are indicated. It is useless to punish the patient's stomach with specific remedies against cancer, they will prove useless; though, Hyposulphite of Lime, or of Soda may be employed, without any injury to the gastric organ. This, or some other harmless tonic and alterative, may be used as a placebo, to divert the patient's mind, and sustain his spirits, as there is almost invariably an injurious amount of mental and physical depression when the character of the malady is known by him. Severe pain may be relieved by opiates; Belladonna; anodyne plasters, fomentations, or applications of Chloroform across the loins; warm hip baths; and mild counter-irritants. Profuse

hemorrhage may be controlled by the internal use of Tincture of Chloride of Iron, Solution of Perchloride of Iron, Gallic Acid, Gallic Acid and Oil of Erigeron, and other astringents; and, sometimes, pounded ice applied, in a bladder, to the loins has proved serviceable. Retention of urine is frequently caused by the urethra being obstructed with blood-coagula, fibrinous clots, etc., giving rise to great suffering; these obstructions should be pushed back into the bladder by means of a catheter, and then be broken down and washed out from the bladder by injections of warm water. Febrile symptoms may be removed by the Compound Powder of Ipecacuanha and Opium, Compound Tincture of Virginia Snakeroot, and, in some cases, Tincture of Aconite.

RENAL CALCULI.

Calculi in the Kidney or Ureter are not unfrequently a mechanical cause of renal disease. There may only be one calculus present, or there may be two or four hundred, or more; they may vary in size from that of a small pinhead to a large bean, and, in the pelvis, they have been found so large as to weigh even three or four ounces; and great diversity will also be found in their shape. Various changes may be effected in the renal tissue by the presence of these concretions, according to their number, size, and position; as, pyelitis, abscesses, pyonephrosis, and hydronephrosis, all of which have already been treated upon. The varieties of renal calculus are more commonly met with in the following order: 1st. Those which are composed of *uric acid*, and which may appear at any age, but more commonly after middle life, and especially among the gouty, and those who indulge in beer, porter, wine, etc. 2nd. Those consisting of *oxalate of lime*, also termed, from their external appearance, "mulberry calculi," and which are usually associated with dyspeptic symptoms. 3rd. *Phosphatic*, and *cystic oxide* renal calculi, are rarely observed.

The *symptoms* of calculi in the kidney, are, a more or less severe pain in the region of the affected kidney, sometimes amounting to severe paroxysms of nephritic colic. The pain is usually constant, and is ordinarily attended with a sensation of burning heat in the painful part. Sometimes the pain is of an intermittent character, appearing especially after considerable exercise; indeed, in any case, exercise greatly increases the pain. Pressure over the painful part, in some cases occasions much tenderness; in other instances, considerable relief is obtained by a firm and moderate pressure upon the part. In very rare cases, no pain has been felt. The oxalate of

lime concretions usually occasion more pain than those of uric acid; and the pain is also apt to be more considerable in organic lesion of the kidney than when the organ is healthy.—The pain frequently shoots along the course of the ureter, down to the testicle, of the same side, which is often retracted, and sometimes more or less painful and swollen. Pain, or a sense of numbness, is also frequently experienced along the front and inside of the thigh. A feeling of faintness, with nausea and vomiting, are by no means uncommon attendants.—Urination is frequent, and the patient often complains of pain at the end of the penis; the urine will more or less frequently be found to contain blood, pus, and epithelium from the renal pelvis. The hematuria may be absent in a very few exceptional cases, but its presence is the rule; it may be constant, or appear at intervals, and is apt to be more frequent and profuse in the rough, irregular mulberry calculi,—and is always brought on or increased by active exercise, sudden jolts, etc.

The painful, colicky attacks are generally owing to the passage of one (or more) of these concretions from one of the infundibula into the cavity of the renal pelvis, or from one part of the pelvis to another. But its impaction in, or descent along the ureter, is usually attended with the greatest amount of suffering, especially if it be large enough in the latter case, to come in contact with the walls of the ureter, or to distend it. An acute pain in the region of the affected kidney, is suddenly experienced, which shoots in various directions, but principally along the ureter to the groin, end of the penis, and the testicle, which latter is retracted or drawn upward by spasmodic contraction of the cremaster muscle. The pain is accompanied with a sense of deadly faintness, nausea, vomiting, feeble pulse, pale countenance, coldness of the extremities, and other symptoms of collapse, and sometimes epileptiform convulsions. There is a constant desire to urinate, the urine may be wholly suppressed, or be voided scantily or in drops, with burning pain, high color, and often mixed with blood. All these symptoms will continue, until the calculus passes into the bladder, when relief at once ensues,—and this may happen in a few minutes or hours, or not for several hours; when of long continuance, more or less severe febrile symptoms are apt to appear. Generally, a sense of soreness remains for a time after the escape of the calculus, and sometimes, in severe cases, swelling and inflammation of the testicle. If the ureter is obstructed by impaction of the concretion, the symptoms yield less rapidly and less permanently to treatment, and one of the forms of renal disease already

referred to may be induced, and prove fatal with or without uremic symptoms.

In forming a *diagnosis*, the urine should be examined both chemically and microscopically, to determine its acidity or alkalinity, and the character of the crystalline sediments that may occur in it; though, in some instances, the urine may not deposit any sediment. The character of the crystalline deposits, when present, are almost always the same as those of the renal calculi. Besides uric acid crystals, oxalate of lime dumb-bells, etc., the urine usually contains blood, and irregular, caudate, fusiform, etc., epithelial cells from the renal pelvis, ureter, etc. In some other renal affections the blood is moulded in the form of tubes, but in the present, it is in the form of disks scattered throughout the urine. In some cases, it will be impossible to accurately determine the nature of the affection, until the appearance of coagula, hydatids, or calculi in the urine solve the question. The previous history of the patient, taken in connexion with the result of repeated urinary examinations, the locality and extent of the pain, its recurrence in paroxysms, the presence of its usual attending symptoms, (nausea, vomiting, etc.), and the fact that exercise increases the severity of the symptoms, while rest diminishes them, will generally enable us to form a correct diagnosis.

The *prognosis* in renal calculi is by no means an easy matter, as it depends entirely upon the condition of the renal urinary passages, and the size of the stone. If the calculus passes into the bladder, there is an end to anxiety; but if the calculus be very large, occasioning violent, obstinate, and long-continued suffering, everything depends upon its ultimate descent into the bladder. If it becomes impacted, it may present a partial or complete obstruction to the flow of urine,—the patient may die from pain, from the sudden call for double duty upon the healthy kidney, or, at a later period, from the consequent production of one of the renal organic lesions heretofore referred to. If both kidneys are involved the prognosis is grave. Oxalate of lime calculi, are less apt to recur a second time, being usually met with single; while those of uric acid are more apt to form in numbers, and to present themselves at various periods.

The *treatment* of renal calculus is, firstly, to relieve the severe suffering of the patient during a paroxysm; secondly, to favor the removal of the concretions; and thirdly, to prevent their subsequent re-formation. To fulfill the first and second indications, the patient should be placed in a warm bath, and be allowed to remain there until some faintness is induced, which aids in the relaxation

of the spasm, of the ureter, and thus favors the passage of the stone, at the same time, lessening the pain. I have effected a similar object, by injections into the rectum of equal parts of warm Water and Compound Tincture of Lobelia and Capsicum, and the internal use of Tincture of Gelsemium, given so as to produce its relaxing effects. Some have advised Chloroform internally, in doses of ten or twenty drops, every half hour or hour; or else, to keep the patient in a state of partial anæsthesia, by causing him to inhale it, until the stone has passed,—but, this would hardly answer in cases where several days are required for this passage of the calculus, and especially in cases where it was impacted, cases which we can not positively determine beforehand. Hence, after using chloroform for a reasonable time without any desirable relief, its farther use should be dispensed with; or, as with the Gelsemium, it may be employed intermittingly.—Opium has been highly recommended as an internal remedy, or, by injection with warm water when the stomach rejects it, for relief of the pain, and is usually administered in full doses, frequently repeated until the system becomes fairly influenced by it. In case it disagrees, Extract of Belladonna may be substituted for it. The urinary secretion should be favored by a free use of warm demulcent diuretic drinks. And hot poultices of Stramonium, Lobelia, and Hops, or, of pounded Garlicks or Onions, should be applied to the loins or abdomen, as the local symptoms indicate. Not unfrequently a change in the patient's position will afford relief; and manipulating or shampooing the abdomen along the course of the ureters, has been known to facilitate the descent of the calculus.

After the attack has passed, we must endeavor to prevent the subsequent formation of more calculi, by the means pointed out under Gravel, *which see*. Any renal lesion that may remain, must be treated by the appropriate means therefor.—When a renal abscess is formed and points toward the loins, it has been advised to open it and remove any calculi that may be detected by a careful exploration, by means of suitable instruments; and instances of this operation having been successfully performed are on record.

HEMATURIA.

Hematuria or Hemorrhage from the Kidney, may occur as a primary, or as a secondary affection; in the first instance being unaccompanied with any other evidence of disease; in the second, being manifested only as a symptom of some renal disease or injury. The

presence of the blood in the urine, colors this latter fluid from a barely perceptible reddish-smoky tint to a deep port-wine color, according to the quantity of blood discharged; and the urine will be found more or less albuminous, according to the amount of blood present. Sometimes, from the abundance of the hemorrhage, coagula will be observed. It must be recollected that certain articles of medicine and food impart a bloody aspect to the urine, as, madder, cochineal, red beets, etc.; it also has a dense reddish color in several forms of disease, with a considerable deposit on standing; and, it is also apt to be bloody, during menstruation, and vaginal or uterine hemorrhage. Bloody urine imparts a red stain to linen; high-colored urine does not. The only certain method of detecting blood in the urine, is by a microscopical examination, which will show us the corpuscles; but, as the presence of ammonia in the urine, a low specific gravity of this fluid, or its retention for several days, may occasion a disappearance of the blood-corpuscles, or a non-recognizable change in their form, the urine should always be examined as soon as it has been voided. As a general rule, blood is more common in the urine during acute renal maladies, and much less so during the chronic; and mostly occurs in the form of "blood-casts," the blood having been moulded in the uriniferous tubes, and mixed with epithelial-casts.

Hematuria may be owing to a variety of causes, the principal of which will be found included in the following classification: 1. *Local causes.* These are, exposure to cold and moisture; use of stimulating diuretics, as, oil of turpentine; cantharides, etc.; falls or blows upon the loins; violent exercise; calculous formations; ulcers; abscesses; tubercle; parasites; cancer; active or passive congestion; and Bright's disease.—2. *Symptomatic, or Secondary.* From a morbid condition of the blood, in which its presence in the urine is an unfavorable symptom, as, in purpura hemorrhagica; scurvy; cholera; intermittent fever; continued fever; exanthema; excessive and continued mental emotion, etc.—3. *Vicarious, or supplementary to menstruation; hemorrhoids; asthma.* And sometimes cases will be met with in which there will be no known attributable cause for the hemorrhage. A dark-colored blood in the urine, mixed with putrid offensive matters, is indicative of a malignant affection, and will prove fatal.

With those cases of hematuria due to active hyperemia of the kidney from the use of turpentine or cantharides; and to malignant acute maladies, we have nothing to do in this work, and shall simply consider this symptom in its connection with such maladies as may be presented to the specialist in chronic diseases.

The important point in hematuria, is, to determine the exact source of the blood; and this is not generally a difficult matter. If the blood proceed from the *substance of the kidney*, as in injuries, renal congestion, Bright's disease, etc., tube-casts will always be observed in the urinary deposit, together with tubular blood-casts; and symptoms of renal disease will likewise usually be present. If the hemorrhage is profuse, and recurs frequently, and a tumor be detected in the loins, it is due to renal cancer. In abscess, renal embolism, hydatids, and tubercle, no great amount of hemorrhage is apt to occur.

If the blood proceed from the *pelvis of the kidney and ureters*, it is more usually the result of calculous formations; occasionally, of cancer, tubercle, and parasites. Epithelium of the pelvis and ureters may be found in the deposit, and should the blood coagulate in the ureter, these clots when found in the urine will present a long, worm-like appearance. The presence of pain (nephritic colic) from the passage of the calculus, or of the clots, will aid in the diagnosis.

If the blood proceed from the *bladder*, there are no renal tube-casts, nor blood-casts present, and the symptoms are entirely those of the bladder, as, dull pain in the region of this organ, sometimes accompanied with painful erections, and considerable heat in the glans-penis, there is a frequent desire to urinate, with more or less pain at the neck of the bladder, the color of the urine is pinkish or vermillion, and the blood is more apt to be in small flaky clots and does not mix intimately with the urine. The urine is apt to be ammoniacal, with much tenacious mucus, and phosphatic deposits in those cases in which the constitution is enfeebled. Vesical hemorrhage may be due to stone in the bladder, to prostatic fungoid disease, to cancerous ulceration of the bladder, to varicose enlargement of the veins of the mucous membrane of the bladder, and to inflammation of this organ from urethral stricture or other cause.

If the blood proceed from the *urethra* it is passed in drops, or in a small stream, and escapes during the intervals between urination. And there may also be a soreness at the point from which it issues.

The *prognosis* of hemorrhage will greatly depend upon the *profuse character* of the discharge, its duration and amenability to treatment, its *source*, and the accompanying symptoms. It is unfavorable when due to a calculus, to lesions of degeneration, malignant affections, or, when very profuse, in which latter instance the patient may die from the resulting debility and exhaustion. When not profuse, and the affections, just referred to are not present, it is more favorable. Hemorrhage from the renal substance is

always of serious import, and especially when it is long continued, recurs frequently, and is accompanied with tube-casts.—It must not be forgotten that coagula remaining in the pelvis of the kidney, or in the bladder, may become nuclei for subsequent calculous formations.

The *post-mortem* appearances will be those already alluded to under the head of the particular disease that may give rise to the bleeding. If the hemorrhage be primary, or vicarious, no lesion of the lining mucous membrane of the urinary passages will be observed.

The *treatment* of hematuria will depend, in a great degree, upon its causes, or the conditions under which it appears. When it occurs as a symptom of acute renal disease, astringents internally are rarely necessary; rest and quiet, with counter-irritation over the loins, and Tincture of Veratrum, of Digitalis, or, of Black Cohosh and Aconite internally, will most commonly be found sufficient. Warm anodyne poultices over the region of the kidney have frequently proved beneficial; and so likewise has a cold wet bandage applied around the loins and abdomen, and then covered with warm, dry blankets. It is only when the hemorrhage is so profuse, in these acute cases, as to threaten life, that astringents will be required.

If the hemorrhage be due to the action of irritants (turpentine, catharides), it is best relieved by the free use of diluents, and a dose of Castor Oil to remove any morbid or irritating accumulations in the intestines. A cold infusion of Marsh Mallow Root and Cleavers may be drank freely; and to lessen pain or febrile action, a dose of the Compound Tincture of Virginia Snakeroot may be administered whenever required. Warm anodyne poultices over the renal region, as, of equal parts of Stramonium Leaves, Hops, and Lobelia, will often prove useful, in addition to the other measures.

If the bleeding be the result of violence, (blows on the loins), the patient should be kept in a state of quiet in bed; leeches or cupping over the loins, followed by hot anodyne poultices, will frequently be found useful; and, if the patient be of full habits, a cathartic may be administered every two or three days, as a derivative to relieve any tendency to congestion. The skin should be kept warm, and the diet be moderate and composed of very digestive articles. Unless the discharge be very profuse, astringents will not be needed. Great prostration may be overcome by small doses of brandy, of Carbonate of Ammonia, or, in many cases, the Compound Tincture of Virginia Snakeroot. As the hemorrhages are apt to return, in these cases, at longer or

shorter intervals, and often from very slight causes, a Compound Tar Plaster worn intermittingly over the region of the kidneys, keeping up the discharge for a considerable time on each application, will be apt to overcome or greatly diminish this tendency, as well as to lessen the chances for any subsequent renal organic lesion, and, especially, if appropriate alteratives be used in conjunction therewith. If the hemorrhage be due to renal calculi similar measures, conjoined with those advised for calculi, will be required.

If the hematuria be vicarious, we must endeavor to restore the original discharge by appropriate measures, and at the same time guard against a too abundant flow.—When the bleeding is periodical, or connected with malarial influence, Sulphate of Quinia; Tincture of Muriate of Iron; Black Cohosh, Geranium, and Quinia; or the mineral acids (White Liquid Physic), will prove serviceable.—When the hematuria is passive, of a secondary character, and not associated with Bright's disease, the mineral acids, especially Sulphuric Acid; Tincture of Muriate of Iron; or Oil of Turpentine in doses of ten or twenty drops every two or three hours, will be of great efficacy, aided by rest and dry cupping over the loins.

When, in any of the above varieties, with the exception of passive hematuria, the flow of blood is abundant, astringents will be required; those which have been found the most serviceable, are, Gallic Acid; solution of Alum; infusion of Beth Root, of Geranium, of Rhatany, of Logwood, or of Matico, etc.; Oil of Erigeron; Oil of Erechthites, etc.

When the hemorrhage is from the bladder, a strong infusion of Peach Leaves and Trailing Arbutus, equal parts, may be used freely with advantage; if much mucus be deposited, Uva Ursi may be employed; if pus, Peach Leaves and Pareira Brava; the Compound Infusion of Trailing Arbutus may also be advantageously used, in all these instances, as well as in the several forms of renal hemorrhage. Ice-cold water, or ice introduced into the rectum, has been highly recommended in cases where active hyperemia exists, and may prove serviceable, however, I have never used it. But injections of mild astringent infusions into the bladder are always useful, as, a solution of Alum (twenty to forty grains to the pint of water), or, infusions of one of the above-named vegetable astringents.—If clots form in the bladder, or if this organ becomes so distended, that neither the urine nor blood can be voided, a catheter with a large eye should be introduced into the bladder, and an injection of cool water, or some cool astringent solution be made, and be repeated several times per day, in order

to break down and remove the clots; and this course may also be pursued when the hemorrhage is of renal origin.—Whenever painful erections occur, the application of cold water to the parts will afford relief.

In order to prevent future attacks of hemorrhage, the cause must be removed by appropriate treatment, whatever it may be, as, stricture, prostatic disease, disease of the bladder, the kidneys, the blood, etc.

There are some other abnormal conditions of the kidneys that require a passing notice, the principal among which are the following:

Parasites or Entozoa in the Kidney, are occasionally met with. The one more frequently met with in the northern temperate latitudes, is the *Echinococcus hominis*; this hydatid has recently been found to constitute the *encysted phase* in the development of a very minute tape-worm (*Fenia echinococcus*), which infests the dog, pig, monkey, sheep, and ox. In certain hot climates, another entozoon, (the *Bilharzia Hæmatobia*), is often encountered not only in the kidneys, but also in the branches of the portal system, the minute pelvic veins, etc. When existing in the urinary organs, it gives rise to hematuria, hydronephrosis, pyelitis, etc.—The *Pentastoma Denticulatum*, and the *Strongylus Gigas*, are also occasionally observed in the kidneys, as well as intestinal worms, and spurious worms.

The left kidney appears to be more frequently the seat of hydatids, and males more subject to them than females. They are more common with those who are much among dogs, who use meats rare or underdone, and are especially common among the Icelanders. The hydatid is contained in a cyst formed in the renal substance, which grows in size, frequently forming adhesions, or causing inflammation and abscess. The parent cyst may burst spontaneously, or, more usually, from some external violence to the lumbar region; it usually contains numerous secondary cysts.

The *symptoms* of hydatids are an enlargement in the flank, round, of an elastic sensation, more or less fluctuating, and, on percussion, yielding a peculiar thrill or fremitus, resembling the vibrations of a repeater watch held in the hand. Pain may or may not be present; but is more apt to exist in the loin, shooting along the course of the ureter to the thigh, at the period when the cyst ruptures, and the inclosed hydatids escape by the urethra. There may likewise be, at this time, symptoms of irritability of

the bladder, retention of urine, with blood or pus in this fluid.—The urine presents its usual characters until the cyst ruptures.

The *diagnosis* of hydatids is not always easy; the tumor in the flank may be confounded with hydronephrosis, or other renal disease. The diagnosis is still more difficult when no tumor can be discovered. When the hydatid vesicles are discharged per urethra, either entire or in fragments, the diagnosis is positive, and, in such cases, should a tumor have been detected in the loin, it may decrease in size, or wholly disappear. It is very rare that hydatids exist in any of the lower urinary passages.

The *prognosis* is much more favorable in those cases where hydatids are passed, without any tumor having been observed in the abdomen. And generally speaking, renal hydatids produce much less serious mischief than hydatids in other organs, excepting the uterus; and this is due to the facility by which they may be discharged through the urinary passages.—A discharge of hydatids may be followed by similar subsequent discharges, but the longer the intervals between these attacks, the less likely are they to recur. Hydatids may be passed for one, two, ten, or thirty years, and then the patient recover; indeed this is the more frequent termination.

The *treatment* consists in destroying the parasite, when the cyst more readily undergoes rupturing. Various means have been advised for this purpose, as, the administration of Oil of Turpentine; Ethereal Oil of Male Fern; Hyposulphite of Potassa, or of Soda; Iodide of Potassium; and Nitrate of Potassa in doses of twenty grains in some diuretic infusion. Phenol Sodique has also been highly recommended, to be taken internally, diluted. Tobacco poultices applied over the region of the kidney, answer a very good purpose, in cases where they are not followed by too much nausea or prostration; they appear to promptly destroy the parasite.—Any painful symptoms must be relieved by the measures heretofore advised, when similar symptoms are present in other organs.—When the tumor formed by the cyst is so large, as to exert dangerous pressure on the organs of the chest, or, when it tends to rupture in some unfavorable direction, it has been advised to puncture it either through the flank, or, through the abdomen, and thus evacuate its contents. This operation is always a dangerous one, and should be performed with much caution. After the evacuation of the fluid, the cavity or cyst may be injected with solutions of iodine; or, a solution of Chlorinated Soda should an offensive odor exist.

Cysts are met with in the kidneys, either scattered throughout the otherwise healthy organs, disseminated in the atrophic form of Bright's disease, or, existing in what has been termed *Cystic Degeneration of the Kidneys*, which degeneration may also be congenital. These cysts vary in size from that of a small pin head to that of a walnut, though they may be larger than this, or even so minute as to require the microscope for their detection. They may be of various shapes, as, round, elongated, irregular, etc., and are usually filled with an aqueous, albuminous, saline, or gelatinous fluid, of a yellowish or yellowish-green color, and sometimes quite clear.

Their *causes* are unknown, although in the congenital cases, there is almost always some co-existing malformations of some part of the urinary organs, or in some other part of the body. By some these cysts have been considered as being at first obstructed and dilated Malpighian capsules, and, by others, as being formed by dilatations of sections of the uriniferous tubes, and occlusion and atrophy of the intermediate tissues.

The *symptoms* are only present in cases where the tumors formed by the cysts are very large, or where there is degeneration of the kidneys, and are similar to those of other renal affections, as, more or less severe pains in the loins, profuse urination, symptoms of great gastric derangement, debility, albuminaria, hematuria, uremia, etc. In long-standing cases there is almost invariably a low specific gravity of the urine. In some cases, when the cysts are of enormous size, a tumor may be detected, the same as in renal tumors from other lesions; and in these cases, as the disease progresses, the ducts of the pyramids become occluded by coagula, or, perhaps, from inflammatory adhesion of their walls, and the tubes of the cortex become formed into saccular dilatations, with more or less numerous cysts. In some parts of the kidney, all traces of the proper tissue of the organ have disappeared. It is very difficult to *diagnose* this malady during life; and the *treatment* is merely of a palliative character; puncturing the cyst, when the tumor formed by it becomes so large as to threaten life. It appears to prove ultimately fatal by convulsions, delirium, or coma, unless some other disease, or some complication should be the cause of death.

Abnormal conditions of the kidneys may exist, with or without accompanying pathological states of these organs; to which states, however, they are more exposed, under certain circumstances.

The kidney may be *fixedly placed in an unnatural situation*, which may be congenital, or acquired, (from neighboring tumor, etc.), and more commonly the misplacement is within or upon the brim of the pelvis,—sometimes forming a tumor in the abdomen, or, in the female, presenting an impediment to the advance of the fetal head,—the left kidney being thus located in the majority of instances. Its *diagnosis* is difficult, but we may suspect it when there is a want of fullness in the corresponding renal region, with a moderate size, smooth, somewhat elastic tumor, in the pelvic vicinity. Nothing can be done for it.

Abnormal forms of the kidneys are sometimes met with, but are difficult to detect during life; the same may be said where there is only *one kidney*, or where *three or four* are present. Of course these are irremediable.

Movable kidneys are also observed occasionally, in which the organ or organs become freed from their attachments, and, being held only by their blood-vessels and excretory ducts, float loosely amid the abdominal viscera. This condition is more common among females, and the right kidney is more liable to it than the left. Among its *causes* have been named tight lacing, blows and falls upon the loin, displacements of other internal organs, hydronephrosis, removal of the capsule of adipose tissue, etc., and it may also be congenital.

The *symptoms* are rather obscure; more or less heaviness and dragging sensations are experienced, or a dullness, especially after exercise or a prolonged standing; in some instances the motions of the misplaced kidney can be readily felt by the patient, and may be mistaken for fetal movements, etc. The tumor can often be felt by the practitioner, especially among those whose abdomens are flaccid; it is oblong; has the shape and feel of the kidney; is generally located between the margin of the ribs and the umbilicus; is not painful, but causes a sickening sensation of faintness when compressed; changes its position with that of the patient, as well as during deep expiration or inspiration; and the tumor can, in most cases, be, at will, pushed in and out of its lumbar space, by the thumb and fingers. A want of fullness may be observed in the loin, in the region of the kidney, and if the space left by the movable kidney becomes occupied by intestine, percussion will elicit a tympanitic, instead of a dull sound. Urination is usually normal. The mobility of the organ becomes more or less destroyed should it contract adhesions with the parts in its vicinity. As more serious diseases may be confounded with movable kidney, a careful examination should be made whenever an

enlargement or tumor in the abdomen is brought under observation, in order that the patient may not be necessitated to undergo treatment for a difficulty that is generally harmless.

The *treatment* required in these cases is usually very simple; the bowels must be kept free from accumulations, and regular in their evacuations, and tight lacing, horseback riding, running, dancing, or other violent kinds of exercise must be wholly avoided. To relieve the dragging sensations, as well as those of motion, a tight elastic bandage should be worn around the loins, and the tone of the abdominal muscles be restored, by careful kneading or shampooing once or twice a day. Severe pains, when present, may be relieved by rest, hot anodyne poultices, or the wet bandage, etc. Anemia, or other unhealthy state of the system, must be combated by the appropriate remedies therefor.

Chronic Diseases of the Ureters are very rarely met with, and when present are commonly due to an extension of morbid action from the kidneys or from the bladder. Obstruction from some cause in the ureter itself, or in the lower urinary passages, with more or less dilatation of the ureters above the obstruction, is more usually observed. Sometimes this enlargement becomes so great that it may be detected by careful palpation. Ulceration of the ureters, thickening, as well as perforation of their walls, and even abscess, may also exist. Occasionally cysts have been observed in them, of various sizes, and containing various fluid or hard substances; tubercle has also been met with; as well as complete closure of the canals, or, entire obliteration. The obstruction may be due to compression by a tumor, coagulum of blood, calculus, inflammatory action, adhesions, retention of urine in the lower passages, etc., and which should always be carefully sought for. The chief *symptoms* are pain between the bladder and kidney, along the course of the ureter, and sometimes a swelling in the same situation. Hair-like filaments of pus, floating in the urine, are indicative of ulceration of the ureters. Diseases of the ureters are more important on account of their secondary influence upon the kidneys, giving rise to serious affections of these organs, which may rapidly terminate existence. In actual disease of the ureters, the *prognosis* is always unfavorable; and especially so when an obstruction in them can not be overcome.

When we can determine the cause of the disease, as, urethral stricture, prostatic enlargement, renal calculus, etc., our *treatment* must be directed to its removal. In other respects the therapeutical and hygienic measures must be adapted to the morbid conditions ascer-

tained, both local and general, and to the more urgent symptoms, and which have already been referred to in the preceding renal affections, rendering a repetition of them here unnecessary.

DISEASES OF THE BLADDER, URETHRA, ETC.

CHRONIC INFLAMMATION OF THE BLADDER.

This disease is also termed "Chronic Cystitis," "Cystorrhea," and "Catarrh of the Bladder." It is a catarrhal inflammation of the mucous lining membrane of the bladder, and although it may occur at any period of life, it is more commonly met with among the aged, being generally associated with some impediment to the discharge of urine, as, from enlarged prostate, and among whom it is very apt to prove fatal. Pathologically, it is different from a common inflammation of the mucous membrane, which is more rarely met with.

The *causes* of catarrh of the bladder are various; and it is important for the practitioner, in every case, to satisfactorily ascertain its exciting cause, in order that he may institute the requisite treatment therefor,—and this can only be accomplished after having learned the history of the affection, and by a careful exploration of the urethra and bladder, to determine the presence of stricture, prostatic enlargement, stone in the bladder, etc. The disease usually manifests itself gradually, and may be due to cold, injuries, irritating diuretics or injections, severe horseback riding, recession of cutaneous affections, or, of gout, neuralgic and other diseases of adjacent organs, as of the vagina, rectum, etc.; but its more frequent causes are, urethral stricture, enlarged prostate, stone in the bladder, diseased condition of the bladder, and extension of gonorrheal or renal disease to the bladder. It is also frequently caused by intemperance, a constant habit of retaining the urine for a long time before voiding it, occasioning thereby an overdistended condition of the bladder; by excessive venery, sedentary habits, and is often associated with the more severe results of masturbation.

The *symptoms* of chronic catarrhal cystitis are generally, readily recognized. At first, there will be observed a deposition of more or less mucus on allowing the urine to stand for a time, and which is frequently confounded with seminal discharge; or the discharge in

prostatorrhœa; but the semen may be detected by the microscope; and the prostatic discharge by its viscosity, its resemblance to the white of egg, and its property of being soluble in the urine. As the disease advances, as well as when it is more severe from the first, the mucus increases in quantity, to even several pints per day, and is apt to be accompanied with more or less considerable pus, derived from the kidneys, ureters, or prostate, and even from the bladder itself. This mucus discharge is very viscid, adhering tenaciously to the sides of the vessel containing it, and when we attempt to pour it out, it forms long, tenacious threads. I have treated several cases, in which nearly the whole of the urine was converted by the action of cold into a glairy and thready substance resembling the white of egg; and in one patient, the urine was passed of a white color, very thick and tenacious, becoming nearly solid in a few seconds after it had been passed, and containing triple phosphates in great abundance, together with large corpuscles.—The urine is always alkaline, and more or less acrid, and from the moment it leaves the bladder, it exhales a strong ammoniacal odor, which upon standing becomes extremely penetrating, and often insupportably fetid. Blood may occasionally be observed in the urine, more especially when ulcerations or abscesses have formed.

At first the urinary flow may be natural or increased, but as the disease progresses, the urine becomes scanty, altered in its character, and of more or less difficult evacuation, and the calls to urinate increase in frequency; with these symptoms there is apt to be a dull pain in the region of the bladder, a spasmodic contraction of this organ, or painful tenesmus, and a painful, burning sensation along the urethra.—Usually, there is a persistent sense of uneasiness in the region of the bladder, a degree of heaviness in the perineum, pain and weakness in the back and loins, sometimes extending into the testicles, with irritability of the rectum, and more or less constitutional debility. Sometimes the symptoms are much more severe, and are accompanied with dry and hot skin, thirst, coated tongue, restlessness, and other manifestations of febrile reaction. Impotency, with nocturnal emissions, softness and flaccidity of the penis, and even loss of sexual desire, may arise from this affection.

From what has been stated, the *diagnosis* may readily be determined. The principal difficulties with which the catarrhal cystitis may be confounded, are, renal abscess, and uterine or vaginal disease, but the proper examination for the detection of these maladies will prevent such a mistake. The urethral canal, prostate, and bladder, should always be carefully explored, in order to detect any lesions in them. If these are not present, we must inquire into the

previous history and exposures of the patient, as, to colds, excessive fatigue or labor, employment of irritating injections, suppression of habitual discharges, recession of cutaneous eruptions, etc.

If the disease be allowed to progress, ulcerations and other lesions of the bladder occur, the system becomes greatly debilitated, the various excretory and secretory organs become deranged, debility and emaciation supervene, with hectic fever, nervous irritability, and finally, dissolution.

The *prognosis* of chronic catarrhal cystitis depends upon a variety of circumstances. It is more readily curable in the young than in the old, and long-standing cases are much more difficult of cure than those of more recent date. The danger is proportioned to the intensity of the pains, the abundance of the matters excreted by the bladder, and the degree of suffering, agitation, sleeplessness, and febrile reaction accompanying the local lesion. In case of prostatic disease, ulceration, hypertrophy, cancer, or other incurable lesion of the bladder, the cystorrhea will ultimately prove fatal; if it be due to urethral stricture, or calculus or foreign body in the bladder, the removal of these will generally be followed by a disappearance of the catarrhal affection under proper treatment. Aged persons may, however, labor under chronic vesical catarrh, when not severe in its character, for a long time,—and even die from some other malady. A change in the urine from alkalinity to acidity, occurring suddenly, is considered a fatal indication.

The *post-mortem appearances* vary, according to the extent and duration of the disease. The cavity of the organ is more or less diminished, so much so in some cases as to be hardly capable of holding an ounce or two of fluid; the mucous membrane is often injected, presenting red patches or streaks, and is generally thickened, with an enlargement of its follicles. Not unfrequently, from a softening of this membrane, it may readily be detached from the muscular coat. In more advanced stages, there will be ulcerations, which may even extend into the muscular coat, and nearly penetrate to the peritoneum. The muscular coat having acted with increased energy, its fibres become more voluminous, and project into the interior of the organ, giving rise to a sacculated appearance of the bladder, and which is often accompanied with a dilated condition of the ureters. In some instances, the walls of the bladder are much thinner than usual; and in others, the hypertrophy may render them an inch in thickness. The mucous membrane may, in some cases, be pale, in others, it may present almost every shade of color, as red, violet, gray, green, black, etc., usually in spots. False membranes may also be observed on the mucous membrane, either free

or adherent, and which when voided with the urine during life, have been mistaken for detached pieces of mucous membrane. The principal morbid alterations are, thickening, hypertrophy, sacculation, contraction of the cavity, change of color, false membranes, softening, and ulceration. The morbid action generally extends, in advanced cases, to the adjacent urinary organs.

In the *treatment*, after having determined the disease to be due to certain lesions, we must first remove them, as, calculus in the bladder, prostatic disease, urethral stricture, disease of the rectum, etc.; using the necessary precautions in so doing, and allaying any inflammation by means of warm baths, demulcent diuretics, anodyne injections or suppositories into the rectum, leeches to the perineum and groins, rest, rigid diet, Gelseminum, Aconite, etc. And these means should be continued with a perseverance equal to the seriousness and obstinacy of the symptoms. Should the catarrh continue, after the exciting cause has been removed, it must then be treated as named below.

In the absence of inflammatory symptoms in this disease, stimulating diuretics will be found valuable, and, as the system becomes habituated to their use, it will be found advisable to employ them alternately. Among the most valuable diuretics are, Uva Ursi, Buchu, Trailing Arbutus, and Queen of the Meadow. The Compound Infusion of Trailing Arbutus will be found a very excellent agent; I have used it for the last thirty years with great success; in cases of febrile manifestations, the Gin in it should be omitted, employing only a simple infusion of the articles. A decoction of Button Snakeroot (*Liatris Spicata*), with or without the addition of Chimaphila, will also be found a very useful remedy.

Considerable advantage may frequently be obtained from the internal administration of the following mixture: Dissolve Alum ten grains in Water four fluidounces, to this add Benzoic Acid ten or twenty grains, and mix for a dose. This dose may be repeated three times per day, and will be found more especially useful in cases of excessive mucus discharges with phosphatic deposits. In similar instances, I have likewise witnessed the most decided and permanent effects from the daily use, for some days or weeks, of the Compound Balsam of Sulphur, as well as of the genuine Harlem Oil; using freely, at the same time, of an infusion of equal parts of Dioscorea, Queen of the Meadow, and Dwarf Elder.—In many cases, where Copaiba, Cantharides, Uva Ursi, Buchu, etc., were of no service, I have advised the free infusion of the pods or hulls of the common Bean, and which has been followed by the most happy results. Various other agents have been employed with

success, as, the Fluid Extract of Hydrangea; the Compound Copaiba Mixture, as a stimulating diuretic; Tincture of Chloride of Iron, in cases of anemia and debility; and Compound Tincture of Colchicum, where gouty or rheumatic tendencies are manifested. And when there is much pain or irritation, Opium or Morphia may be administered internally, or be introduced into the rectum in the form of suppositories.

Retention of urine requires the introduction of the catheter to evacuate the bladder, and thus avoid a troublesome complication; but if the attempt to pass the catheter causes pain, spasms, and contractions of the urethra, or if it occasions a flow of blood,—in a word, if the operation produces too much suffering, and increases the irritation, we must abandon it, and have recourse to sedatives and anodynes, which may so far diminish the local irritation as to re-establish the urinary flow, or, permit the passage of a wax bougie. I have frequently overcome the difficulty, in similar cases, by injecting into the urethra every one, two, or three hours, or according to the urgency of the symptoms, a small portion of a mixture of Extract of Belladonna half a drachm or a drachm with a fluidounce of Glycerin,—at the same time applying cataplasms of pounded Stramonium Leaves to the perineum, or, of Stramonium and Lobelia, aided in obstinate cases by anodyne suppositories.—When it is positively required that the catheter be passed into the bladder, and the above-named symptoms prevent us from attempting the operation, we may often succeed, after having produced complete anæsthesia by ether or chloroform.

The direct application of medicinal fluids to the affected mucous coat of the bladder will be found exceedingly beneficial in all chronic cases; and great care should be taken to filter these fluids, or to have them clear, so that no minute particle of solid matter may be passed into the bladder, to form the nucleus for a future calculus. The fluids that may be injected into the bladder, through a silver or gum-elastic catheter, should vary in quantity from one to four fluidounces, and they may be allowed, each time, to remain in the bladder as long as no pain or uneasiness is occasioned thereby. A tepid infusion of Golden Seal and Solomon's Seal Root, will be found to exert a very beneficial effect on mucous membranes laboring under chronic catarrhal inflammation. Or an infusion or decoction of equal parts of White Indian Hemp, Black Cohosh, and Golden Seal. If much pain or irritation is caused by any of these fluids, a small portion of Solution of Sulphate of Morphia may be added to them; in many cases the addition of common Salt to the

fluid employed (three or four drachms to the pint), will be found to have a remarkably soothing effect.

When pus or blood appears in the urine, astringent liquids should be employed, as, an infusion or decoction of equal parts of Golden Seal, Geranium, and Witch Hazle Bark; of Logwood; or, of equal parts of Rhatany, Cinchona, and Barberry Bark.—Various other fluids may be employed in this affection, as, dilute solutions of Chlorate of Potassa; Chlorate of Soda; Permanganate of Potassa; very dilute Carbolic Acid or Phenol Sodique; Chloride of Zinc; weak solution of Malic, Citric, or Tartaric Acids, etc. These agents will always exert a much better influence, if the bladder be thoroughly washed out just before their employment, by tepid water,—using for this purpose a double-channelled catheter. The injections should be passed immediately after the urine has been evacuated from the bladder, and may be repeated two or three times a day, as the patient can bear, or according to the symptoms produced.

The following have been highly recommended for injections into the bladder: 1. Take of Nitrate of Silver from five to eight grains, Tincture of Hyoseyamus two fluidrachms, Distilled Water four fluidounces; mix, for an injection. In all cases where Nitrate of Silver is injected, the bladder should be thoroughly washed out in a few minutes afterward with tepid water, in which some common salt has been dissolved. 2. Take of an infusion of equal parts of Elm Bark and Solomon's Seal four fluidounces, to which add Oil of Cajuput five minims dissolved in one fluidrachm of Alcohol; agitate together, and inject. 3. Carbonic Acid Gas, in quantities of from two to four ounces, injected, and retained for an hour or two if possible; repeating it two or three times a day, or, once in every two or three days, according to circumstances.—I place no confidence whatever in cauterization of the bladder, or of its neck.

When the chronic catarrh obstinately persists, counter-irritation may frequently be employed with benefit. The Compound Tar Plaster applied intermittently over the inferior part of the hypogastrium, to the perineum, and to the lumbo-sacral region, will be found a superior remedy; while, at the same time, some other irritant may be applied to the inside of the thighs, as, the Compound Tincture of Camphor, Croton Oil Liniment, etc.

In addition to these means, the bowels must be kept regular; the surface of the body be frequently bathed with a stimulating alkaline solution, and a Spirit Vapor Bath be administered every week or two. The diet should be light but nutritious, easy of di-

gestion, avoiding fats, stimulating drinks, and other irritating articles. In exceedingly depressed conditions of the system, Wine may be needed, or, Tincture of Prickly-ash Berries in milk or mucilage, etc. Exposures to cold and damp, and to sudden changes of temperature must be carefully avoided; the body must be well clothed, wearing flannel next the surface, and especial attention should be paid to keeping the feet dry and warm. The bladder should be frequently evacuated, at regular intervals; and coition and horseback riding must be positively prohibited. A scrofulous or syphilitic taint, or, a suppressed cutaneous eruption, should, in addition, have the appropriate remedies used in conjunction with the above measures. If the disease can not be cured by these means, we may have the satisfaction of relieving the patient, and indefinitely postponing the sorrowful period of disorganization of the affected parts.

Ulceration of the Bladder may follow the acute or chronic forms of cystitis, and is not always readily detected in the earlier stages. But in cases of long standing, where there is a severe and constant pain, increased by micturition, which is difficult, and the urine contains pus streaked with blood, we may suspect the presence of ulceration, especially in the absence of any symptoms of renal or prostatic disease. The ulceration may destroy more or less of the mucous coat of the bladder, and even lead to perforation of its several coats, forming fistulous communications with adjacent organs. The coats of the bladder not destroyed by the ulceration are apt to be more or less hypertrophied or thickened. The disease is generally fatal in the more severe and extensive ulcerations; in milder cases, the only chance for the patient, is the injection two or three times a day, into the bladder, of a strong decoction of equal parts of Golden Seal and Geranium; demulcent diuretics, with a small proportion of Alum dissolved in them; and anodynes, etc., according to indications, to relieve urgent symptoms. Rest and quiet are necessary, and the diet should be light, unirritating, and nutritious. Any morbid quality of the urine must be removed by the usual means.

IRRITABLE BLADDER.

Irritability of the Bladder is sometimes met with, either as a primary or a secondary affection; occasionally, it is very severe in its character, and quite difficult of removal. It may occur at any period of life, but more frequently from eighteen to forty years of age.

The *causes* of irritable bladder are numerous, and, in some instances, are very difficult of detection. In the very young, it is more commonly observed among those of nervous, irritable habits; and in those more advanced in life it usually appears to be a secondary or sympathetic malady. Exposures to cold, or to sudden changes of temperature, stimulating diuretics, error in diet, premature or frequent sexual excitement, venereal excesses, masturbation, or an abnormal condition of the urine, may, independently of any existing lesion, occasion an increased sensibility of the nervous system of the mucous membrane of the organ; while on the other hand, this sensibility may be augmented and kept up by a chronic cystitis; disease of the kidneys; prostatic disease; gonorrhea; urethral stricture; stone or foreign bodies in the bladder, or other disease of this organ; gout; rheumatism; gastric and intestinal affections; abnormal states of the brain and spinal cord; disease of the reproductive organs, etc.;—and, sometimes, the irritability may be induced by hardened feces; lithotomy; pressure of the enlarged womb; pelvic tumors; and, occasionally, it follows as a sequel of some of the more severe febrile affections. It is very important, in order to effect a successful treatment, that the cause of the irritability be correctly determined.

The *symptoms* of this affection are frequent calls to urinate both during the day and the night, and the evacuation is either accompanied or succeeded by (perhaps both), great pain, sense of burning and of spasm at the neck of the bladder, frequently extending the whole length of the urethra. The urine may be natural in quantity and quality; it may be augmented or lessened in quantity, and its chemical characters may be changed. More commonly, it is of a high color, often having a light-greenish tint, acid, of low specific gravity, and containing considerable mucus, but not so tenacious as in catarrh of the organ, and, perhaps, diseased epithelium from the bladder. The deposit is of an ashy color, and consists of phosphates, and occasionally some urates. In connexion with these symptoms more or less pain is generally experienced in the bladder, shooting in various directions, and from the excessive sensitiveness of the parts, especially among young adults, erections, and spontaneous seminal emissions frequently occur. When the disease is primary, being due to exalted nervous sensibility of the parts, the pain being very severe and the symptoms coming on periodically, it is termed *Neuralgia of the Bladder*, and is treated upon as a separate and distinct disease by several authors.

That form of the disease, termed *Spasm of the Bladder*, the same as neuralgia of this organ, is more common to persons advanced in

years, and may be known by the spasmodic or cramp-like contractions of the bladder, which generally occur suddenly, with violent pain and a feeling of constriction, constant desire to void urine, but no ability to do so, and likewise a frequent desire to evacuate the rectum, or more or less tenesmus, and sometimes a protrusion of the bowel. Fever is absent, unless the spasm accompany acute cystitis, but great anxiety, restlessness, and clammy perspiration are frequent.

If the disease be not removed, the general health becomes ultimately involved, with more or less debility, emaciation, gastrointestinal derangements, impaired cutaneous functions, etc., and, in some instances, even hectic fever.

In the primary or idiopathic variety, the *prognosis* is generally favorable, as, however obstinate the symptoms may be, they eventually give way under proper treatment. In scrofulous, debilitated patients, the disease is peculiarly obstinate to treatment. In the secondary or sympathetic variety, the prognosis is favorable when the causes of the irritation can be removed. But if these can not be overcome, the prognosis will then depend upon the nature of the cause, the character of the symptoms present, and the general condition of the patient.

The *treatment* of this disease will depend entirely upon its cause, and every endeavor should be made to satisfactorily ascertain this, not forgetting to make a careful examination of the urine passed.

If the irritability is due to exposures, resulting in hyperemia or inflammation, rest and quiet, purgatives, low diet, spirit vapor baths, diaphoretics, demulcent diuretics, warm hip baths, anodyne suppositories, and, in very severe cases, leeches to the perineum, are the remedial means to be pursued.—If stimulating diuretics, (cantharides, turpentine, etc.), be the cause of the malady, their use must at once be discontinued, and recourse be had to warm hip baths, anodyne suppositories, demulcent diuretics with or without anodynes, according to the symptoms, and hot anodyne applications to the perineum and across the region of the bladder.—If error in diet be the cause, the use of the offending articles should immediately be stopped, and the proper measures be taken to correct the secretions and remove any digestive disorder that may exist; keeping the bowels regular by laxatives; administering anthelmintics if there be indications of worms, and at the same time, employing the hip bath, demulcent diuretics, (anodynes if necessary), as well as carefully regulating the diet.—With regard to venereal causes, coition, or masturbation, must positively be discontinued, and sexual excitement be avoided as completely as

possible. The evil consequences resulting from these causes, as, nocturnal seminal emissions, prostaticorrhea, gleet, etc., must be overcome by the appropriate treatment for these difficulties.

If the patient is rheumatic, gouty, or scrofulous, or if the system is tainted with syphilis, the proper means for these maladies should be at once and perseveringly employed.—If the urine be abnormally acid, alkalies, as the Bicarbonate of Soda, or of Potassa, should be given, with such other treatment as may be required to effect a healthy condition of the system; if it be alkaline, or neutral, the treatment named hereafter for Phosphatic Gravel, may be pursued,—and it is in these cases, that washing out the bladder by demulcent, soothing fluids, will be found especially useful.—Indeed, in all cases, any peculiarity observed in the chemical nature of the urine, should be obviated by the means named for these conditions, under the head of Gravel, Diabetes, etc.

When the vesical irritability occurs with young females emerging into womanhood, it may be dependent upon some menstrual derangement, upon spinal irritation, or, perhaps, upon both combined; preparations of Iron, regularity of bowels, Compound Syrup of Partridge Berry, counter-irritation along the tender parts of the spinal column, warm hip baths, cold douches along the spinal column, regularity of diet, and exercise in the open air, will generally effect a cure, unless the irritability be dependent upon some other functional or organic lesion. The presence of hysteria may be overcome by the means generally employed for this symptom.

In cases where the irritability is dependent upon other disease, as, anal fistula, hemorrhoids, stricture, enlarged prostate, pelvic tumors, uterine displacements, renal disease, etc., the primary malady must first be removed or materially improved, and the irritable condition of the bladder will disappear, or be greatly relieved. But in conjunction with these means, treatment must also be pursued to alleviate as much as possible the sufferings caused by the vesical irritation, as, the use of hip baths, demulcent diuretics, anodyne suppositories, etc.—When urethral stricture is the cause, not unfrequently the careful passage of an elastic catheter into the urethral canal, will afford prompt relief; though, in some cases, it will augment the irritability. The bougie or catheter should be allowed to remain in the urethra, five or ten minutes each time, and its introduction should not be repeated again until two or three days afterward, and so on. Anointing the catheter with Glycerin in which Extract of Belladonna has been dissolved, previous to its introduction, will, in most cases, facilitate the desired result.

In cases of irritable bladder, associated with retention, or incontinence of urine, much benefit has followed the use of the following preparation; Take of Tincture of Cantharides, Tincture of Colchicum, Tincture of Digitalis, each, four fluidrachms, Tincture of Lupulin six fluidrachms; mix. The dose is from twenty to thirty drops in a little water or mucilage, three or four times a day. In other instances, the following has been of service: Take of Atropia one grain, Distilled Water four fluidrachms, Hydrochloric Acid two fluidrachms, Alcohol one and a half fluidounces; mix. The dose is ten minims in an ounce of water, to be repeated every night and morning. Of course the effects of this preparation should be carefully watched, diminishing the dose if required, or suspending its use entirely for a time, and then recommencing it in much smaller doses. A pill composed of one-eighth of a grain of Extract of Belladonna, one-twentieth of a grain of Strychnia, and one grain of Alcoholic Extract of Aletris, and given two or three times a day, has also afforded permanent relief in many instances.

In the spasmodic and neuralgic varieties, if the measures just named do not afford relief, the internal use of Tincture of Chloride of Iron, together with the application of the Compound Belladonna Plaster to the lumbo-sacral region, or to the perineum, will frequently afford prompt relief.—In neuralgia of the bladder the following pill, employed in conjunction with the Compound Tar Plaster to the lumbo-sacral region, will be of benefit: Take of Strychnia one grain, Extract of Aconite eight grains, Sulphate of Quinia forty-eight grains, Extract of Hyoscyamus eight grains; mix thoroughly together, and divide into sixteen pills, of which one pill is a dose, to be repeated three times a day. I have likewise derived much benefit from the internal use of Tincture of Kalmia, in conjunction with a rather free employment of an infusion of Peach Leaves, or Wild Cherry Bark. A very excellent preparation for irritability of the bladder in almost all instances, is composed of Fluid Extract of Buchu two fluidounces, Tincture of Gelsemium five fluidrachms, Tincture of Sheep Laurel three fluidrachms; mix. The dose is a teaspoonful, in some mucilaginous diuretic, to be repeated three or four times daily. Or, the treatment heretofore recommended for Neuralgia may be pursued. (*See Vesico-urethral Neuralgia*, page 300.)

In this affection, the body should be warmly clad; exposures to cold and sudden changes of temperature must be avoided; the diet should be properly regulated, using but little animal food, no acids, cheese, nor stimulants of any kind; the bowels should be kept regular; the calls to urinate should be postponed as long as possible,

because a frequent micturition often becomes a habit very difficult to overcome; and coition must positively be avoided. Among the agents that have been found of value in this affection, may be named,—Tincture of Poke Root in doses of a fluidrachm every three or four hours; infusions of Uva Ursi, Wild Carrot, Trailing Arbutus, Cleavers, Pareira Brava, Couch Grass (*Triticum Repens*), Cutting Almond (*Parthenium Integrifolium*), Thimble Weed (*Rudbeckia Laciniata*), or False Gromwell; Fluid Extract of Hydrangea; Harlem Oil; Tincture of Stavisagria; and injections into the bladder of a solution of Nitrate of Silver, (from half a grain to two grains to the fluidounce), used especially in atonic or relaxed conditions of the mucous membrane. Occasionally much relief will follow injections of a weak solution of Malic, Citric, or Tartaric Acid.

PARALYSIS OF THE BLADDER.

Paralysis of the Bladder may be partial or complete; it is due to a partial or complete loss of the contractile power of the bladder, as well as of its organic sensibility. Want of power of the abdominal muscles is frequently associated with it. It is a very common affection among aged men, though it may occur at any age.

Like other organs, when exposed to the causes of disease, the bladder is liable to have the exercise of its functions more or less impaired; it loses its strength and contractile power, is unable to expel the whole of the urine contained in it, and thus gives rise to a retention of this fluid. All old men do not experience the infirmities arising from weakness or paralysis of the bladder; but still, very few are exempt from it. Those aged persons who do labor under this malady, not being commonly much disturbed by it, especially in its early and more easily curable stages, pay but little attention to it, believing it to be a necessary consequence of their age; consequently, they neglect consulting a physician, until the difficulty has so far advanced as to be nearly, if not wholly, irremediable.

The causes that may induce vesical paralysis are numerous; among the principal ones may be named, a too free use of diuretics, long-standing gleet, repeated attacks of gonorrhea, stricture of the urethra, prostatic disease, sedentary occupations, long-continued intellectual labors, venereal excesses, and masturbation. The habit that many persons have of retaining their urine for a long time, is a very common cause. Paralysis of the bladder often follows

blows, or other injuries upon the hypogastrium; exhausting diseases; lesions or injuries of the brain and spinal cord; uterine displacements; vesical inflammation; constitutional debility; rough and improper employment of catheters or bougie; and surgical operations in the neighborhood of the organ. The mind also exerts considerable influence in occasioning the paralysis, as is frequently observed in hysterical females. Urinating while lying upon the side of a bed, is an unfavorable position for this evacuation, and will eventually lead to weakness of the bladder. Those who practise coition in a standing position, are very apt to be attacked with vesical catarrh and paralysis. A temporary paralysis of the bladder may follow the frequent use of anodyne suppositories, pressure of the fetal head during labor, as well as morbid growths in the neighborhood of the organ, and a rectum distended from any cause. Gouty and rheumatic persons are liable to the disease in old age.

The *symptoms* of paralysis of the bladder manifest themselves more or less rapidly, according to their cause. The first symptom generally noticed is a difficulty in expelling the urine at the start; it does not flow promptly, and when it commences the flow is feebly ejected, or is voided in jets; sometimes, the person will have to wait a considerable time before the urine commences to flow; and at other times, he can expel it only by making efforts to do so, contracting the abdominal muscles which compress the bladder, and thus making amends for the insufficiency of the contractions of this organ. As the disease progresses, the urine, instead of passing in a full, long stream, falls vertically between the patient's legs; from the more feeble vesical contractions, much less urine is evacuated, and more and more of this fluid remains in the reservoir after each evacuation, and the calls to urinate become more and more frequent. If the hypogastrium be examined, the tumor formed by the distended bladder will be found above the pubes, frequently extending as far upward as to the umbilicus. There are some persons, however, in whom the bladder is so small, that this tumor in the lower part of the abdomen does not occur, unless there be a complete suppression of the urinary flow. Owing to its retention in the bladder, the urine becomes changed in its quality, more especially in those cases originating from lesions of the spinal cord or brain; it becomes very acrid and irritating—alkaline, turbid, and phosphatic, with considerable mucus,—destroying the sensibility of the internal lining membrane of the bladder, and occasioning a thickening of its walls, as well as rendering the patient very liable to vesical calculus.

In many cases, the patients experience a sense of heaviness and uneasiness in the region of the bladder, perhaps pain, often extending to the glans penis; but more commonly, no particular symptoms of this kind are felt. When pain and uneasiness are the commencing symptoms, they eventually disappear.—Among those who suffer from venereal excesses or masturbation, there is a sense of weakness in the loins and lower extremities, and paraplegia may result, with complete vesical paralysis.—When the urine accumulates in the bladder, and is not evacuated by the catheter, it eventually occasions such a distension of the organ, that its contractions become impossible, and there is then complete paralysis with retention, or, if there is not enough opposing power at the neck of the bladder to prevent the flow of urine, this fluid dribbles away involuntarily by regorgement. And if not relieved by catheterism, nausea, vomiting, profuse perspiration of a urinary odor, small, frequent pulse, and swelling of the extremities, may occur,—and even delirium, coma, and death.—We may know when the urine flows by regorgement, by its passing away continually in a small stream or by drops, and when the vesical tumor produced by the distension can be felt above the pubis, and especially by catheterism which evacuates an abundance of this fluid.—Hysterical paralysis of the bladder, is met with among females during their menstrual life, and more especially during the first ten or twelve years; it is owing to want of volition in most cases, and generally requires no interference by catheterism;—the urine in these cases, presents the same appearance as when the urinary retention is absent, undergoing no change at all.

Paralysis of the neck of the bladder may occur independently, and is known by an inability to retain the urine; or, this fluid may pass away involuntarily, on laughing, coughing, sneezing, lifting, or on any sudden exertion. Females who have undergone several severe labors are very apt to suffer from this affection.

The *prognosis* depends entirely upon the cause of the malady. It is much more favorable among young persons, especially when prompt treatment is pursued. In advanced age the causes are generally incurable, and the bladder having a greatly diminished tone and energy, responds but feebly to treatment,—yet life may be prolonged by appropriate measures. In cases where the cause is curable, the disease of the bladder may be cured, by not allowing its overdistention during the remedial treatment for its cause. If the bladder be permitted to remain distended four or five days, it is very doubtful whether catheterism would then be of much avail,—though it should be undertaken, nevertheless. Organic lesions, and espe-

cially of the nervous centers, are almost invariably beyond the resources of art; and the paralysis may extend to other parts of the system, producing paraplegia, or hemiplegia, etc.

The *post-mortem appearances* are a dilated condition of the bladder, its walls being thin, and its mucous lining membrane pale; at times there will be ulcerations, or softening of its coats. Sometimes, inflammatory patches, or a red, or even slate-colored appearance of the inner membrane will be observed.

In the *treatment*, after having fully assured ourselves that the urethral canal is free throughout its extent, there being no stricture, nor prostatic disease, and that there are no calculi nor foreign bodies in the bladder, the first point to attend to is, to evacuate the bladder by the gentle and careful introduction of a catheter, being very careful, when there is considerable distension of the organ, not to allow the urine to pass away too rapidly, as well as not to remove all the fluid at once,—the sudden abstraction of a large quantity of urine has been followed by rapid collapse and death. The catheter must not be allowed to remain after the necessary amount of fluid has been removed; it is preferable to re-introduce it every time it is required to empty the bladder, say every four or five hours. However, when there is great difficulty and pain in passing this instrument, it may be allowed to remain in the canal after its introduction, unless too much irritation be occasioned by its presence,—removing and cleansing it after twenty-four or forty-eight hours, and then, if required, re-introducing it,—its outer extremity should be closed with a cork or plug to prevent the urine from constantly passing away. But, it must be borne in mind that the organ may become accustomed to this artificial aid and remain in a state of permanent weakness, if we rely too much upon it; consequently, the patient must be required from time to time to test the contractile power of the bladder, so that the use of the instrument may be needed only occasionally, or be dispensed with altogether.

Patients should be taught to introduce the catheter themselves, employing as large a one as can be introduced with facility, and should likewise be instructed to empty the bladder thoroughly each time, for if a small portion of urine remain, its decomposition will influence the urine subsequently discharged into the organ, and thus occasion abnormal changes in the mucous lining membrane. In many cases, the prompt employment of the catheter will alone effect a cure.

The medical man can readily determine that the bladder is recovering its elasticity, and may even be able to evacuate itself naturally, by the urine flowing in a full, rapid stream through the catheter.—

When the patient urinates without the aid of this instrument, the evacuation being made slowly and in small quantity, and especially, when it is accompanied by a feeling of heaviness in the neighborhood of the neck of the bladder, this organ has not yet recovered its contractility, and the catheter will still be necessary.

Other measures must however be employed, in most cases, in conjunction with the catheterism. In the early period of the disease, diaphoretic drinks rendered slightly diuretic will be found of much service, aided by stimulating alkaline baths, frictions, stimulating liniments over the loins, and especially frictions over the hypogastrium, the groins, the perineum, and inner part of the thighs. Where there is debility, tonics will be required; and preparations of Iron for anemia. In all cases the bowels must be kept regular, and much benefit will be derived from gentle purgatives, repeated at given intervals. Sometimes, emetics will prove useful, especially among old men, when indicated by the state of the tongue and the color of the skin. Cool douches to the lumbar and sacral regions will also often be found of value.

These means must be favored and sustained by moderate exercise, nourishing food, and properly regulated sleep. The best time for exercising is in the morning before breakfast, in the open air, the air being dry; if it be cold, more clothing should be worn so as not to expose one's self to colds or other inconveniences. Frictions every morning and evening, and walking, are the only exercises to be allowed, until the strength will permit more active exercise. Hair mattresses, or those made of cotton, or other rather firm material, should be used for beds to sleep upon; feather-beds must be prohibited. Sedentariness, as well as fatigue must be carefully avoided; nothing is so well calculated to increase the weakness of the bladder than lying in bed for a long time, or sitting on warm stools or cushions; while thus sitting, or lying in a warm bed, a desire to urinate is hardly felt.—Studious and literary men are subject to weakness of the bladder, not only from their sedentariness, but also from the tense, concentrated condition of the brain, the influence of which organ is necessary to animate the action of all the other organs of the body. Thus, when a person is occupied in close meditation, or active study, all the functions languish, perspiration diminishes, urine is secreted more abundantly, and, the general sensibility becoming greatly lessened, the person does not feel the stimulus the urine excites in the bladder, or, if it be felt, the call is apt to be neglected until the bladder becomes more than usually distended.

In more advanced cases, and especially in the vesical paralysis of

old men, various remedies have been used to impart tone to the bladder, and restore its contractile power. Injections, into the bladder, of cold water, or of cold infusion of Prickly-ash Bark, or of Bayberry Bark, have sometimes proved successful; injections of Tannic Acid, of Alum, of infusion of Geranium, have likewise been found serviceable, as well as the following: Take of Strychnia one grain, Water from three to five pints, Nitric Acid ten drops; mix and dissolve the Strychnia. Of this, from three to four fluid-ounces may be injected at a time, repeating the operation two or three times a day. If the paralysis be dependent upon some incurable disease, this injection should not be employed.—Ergot of rye has also been recommended, in doses of twenty or thirty grains of the powder, or, a fluidrachm of the tincture (six ounces to a pint), repeated two or three times a day; but its use should not be continued for too long a period at any one time. Tincture of Arnica in doses of forty to sixty drops, three times a day, carefully watching its effects, has likewise been advised. Considerable benefit may be derived from the use of the following pills: Take of Strychnia one grain, Extract of Arnica from forty-eight to eighty grains, Cantharides two grains; mix thoroughly together, and divide into sixteen pills. One pill is a dose, which may be repeated three times a day,—if they cause gastric irritability, strangury, or spasmodic twitchings, suspend their use for a time, employing some other preparation in the meanwhile. In order to give size to these pills, that they may be more easily swallowed, a sufficient quantity of some Extract should be added, as, of Aletris, Indian Hemp, Black Cohosh, Cypripedium, or, Water-pepper, etc. Or, the following will be found useful in many cases: Take of Alcoholic Extract of Queen of the Meadow two scruples, Xanthoxylin (oleo-resin) one scruple, Strychnia one grain; mix thoroughly and divide into twenty pills, of which one may be given two or three times a day.

Galvanism, cold douche, hip baths, stimulating embrocations, firing along the lumbo-sacral region, Croton Oil Liniment, and especially the intermittent use of the Compound Tar Plaster to the perineum, and to the lumbo-sacral region, are among the useful and advisable means of local stimulation and counter-irritation, to be employed in conjunction with the internal medicines. An injection into the rectum, in cases where there is an obstinate vesical paralysis, with a lack of nervous energy of adjacent organs, will frequently prove beneficial,—the following may be employed: Take of strong infusion of fresh Horse-radish Root eight fluidounces, Tincture of Prickly-ash Berries four fluidounces, Tincture of Nux Vomica three fluidrachms; mix. Inject into the rectum about half

a fluidounce, repeating it three or four times a day, as may be required.

Diseases of neighboring parts must be properly attended to in all cases; for, if permitted to remain uncured, we can not hope to remove the vesical affection. Lesions of the nervous centers, as well as of the kidneys, may be relieved and life be prolonged, by conjoining the appropriate treatment for these lesions, with that adapted to relieve the bladder, although a cure is ordinarily out of the question. When there is an imperforate urethral stricture, or an excessive prostatic enlargement, the only chance for the patient is puncture of the bladder.

If the disease is of an inflammatory form, it must be treated upon general principles, meeting the various symptoms according to their indications.

Hysterical paralysis is rendered worse by catheterism; it should never be undertaken. The usual treatment for hysteria is all that will be necessary, tonics, antispasmodics, and measures to strengthen the mind and general system.

RETENTION OF URINE.

Retention of Urine differs from *Suppression* of Urine (*Ischuria Renalis*) in having this fluid excreted by the kidneys, but from some cause in the ureters, the bladder, or the urethra, it is not discharged externally. In *suppression*, the urine fails to be excreted by the kidneys, and if the functions of these organs fail to be restored, the patient, in the course of from thirty to forty hours, dies suddenly in a comatose condition, or in convulsions, (uremia). *Suppression* is generally due to some renal affection, or to gout.

Retention of urine is more commonly *caused* by paralysis of the bladder; enlargement of the prostate; and stricture of the urethra. It may also be owing to vesical inflammation; vesical irritation from gravel or stone in the bladder, or from cantharides or turpentine taken internally, or, absorbed from a blister or embrocation; injuries to the bladder; tumors; a calculus in the urethra, etc.—When the retention is complete it is termed *Ischuria Vera*, or, *Ischuria Vesicalis*; when the urine is voided drop by drop, with great difficulty, being attended with a hot or scalding pain, and tenesmus of the neck of the bladder, it is termed *Strangury*; when it is passed with considerable difficulty, pain, and scalding sensation, it is termed *Dysuria*, and which is apt to be the first stage of a complete retention.

The *symptoms* of retention of urine are, an inability to void the urine on attempting to do so, and after several ineffectual attempts the patient becomes fatigued with his efforts, and also alarmed. An uneasiness and pain is experienced in the region of the bladder, which extends to the thighs and loins, the distended bladder forms a tumor above the pubes, hard and enlarged, which can be felt, and which is more or less painful on pressure. In some cases the urine may dribble away by drops, or in occasional small streams when the patient makes an effort, but this does not relieve the sufferings. The desire to urinate becomes more and more urgent, the patient strains, but accomplishes nothing in the way of urinating. As the difficulty progresses, the pulse becomes hard and frequent, the face flushed, the skin hot, the heart beats rapidly, the tongue is covered with a white fur, and the countenance of the patient expresses anxiety and alarm. As the kidneys continue to excrete urine all the time, the danger lies in a rupture of the bladder, in peritoneal inflammation, or, in death from absorption of the noxious elements of the urine. The bladder has been known to contain a gallon of of urine without rupturing, but when this accident does occur it is usually on the third or fourth day.—When there is paralysis of the bladder, there may be no uneasy sensations experienced, and the urine may accumulate to a dangerous extent, without the patient having any suspicion of his true condition.

A retention of urine, when not due to obstruction of the ureters, may readily be *determined* from *suppression*, by the vesical tumor felt above the pubis, and by the flow of urine when a catheter is passed into the bladder, both of which are absent in suppression. It must be borne in mind, however, that a retention may exist, and at the same time even more or less urine be discharged by regorgement or overflow. But if the catheter can not be passed to the bladder, from obstruction in the urethra, this will generally be found owing to prostatic enlargement, to urethral stricture, or to a calculus or foreign body in the urethra. To determine which of these is present, it will be necessary for the physician to institute a careful examination as to the previous history of the patient, and the character of any symptoms connected with the urinary organs.

The *prognosis* of retention of urine is usually favorable; it is unfavorable in those cases where the catheter can not be introduced to remove the accumulated urine, where the retention has not been suspected, or where it has been improperly treated.

The *treatment* of retention from renal calculus, from prostatic disease, from urethral stricture, or from paralysis of the bladder, is that appropriate to these affections themselves, and which will be

found under their respective heads. The obstruction must in all cases be removed, when it exists in front of the bladder, and if this can not be accomplished, or if it be impossible to introduce a catheter to evacuate the bladder, a surgical operation (puncture of the bladder), may have to be resorted to, an operation which is very seldom demanded under proper management. In some serious cases, however, hydragogue cathartics and sudorifics (Spirit Vapor Bath), will have a tendency to relieve the dangerous constitutional symptoms from urinary poisoning, thus affording more time for the employment of curative measures.

In all cases, congestion must be diminished—inflammation overcome. If the retention be owing to inflammation about the neck of the bladder, or irritation from cantharides, turpentine, etc., the patient should be promptly placed in a very warm hip bath, and be kept there for twenty or thirty minutes; and, on coming out of it, a hot fomentation of equal parts of Hops, Lobelia, and Stramonium Leaves should be applied to the perineum,—or, if fresh Stramonium Leaves can be had, they should be bruised, moistened with hot water, and then be applied to the perineum. If, after an hour, the urine does not pass, a catheter should be introduced; but the length of time we should wait before practicing catheterism, will depend greatly upon the degree of accumulation of fluid in the bladder, and the length of time the patient has been suffering. It is better, generally, to employ an elastic catheter well oiled, not too small, nor too large, passing it in with great care and gentleness, lest the urethra should become inflamed or injured, effects which are very apt to follow unskillful and rude attempts.

In some severe cases, it may become necessary to produce perspiration by administering a dose or two of the Compound Tincture of Virginia Snakeroot, and, also to effect relaxation of any spasm that may be present, by injections into the rectum of equal parts of the Compound Tincture of Lobelia and Capsicum, and warm water, having the patient to retain the injection as long as possible. If the bowels be constipated a purgative should be administered. In cases where the feces are hard and impacted in the rectum, and can not be dislodged by purgatives or injections, I have had to scoop out a portion of the fecal matter before an alvine operation could be procured.

In cases where there are no contraindications to the immediate introduction of a catheter, this operation should be performed at once, even though it should occasion irritation. And its use should be continued once or twice every day, until the urine becomes of a healthy character, and the cause of the retention is removed. It

must not be forgotten that when from irritation, spasm or other cause, it is almost, if not wholly, impossible to introduce the catheter, this operation may frequently be performed with success by the production of complete anæsthesia by chloroform or ether. It is not so much the evacuation of the bladder only, that requires the subsequent continuance of catheterism, as it is to prevent the vesical mucous membrane from becoming irritated by the presence of alkaline urine. And so long as the urine continues ammoniacal, so long will the operation be necessary. Besides, the mucous membrane will be less apt to become irritated if the urine be withdrawn before it has attained a great degree of alkalinity.

Strangury from irritating diuretics, cold, or other causes aside from actual obstructions, may generally be overcome by warm hip baths, warm fomentations, and a free use of cooling and mucilaginous diuretics, as, infusion of Water-melon Seeds, Pumpkin Seeds, Marsh Mallow Root, Cleavers, Parsley, etc. The Tincture of Chloride of Iron will frequently be found very useful in cases of retention, especially when it is associated with anemia, or much debility. Among infants and young children, retention of urine may be cured in most cases by the warm bath, application of pounded Garlic or Onions over the region of the bladder, and the use of Sweet Spirits of Nitre, in appropriate doses, in some one of the above-named diuretic infusions.

In dysuria, and ordinary urinary difficulties, where the urine is high-colored, scalding, or in diminished quantity, much benefit may be derived from the use of Compound Infusion of Trailing Arbutus; Compound Pills of Soap; cold infusion of Cleavers, or Sickel-grass; or, Oil of Pumpkin Seeds, six or twelve drops, four or five times a day.

In cases of hysterical retention of urine, catheterism is seldom if ever demanded, though we may threaten to use it, in the hearing of the patient; indeed, catheterism, in these cases, is generally of more disservice than benefit—but we must be careful not to allow the patient to suffer, when the operation is really needed. A cold douche to the genitals will usually be found all that is necessary.

INCONTINENCE OF URINE.

Incontinence of Urine or Enuresis is a disease which may occur at any time of life, but is common to children and aged persons, in which they involuntarily discharge their urine, especially at night. And sometimes instances are met with in which the patient has no

ability, whatever, to retain the urine, which is more or less constantly escaping.

The *causes* of incontinence of urine are various; it may be owing to a distension of the bladder with irritability; to paralysis of the bladder; to prostatic enlargement; to injuries or lesions of the spinal nerve; to mechanical pressure, as from tumors, pregnancy, etc.; to masturbation; to the presence of gravel or foreign bodies in the bladder; and to a rheumatic or gouty habit.

The *symptoms* are, a constant dribbling of the urine as fast as it enters the bladder; or, it may pass away involuntarily, whenever a certain quantity has been retained in this organ, either in an ordinary stream, or by drops. Children are especially liable to void their urine during sleep, and when lying on their backs.

The *prognosis* is favorable, unless there be some incurable abnormal condition present. And great care must always be had to discriminate between the various causes of the incontinence, as well as not to confound it with the "flow from regorgement," which often occurs in retention of urine.

The *treatment* of enuresis will vary somewhat, according to its causes; if it be due to irritable bladder, vesical paralysis, gravel, prostatic disease, urethral stricture, lesions of the brain and spinal marrow, or vesical inflammation, our remedial measures must be chiefly directed to the removal of the primary affection, without which we can expect no permanent relief.

In cases due to debility or relaxation of the bladder, with morbid irritability, as is often met with among masturbators, and persons given to sexual excesses, high living, and irregular habits, as well as among delicate and weakly children, I have found the following simple and pleasant remedy very efficacious: Take of Isinglass (*long staple*) one ounce, Water a pint; boil together until the isinglass is dissolved, then strain, add good sweet Milk a pint, put the whole over the fire again, and allow it to "just boil up," remove from the fire, sweeten with loaf-sugar, and grate nutmeg upon it. When properly made it resembles custard. The dose of this for an adult is an ordinary tumblerful four or five times a day.—The Compound Infusion of Trailing Arbutus will frequently remove the irritation, either with or without the free use of a strong infusion of equal parts of Beth Root, Bayberry, and Wild Cherry Bark; and in some instances, among adults, the following mixture will be found useful: Take of Tincture of Cantharides, Tincture of Digitalis, Tincture of Colehieum Seed, each, one fluidounce, Tincture of Lupulin, one fluidounce and a half; mix. The dose is twenty or thirty drops, three or four times a day.

To give tone to the bladder, the following preparations have been advantageously employed: 1. Take of Tincture of Acetate of Iron, Tincture of Nux Vomica, each, equal parts; mix. The dose is ten or fifteen drops in water, to be repeated twice each evening, at intervals of two or three hours.—2. Take of Tincture of Chloride of Iron half a fluidounce, Tincture of Cantharides one fluidounce; mix. The dose is thirty or forty drops, two or three times a day.—3. Take of Black Oxide of Iron forty-eight grains, Extract of Nux Vomica one grain; mix thoroughly, and divide into twenty powders, of which one may be given every night and morning.—4. Take of Tincture of Chloride of Iron two fluidrachms, Balsam Copaiba one fluidounce, Strychnia, dissolved in a little Alcohol acidulated with a drop or two of Nitric Acid, one grain, Infusion of Quassia twelve fluidounces; mix, and administer a fluidounce three times a day,—for aged persons.

When the disease is associated with irritation of the spinal nerves, the cold douche should be applied to the lumbar and sacral portions of the spinal column twice a day, counter-irritation should also be applied along the same portions of this column, as, firing, or rube-facient embrocations, and the electro-magnetic current may be passed through the bladder and along the spinal column daily. In some cases, the Compound Tar Plaster over the lumbo-sacral region, or over the tender parts, will be useful.

Incontinence in children has been cured by Cantharides, Belladonna, Extract of Nux Vomica, etc. The Isinglass custard, heretofore referred to, in conjunction with a Belladonna plaster over the lumbo-sacral region has effected cures. In a few cases I have effected cures by the administration of a compound Fluid Extract of equal parts of Water Eryngo, Button Snakeroot, and Queen of the Meadow.

Among children enuresis is often the result of habit, or carelessness in not being made to urinate immediately before going to bed; it will, therefore, be necessary to attend to this, as well as to awaken the child at certain periods through the night, for the purpose of evacuating its bladder.

In some cases, it will be found that the urine is passed during sleep, while lying in one particular position, as for instance, on the back—by changing this position, some benefit may, at times, result.—Where children are in the habit of taking suppers, very little fluid should be allowed them, and tea and coffee must be abstained from, even for some time after a cure has been effected. The diet should be principally boiled milk, and wheat flour, with a little cinnamon or nutmeg to flavor it. Sometimes a stimulating

strengthening plaster will be found a valuable auxiliary, when worn over the lumbo-sacral region.—In cases where no cure can be effected, contrivances must be resorted to (portable urinals), to receive the urine as it passes, and to prevent it from soiling the clothes, as well as to protect the neighboring parts from becoming excoriated by contact with it.

GRAVEL.

The debris or disintegrated elements of the several tissues of the body, are to a considerable extent removed from the system in a soluble state, through the urine, under the form of several acids, alkalies, calcareous matters, salts, etc. But from certain causes, one or more of these urinary elements may exist in excess, and will be deposited in greater or less quantity upon allowing the urine to stand for a short time; not unfrequently, these deposits will be found to consist of foreign substances, or matters that are not found in normal urine. Occasionally, however, this deposition is made in the kidneys or ureters (renal calculus), or in the bladder, in the latter instance occasioning gravel, or, vesical calculus. In perfect health no deposit is found in the urine, until after it has been voided and undergone decomposition. Stone or vesical calculus is the result of urinary deposits formed upon a nucleus in the bladder, as, some foreign body introduced into the organ from without,—a nucleus formed by deposits from the urine while in the bladder,—or, a renal calculus, which having entered the bladder becomes the nucleus for future depositions.

It is not my intention to devote any attention to stone or vesical calculus proper, which, for its removal, involves a surgical operation; but to those smaller and more numerous formations of calculi, to which the term “Gravel” is applied, and which are nothing else than renal or vesical calculi, of small size sufficient to enable them to escape through the urethra when urine is voided.—The *causes* of the formation of calculi have not been satisfactorily determined; the more commonly received opinions as to these causes will be named hereafter under each variety. It may, however, be proper to state that no age is exempt from these concretions; they have been found in suckling infants, even along the various periods of life to extreme old age. And they are more frequently met with among those whose habits dispose to debility and disease, aside from any hereditary predisposition, as, among sedentary persons, those who are exposed to cold and moisture; who

have insufficient food; who are irregular or intemperate in their habits; who are obliged from location to drink calcareous or other impure waters; who stimulate the kidneys too much by stimulating drinks; or who are laboring under any affection that can exert an unhealthy influence upon the kidneys and the blood, as, gout, rheumatism, repeated colds, prostatic disease, urethral stricture, renal disease, or lesions of the spinal cord, etc.

The *symptoms* of gravel may be the same as those described for Renal Calculus; or, the only symptom observed may be the passage of a sandy or gravelly deposit with the urine, which is either formed in the bladder, or in the kidneys; in the latter instance, being so small as to readily pass through the ureters and without causing pain. The gravel passed may consist of one, two, or more calculi of various sizes, or it may form a layer of numerous minute calculi, very much resembling sand. If these gravelly deposits are not expelled with the urine, they form a nucleus upon which layer after layer of urinary deposits is formed, eventually developing a *stone* or vesical calculus. These layers may consist of the same kind of deposit throughout, or, they may be formed of different materials, according to the character of the urine at the time they were deposited. And, as the gravelly deposits, as well as the urine, vary considerably in their chemical characters, I will now consider the principal varieties under their respective heads. (*See Urea*, pages 108 and 856.)

URIC ACID GRAVEL. (*Lithic Acid*.)

Uric acid and urates are found in urine, when they exist in excess in this fluid, and when the solvent power of the urine on uric acid or on the urates is greatly reduced, by a too acid condition of the urine, by a deficiency of chloride of sodium, and by the presence of alkaline phosphates in this fluid.—In addition to the remarks on Uric Acid, pages 110 and 856, I will state that intemperate persons, those who indulge in lying long in bed, who have a habit of retaining the urine in the bladder for a long time, who are exposed more or less continually to changes of temperature, or, who use much animal food with but little exercise, are liable to an excess of this acid in the urine.—In the *treatment*, the Compound Infusion of Trailing Arbutus will, probably, be found one of the best agents for the removal of this kind of gravel, yet offered to the profession. It may be used in conjunction with the use of Acetate or Citrate of Potash, suspending the employment

of the alkali whenever the urine becomes ammoniacal, or deposits phosphates.—For the solution of uric acid, the above-named alkaline salts are given to an adult in doses of forty or fifty grains dissolved in three or four ounces of water, and repeated every three hours; for children, the dose is from fifteen to thirty grains.

Among the remedies that have been successfully employed in uric acid gravel may be named, the Compound Pills of Soap; cold Infusion of Cleavers, Broad-leaf Cactus, or, Sickle-weed; Infusion of Wild Carrot Root; Syrup of Apple-tree Bark; Oil of Pumpkin Seeds, etc. No great success has yet followed the solvent treatment by injection of alkaline solutions into the bladder for stone; but when the calculi are small, and known to consist of uric acid, they may be so far dissolved and reduced in size as to permit them to escape through the urethra,—but the process is a slow one. Alkalies internally answer a much better purpose—and particularly in renal calculus where the calculus becomes obstructed or impacted. Nine-tenths of renal calculi are composed of uric acid.

Urates, when in excess, are frequently due to some derangement in the functions of the skin, to intemperance in eating or drinking, and may be found associated with the same conditions as named under Uric Acid. They require a similar treatment. (*See Urates*, pages 111 and 857.)

PHOSPHATIC GRAVEL.

When the urine is alkaline, phosphates are apt to be present; if the alkalinity be due to fixed alkali, the basic phosphate of lime, as well as carbonate of lime, may be precipitated; if it be due to carbonate of ammonia, the deposit will consist of the triple, mixed or secondary phosphates. (*See Phosphoric Acid and Phosphates*, pages 114 and 858). In addition to what has been heretofore remarked concerning *treatment*, I will observe that dilute acid solutions injected into the bladder have been found useful in phosphatic deposits. Syrup or sugar, used at meal-time, has been found to prevent a phosphatic deposit in the urine, in many instances. Infusions of Buchu, of Pareira Brava, and Fluid Extract of Hydrangea, have also proved beneficial. Tonics and alteratives are usually required, with attention to the skin, bowels, etc.; moderate exercise, nutritious diet; and, if necessary, anodynes to allay any general or local irritation.

As uric acid and phosphatic conditions of the urine, frequently

alternate with each other, the urine must be frequently examined, so that we may vary the treatment to suit the character of the deposit prevailing at the time.

OXALATE OF LIME GRAVEL.

I have but little to add to what has already been stated on pages 123 and 861. A pill composed of Aletridin, Leptandrin, Hydrastin, each, one grain, Extract of Nux Vomica one-twentieth of a grain, and given three times a day, will be found very advantageous, in conjunction with dilute Nitro-hydrochloric acid, in cases where gastro-hepatic derangement is present.—Any accompanying lesion should be removed or relieved by appropriate treatment, in all cases where oxalate of lime is present in the urine; and the use of calcareous water as a drink, as well as of articles containing oxalic acid, as sorrel, rhubarb plant, salad, onions, etc., as well as saccharine substances should be avoided.

CYSTINE DEPOSITS.

In addition to the *treatment* named on page 122, I will observe that alkaline solutions, as just referred to under Uric Acid Gravel, when they render the urine alkalescent, dissolve cystine much more readily than they do uric acid. Weak solutions of Nitric, Muratic, or Phosphoric Acid, injected into the bladder, also dissolve it, but more slowly.

Hippuric Acid, and other deposits will be found referred to on page 113.

GONORRHEA.

Gonorrhea, vulgarly called *Clap*, is an inflammation of the mucous membrane lining the urethra, generally of the anterior portion, and is accompanied with a muco-purulent, or purulent discharge of an infectious nature; it is a specific urethritis, due to the application of a morbid matter, generally, at the time of an impure cohabitation. Yet it may be due to an application of gonorrheal matter to the meatus, without cohabitation; or, to sexual contact during menstruation, which is occasionally met with. I have known gonorrhea to result from the meatus coming in contact with gonor-

rheal matter, partially dried, on sheets upon which the persons lay while sleeping in steamboats,—and though this mode of contracting the disease has been denied by some medical men, I have the most satisfactory evidence of its correctness.

An acrid leucorrhea may also give rise to a gonorrhea; indeed, instances are frequently met with where the husband has contracted a severe urethritis from his wife, who was affected with only a leucorrhea, or, perhaps, some vaginal inflammation; great care is, therefore, necessary, before pronouncing upon the disease, as the health and character of the parties, as well as the reputation of the physician, may be jeopardized by too premature or hasty conclusions. The urethritis thus produced may be infectious or not; in many instances, I have had positive reasons for knowing that the inflammation thus caused, was as infectious as the gonorrhea from an impure coition. I can see no reason why an acrid discharge from acute vaginitis, or an acrid leucorrhea, when it does develop urethritis in the male, may not be of an infectious nature. Indeed, I consider these affections, together with uncleanness of the parts, as the true and original source of gonorrhea. I have likewise no doubt but that many persons who have cohabited with females, at the period of menstruation, or when laboring under leucorrhea or vaginitis, might have escaped the subsequent attack of gonorrhea had they not aided the cause by excessive drinking of stimulating liquors immediately before or after the sexual acts, thereby rendering their urine more acrid and irritating.

I know of three instances in which immoral married women not laboring under gonorrhea or leucorrhea, imparted severe gonorrhea to their paramours; in each instance the men were married, and had not been with other women; and each of the females was affected with a constitutional syphilitic taint derived from her husband,—these women remained free from gonorrhea, while the other parties suffered. In one of these three cases, after the cure of the gonorrhea, the paramour continued cohabitation with the female for some time, without a renewal of the disease.—With some persons, a drop or two of a saturated solution of sal ammoniac let fall into the urethra, and allowed to remain there, will cause a severe urethritis, with a discharge that will prove equally as infectious as that from gonorrhea. We may have a non-infectious or an infectious gonorrhea (urethritis), the same as we may have an infectious or non-infectious ophthalmia.

A free indulgence in vinous and fermented liquors, internal use of turpentine or of cantharides, masturbation, and the introduc-

tion of foreign bodies into the urethra, are all occasional causes of gonorrhea.

The *symptoms* of gonorrhea more generally appear in from two to four days after an exposure; but, with some persons, they will not be developed until after two or three weeks. Sometimes, the first symptom observed will be a more or less severe burning pain on urinating; but, more commonly, the disease commences with an uneasy, itching sensation in the glans penis, with a fullness and redness of the lips of the meatus, and a soreness and tingling along the whole course of the urethra; a drop or two of a whitish purulent matter may be observed at the orifice, and micturition is attended with a scalding or burning pain, which, in first attacks, is frequently most acute. In a day or two, and sometimes later, this first stage is followed by an increased discharge of muco-purulent matter, which is sometimes thick, and at others very fluid, and of a yellowish color, often tinged with green, from the presence of blood-corpuscles. The glans penis presents a red and inflamed appearance, the urethral canal is quite sensitive and tender on pressure, the lips of the meatus are much swollen and red, the stream of urine becomes smaller, and, whenever voided, occasions much pain and scalding. In connection with these symptoms there may be soreness or pain in the groins, tenesmus, and most commonly an irritable condition of the bladder, with frequent calls to urinate, and a constant uneasiness about the scrotum, perineum, and anus. Sometimes febrile symptoms are present; and, the patient becomes pale and loses flesh rapidly. If the inflammation of the urethra be severe, more or less blood will be observed in the matter discharged. Most generally, after a person has had the disease one or twice, subsequent attacks are apt to be much milder, being, as it were, of a chronic character from the start.

“When the disease is located in the fossa navicularis—that portion of the urethra within the glans penis—the pain of micturition is confined to this part, and the discharge is comparatively small in quantity; when in the spongy portion, extending from the glans to the bulb, chordee is frequent, and the discharge abundant; when the bulbous portion is affected, there is pain in the perineum, chordee, and considerable irritability of the bladder; while, when the membranous part has to bear the brunt of the disease, there is most severe pain in the perineum, a frequent desire to micturate, tenesmus, and perhaps swelling of the prostate and testicles.” (*Tanner.*)

Chordee or painful nocturnal erection, is a very common symptom, especially when the urethritis is acute; it usually comes on

while the patient is in bed, sleeping and warm. It is more generally met with in the first attacks of gonorrhea; at the time of the erection the penis is curved downward, and the pain is so severe as to awaken the patient, and sometimes it occasions an involuntary emission of semen. Occasionally, it gives rise to hemorrhage from the urethra, owing to laceration of the mucous membrane, and which, when not too profuse, is of benefit. As in these cases of nocturnal erection, plastic lymph is effused around the urethral canal, the chordee may remain, after the urethritis has been removed, but with less severity, and may continue until absorption of this plastic matter has taken place.

Phymosis, or a swelling of the prepuce over the glans penis, so that it can not be drawn backward; and *Paraphymosis*, in which the prepuce becomes swoln behind the glans penis, so that it can not be drawn forward,—may be a consequence of the inflammation; though they frequently occur from various irritating causes. I have known them to be occasioned by masturbation.—The glands of the groin often become swoln and indurated from the excessive inflammation present, giving rise to *Sympathetic Bubo*.—Not unfrequently *gonorrheal epididymitis*, or *orchitis* exists, either from extension of the inflammation; or from sympathy, in which a testicle swells and becomes hard, with inflammation, and occasioning more or less excruciating pains, extending from the testicle upward to the inguinal canal, and into the small of the back, with symptomatic fever. The left testicle is the one more commonly affected; and not unfrequently the inflammation will leave one testicle and affect the other, and then perhaps return again to the first.—Sometimes small, hard swellings may be observed on the lower surface of the penis, along the course of the urethra, which may suppurate and give rise to troublesome fistulous ulcers.

If gonorrhea be properly attended to, it may be generally cured in from three to seven days; some persons, however, will require as many weeks, or even longer, especially in those cases where the cure is attempted by medicines, by mouth, alone. The disease is very apt to prove obstinate among those who have masturbated considerably, frequently requiring several weeks or even months for a cure. It will also be found more difficult of cure among persons of a scrofulous habit of body, and those who are anemic, as well as among those who continue using intoxicating liquors, high-seasoned food, much exercise, coition, etc., during treatment. With such persons a chronic gonorrhea or *Gleet* is very apt to ensue, and, in some instances, especially where there has been a neglect of proper cleanliness, the constitution becomes somewhat affected, as

manifested by rheumatic pains, excoriations or ulcers on the glans penis, sore throat and mouth, sores on the body and head, loss of hair, etc. (*See the remarks at the close of the treatment of this affection.*)

Long-standing, or improperly-treated gonorrhea, is very apt to be followed by *Stricture of the Urethra*.—And from the contact of gonorrheal matter with the neighboring parts, as, the corona glandis, perineum, etc., *Warty Excrescences* are apt to arise.

A primary chancre in the urethra may give rise to symptoms that may be mistaken for gonorrhea, but it may be known from gonorrhea by the following circumstances: It is more liable to be accompanied with a suppurating bubo; on everting the edges of the meatus, or opening the canal by means of a small forceps, the ulcer may be seen; we may also see it by means of an endoscope; the discharge is usually small in quantity, sanious, and bloody; a circumscribed induration will generally be felt at the part of the urethra where the ulcer is seated; a piece of lint attached to the end of a probe, will, when passed into the urethra, produce a soreness on coming in contact with the chancre, and when withdrawn will be found stained with the chancreous matter.

Among females gonorrhea is apt to cause similar symptoms, but usually of less severity,—as, heat and soreness in urinating, a discharge of colored matter, slight pain in walking, uneasiness in sitting, etc.

Cessation of pain and burning during micturition, diminution of the discharge, and of the vesical irritability, a gradual change of the matter discharged from purulent to mucous, and an improvement in the feelings and strength of the patient, are favorable indications, the forerunners of an approaching cure. (*See Gonorrheal Rheumatism, page 429*).

Treatment. As already remarked, when gonorrhea appears in the male for the first time, it is almost always accompanied with a greater degree of inflammation than in any subsequent attacks. When, therefore, we are called upon to treat the disease during its active inflammatory period, we should commence the treatment by the administration of an active purgative, as, the Compound Powder of Jalap, with Cream of Tartar added, or, Podophyllin and Cream of Tartar. The patient should also drink freely of some mucilaginous fluids, as, an Infusion of Marsh Mallow and Burdock Roots, with or without the addition of Alum, which addition will be found very advantageous in many cases, while with others, the addition of Nitre to the mucilaginous infusion will prove very serviceable. If the patient can remain at home, quiet, during the

first and second day of the attack, it will be much to his advantage. Fresh Stramonium Leaves, bruised, and applied around the penis, will be found most valuable; or, in their absence, a poultice of equal parts of the dried Stramonium Leaves, Lobelia Leaves, and Hops. With some, these poultices will answer a better purpose, if applied cold; with others, warm. In addition to these measures, injections carefully made into the urethra, immediately after each urination, will be found exceedingly useful; they may be composed of Glycerin one fluidounce in which is dissolved Extract of Belladonna half a drachm. What is termed the *abortive treatment*, by injections of Nitrate of Silver into the urethra, has often proved successful, but it is attended with considerable risk, and in my opinion is never required, and should never be used in any case.*

After the more active symptoms have been subdued, as well as in those cases where the disease is subacute or chronic from the commencement, injections should be used. For many years past I have entirely dispensed with the use of Copaiba and Cubebs in the treatment of this disease, and have in all cases, with but a few exceptions, effected cures without any internal medicines, save a purgative or two; using mild injections alone, and which have proved fully as efficacious as when similar solutions have been applied to an inflamed eye, or other inflamed mucous surfaces.

The injections should always be used immediately after urinating, and the patient should not urinate for at least half an hour afterward. A small glass syringe, or one made of hard rubber should invariably be used in preference to a metallic one; and the injections should be repeated three times a day. During their employment and until cured, the patient should support the scrotum and testes in a suspensory bandage, especially if he has to stand or move about much. The injections I more generally prefer, are the following:

1. Take of Sulphate of Quinia twenty grains, Elixir Vitriol one fluidrachm; mix, dissolve the Quinia, and then add to the solution, Camphor Water one fluidounce, Distilled Water three fluidounces, Solution of Iodide of Iron half a fluidrachm. I now make this injection known for the first time, and it will be found truly

*I have cured two cases of gonorrhea, in the early inflammatory stage, by hypodermic injections of solution of Muriate of Morphia. These injections will also be found very efficacious in the early stage of many inflammatory affections, as, Enteritis, Hepatitis, Nephritis, Pleuritis, Pneumonia, Conjunctivitis, Scleritis, Iritis, Choroiditis, Retinitis, Crural Phlebitis, Mammary Abscess, Pericarditis, Rheumatism, etc., and also in Asthma.

valuable. In case it acts too severely at first, it may be diluted with a little water, each time of using it.

2. Take of Strychnia two grains, strong Nitric Acid four drops, Distilled Water two fluidounces; mix, and dissolve the Strychnia.

3. Take of Chlorate of Potassa forty grains, Alum ten grains, clear soft Water three and a half fluidounces, Rose Water half a fluidounce; mix.

4. Take powdered Geranium two drachms, powdered Golden Seal half an ounce, Glycerin two fluidounces, Boiling Water two fluidounces; mix, let them stand for several days, frequently shaking, filter, and add from four to eight grains of Acetate of Zinc. This is especially useful in obstinate chronic cases, and in gleet.

Occasionally, other injections will be found serviceable, and, indeed, many have been recommended, but I will only name those that I have found useful, as :

5. Chloride of Zinc one grain, Distilled Water a fluidounce; mix.

6. Sulphate of Zinc two grains, Distilled Water a fluidounce; mix.

7. Acetate of Zinc from one to three grains, Distilled Water a fluidounce; mix. Iodide of Zinc may be substituted for the Acetate in scrofulous patients. A grain or two of Hydrochlorate, Sulphate, or Acetate of Morphia may be added to these solutions, if required.

The strength of the solutions may be increased as long as no irritation is produced. As an injection taken at bed-time favors chordee, it will be better to use the last injection about two hours before retiring for the night. The first and second formulæ for injections may be beneficially passed into the bladder, when the neck of this organ is inflamed or irritable, as manifested by frequent desire to urinate; and, in which case astringent injections should not be used. It may be proper to observe here, that sometimes injections appear to keep up the discharge; this may be obviated in most cases, by diluting the solution used, or by injecting only once or twice a day. A stricture of the urethra, or irritation at the neck of the bladder, will also keep up the discharge; the presence of stricture may be ascertained by the introduction of a bougie, and its cure by appropriate treatment will be followed by a gradual disappearance of the discharge. Vesical irritation may be removed by mucilaginous or alkaline drinks, sedatives, anodyne suppositories, quiet, etc.; Tincture of Sheep Laurel added to the mucilages, will also be found of essential service.

Soft pledgets of lint, introduced within the urethral canal to the

length of an inch or two, to keep the inflamed walls from contact with each other, and constantly kept moistened with one of the above solutions for injection, will often effect a cure. A new pledget should be introduced after each urination. It should not be too large in diameter, or it will increase the pain; a fine thread passed through the pledget, will prevent it from passing downward to the bladder, and will also enable the patient to withdraw it, whenever it is desired.*

Should internal remedies become necessary, as is apt to be the

* I have just noticed a statement taken from the *London Lancet*, relative to a new mode of cure for gonorrhea, by Mr. H. Thompson, at University College Hospital, and which I should deem an effectual method, from the fact that I have cured several cases by anointing the pledgets of lint, referred to above, or cotton-wick, with medicated ointments, and then passing them into the urethra. The statement is as follows:

"Believing that the imperfect action of injections depends upon the very short time that they are in contact with the mucous membrane, Mr. Thompson conceived the idea of applying the astringent in such a form as would enable it to remain for a much longer period in contact with the inflamed surface. Under his direction Messrs. Bell & Co. have constructed 'soluble bougies,' two or three inches in length, made of cacao butter, containing the drug it is wished to apply. They are cast in moulds, are perfectly firm and smooth, and may be used in any length, but that named has been deemed the best. A soluble bougie is equal in size to about No. 8 or 9 of the catheter scale, and may be introduced (having been previously oiled) by the patient himself into the urethra, where the material gradually melts in the space of about ten minutes. The patient is directed to slip one of these bougies into the passage on going to bed.

"After trying many methods of retaining the bougie *in situ*, Mr. Thompson has adopted the following: A piece of adhesive plaster is cut, nearly an inch wide and five inches long. A piece of Taylor's stout lint, of the same size, is rolled up into a little pad and laid on the center of the plaster, which is warmed and applied along the lower surface and dorsum of the penis, the prepuce meanwhile being fully retracted. A second strip of plaster, half the width of the first, is then put closely around the glans penis transversely. The bougies are made to contain either a quarter of a grain of nitrate of silver, a grain of tannin, two-thirds of a grain of acetate of lead, or ten grains of nitrate of bismuth, as astringents; while others are sedative also, and contain two grains of opium, or two of belladonna. Other materials can, of course, be employed. By this plan Mr. Thompson has satisfied himself that the active agent is kept for several hours in contact with the urethral surface, and is moreover, necessarily squeezed into the lacunæ, which often, doubtless, escape being acted upon by injections. It is by many supposed that these lacunæ, from harboring the discharge and escaping treatment, are the main cause of the persistence of gonorrhea. However that may be, there would seem little doubt that this mode of treatment permits the effectual application of the astringent, and thus promises better results than can be attained by the transitory action of injections. It is as yet too early to pronounce a decisive opinion of this process; but it is very ingenious, and we shall watch the results with interest." (*Lancet*.)

case when there is obstinate irritation at the neck of the bladder, and among certain strumous constitutions, I prefer the following :

1. Take of Canada Balsam half a fluidounce, Spirits of Nitre Dulcis two fluidounces, Oil of Turpentine one fluidrachm, pulverized Camphor thirty grains; mix well together. The dose is a teaspoonful three times a day. When the inflammatory symptoms have subsided, as well as in gleet, pulverized Kino half a drachm, may be added to the above.

2. Citrate of Iron and Quinia in doses of twelve grains, three times a day.

3. Take of Tincture of Chloride of Iron, Tincture of Cantharides, Tincture of Opium, each, two fluidrachms; mix. Dose from half a teaspoonful to a teaspoonful, to be taken in mucilage.

4. Take of Oil of Erigeron two fluidrachms, Oil of Sassafras one fluidrachm; mix. The dose is fifteen or twenty drops on sugar, to be repeated every three or four hours.

If Copaiba is preferred, the Compound Copaiba Mixture will be found equal to any.—A pill composed of equal parts¹ of Sumach Gum (the gum that exudes from the bark of *Rhus Glabrum*) and Canada Balsam, and pulverized Iron by Hydrogen, a sufficient quantity to form a pill-mass, will be found quite efficacious; it should be divided into five-grain pills, and one be taken every three hours. If the patient be of full habit or strong, pulverized Witch Hazle Bark may be substituted for the Iron.

Chordee is a very troublesome symptom, for which various means have been recommended; among them I prefer the following: Take Lupulin twenty grains, pulverized Camphor ten grains; mix for a dose—to be taken an hour before going to bed, and repeated at bed-time. The penis should also be well rubbed, along the direction of the urethral canal, with a mixture of Extract of Belladonna one drachm, Glycerin one fluidounce; or the following may be substituted: Take of Oil of Stillingia twenty minims, Oil of Lobelia forty minims, Tincture of Stramonium Seeds, Olive Oil, each, two fluidrachms; mix. Other compounds have also been successfully used, as, for instance, take of pulverized Opium a grain or two, pulverized Camphor ten grains; mix for a dose, to be taken at bed-time. Or, in cases where opium disagrees, the Camphor may be made into two or three pills with about five or six grains of Extract of Hyoseyamus. Ten grains of Camphor with two-thirds or one-fourth of a grain of Extract of Belladonna, is likewise beneficial. An injection into the urethra of a teaspoonful of a solution composed of Extract of Belladonna half a drachm, Glycerin, Water, each, half a fluidounce, will often prevent chor-

dee, especially if used some twenty or thirty minutes before going to bed. An ice-cold compress to the perineum will be very effectual. A suppository of Extract of Belladonna and Butter of Cacao, worn in the rectum during the night, has also afforded much relief. The patient should not lie upon his back, should sleep upon a hard mattress, and not be covered too warmly, and, when the chordee comes on, he should have a basin of cold water near, that he may at once arise and cold douche the organ. In all cases, the patient should not eat or drink anything for two or three hours before bed-time, and should have both the bladder and rectum evacuated before retiring. If very thirsty, at this time, he may relieve it by sucking a small piece of ice.

After a gonorrhea, that has been accompanied by a severe and obstinate chordee, is cured, there sometimes remains a contraction at the frenum, by which the penis is drawn downward, when erect, the same as in chordee, and which is sometimes termed "chronic chordee,"—a hardness will also usually be felt on the anterior surface of this portion of the canal, through the external coverings of the urethra; I have found the following preparations very efficacious in removing this condition,—they should be well rubbed over the part three or four times a day, or else be applied on lint: 1. Take of Extract of Conium (or of Belladonna) half an ounce, Oil of Stillingia one fluidrachm, Camphor, Laudanum, each, half an ounce; mix, and triturate thoroughly together. 2. Take of Oil of Sassafras half a fluidounce, Camphor, Opium, each, half a drachm, Iodine twenty grains; mix, and triturate thoroughly together.—Sometimes, from the inflammation and the chordee there will be an obliteration of some of the cells, (from rupture, or lymph deposit), in which case the patients will never afterward have perfect erections.

If *phymosis* or *paraphymosis* attends, an operation is not necessary. Apply over the swollen part, a warm or cold fomentation, as appears to answer best, of equal parts of Lobelia, Stramonium Leaves and Hops; and if the symptoms are obstinate, leeches may also be applied. If necessary, the means named for phymosis, etc., in the Note, page 449, may be employed.—When either of these difficulties are of long-standing, the following means should always be tried before resorting to an operation: Rub well upon the swollen and indurated part, a strong solution of Iodide of Ammonium, and then apply over it the following astringent poultice: Take of Lobelia, Bayberry Bark, Witch Hazel Bark, and Bloodroot, each, in powder, half a drachm, pulverized Elm Bark half an ounce; mix,

and form a poultice with water a sufficient quantity. Sometimes, an operation may be required,—but rarely, however.

Sympathetic Bubo may generally be relieved by a plaster of Extract of Belladonna, worn constantly upon the enlargement, the patient keeping as quiet as possible; or, the following may be kept constantly applied to the tumor by means of lint: Take of Tincture of Conium Maculatum, Water, each, a fluidounce, Muriate of Ammonia two drachms; mix, and make a lotion. If the bubo be severe, or tends to suppurate, as is sometimes the case with scrofulous subjects, treat as named in *Note on* page 451. Iodized Oil of Juniper will be found an excellent local application for syphilitic bubo.

Gonorrheal epididymitis or *swelled testicle*, requires that the patient should remain in bed, in a state of quiet, and a poultice of equal parts of Lobelia and Stramonium Leaves should be applied to the parts, renewing it two or three times a day. Each time before applying the poultice, have the scrotum thoroughly rubbed with the following liniment: Take of Camphor, Olive Oil, Oil of Anise, each, half an ounce; mix. In the early part of the attack, especially when it is very severe, leeches should be applied to the scrotum, before the other measures are adopted. It has been advised to apply them just below the external ring of the abdomen, over the cord, instead of to the scrotum, as being much more advantageous. If the constitution suffers much, give the Compound Powder of Ipecacuanha and Opium. When the inflammation is very severe, nauseating doses of Lobelia will be found highly beneficial.—A strong solution of Hydrochlorate of Ammonia in Water applied to the scrotum on a single thickness of muslin, so that it may evaporate and keep the part cold, and even the application of ice-cold compresses, have been used with advantage, but I have never had occasion to employ them.

When the swelling has continued for some time, febrile or active inflammatory symptoms being absent, continue the poultices, and instead of the above liniment use the following: Take of strong Aqua Ammonia, Oil of Sweet Almonds, each, a fluidounce, Tincture of Capsicum two fluidrachms; mix. And internally give the following pills, one or two a day, gradually increased: Take of Extract of Conium half a drachm, Iodine fifteen grains; mix thoroughly together and divide into thirty pills.—An indurated condition of the epididymis may follow swelled testicle, resulting in sterility, the fluid discharged during coition containing no spermatic filaments—of course this only follows double epididymitis. Iodide of Ammonium, in solution, to the part, the use of a

suspensory bandage, regular bowels, attentions to the skin, and Iodide of Ammonium internally, are the means to pursue to remedy this difficulty.

Warty excrescences may be removed by carefully touching them with Nitrate of Silver; strong Nitric Acid; Chromic Acid twenty-five grains to two fluidrachms of Water; or a mixture of Tincture of Chloride of Iron, dilute Hydrochloric Acid, each, two fluidrachms. In applying these articles, care should be taken not to permit them to come in contact with the neighboring healthy tissues, but only with the morbid vegetations. A saturated solution of Hydrochlorate of Ammonia; powdered Savin Leaves and Alum, equal parts; and Hydrochlorate of Ammonia dissolved in Vinegar, have all been found useful as local applications. Dr. Goddard has found an application of powdered Bistort or Tormentilla Root, to be very efficient. When the excrescences are large, they should be removed by ligature when their base is broad, or clipped off with a sharp scissors when it is small, and the portion left behind from which they spring should then be destroyed by the application of caustic to the cut or exposed surface.

The *eczema* on the glans, and even on the body of the penis, in the form of small red vesicles with heat and itching, which is often observed after coition, may be due to uncleanness, leucorrhea, etc., and may be readily removed by cleanliness, and bathing with the Lotion of Borax with Morphia. It frequently occurs even among cleanly parties without any attributable cause. If the itching be due to lice, *pediculus pubis*, washing twice a day, for several days with undiluted Cologne will thoroughly remove them; or, with a dilute solution of Carbolic Acid.

Gleet or *Blennorrhœa* is the result of an improper or unsuccessful treatment of gonorrhœa, or of an entire neglect of treatment. It consists of a persistent slight discharge from the urethra, without any scalding or pain during urination. The discharge may be so small as merely to glue the lips of the meatus together every morning, or it may amount to a drachm or two per day; it may be clear and transparent, thin, thick, or purulent, and sometimes passes in coagulated shreds or masses. An itching sensation in some part of the urethral canal, and obscure, transient pains, generally accompany it. And when the prostate or vesical neck is irritated, there will be frequent calls to urinate. The urine usually contains more or less mucus, and sometimes a few pus-globules, with epithelial cells and free nuclei. Although gleet patients have had sexual intercourse without any infection, still, it has been fully demonstrated by past experience, that the discharge is infec-

tious, and that no woman is safe with whom they have sexual congress.

The conditions present during gleet, and which appear to be its sustaining cause are, a chronic granular inflammation of some portion of the urethral wall, or of the prostatic portion, as has been detected by the endoscope,—with, in many cases, granular ulceration; urethral stricture or growths within the canal; morbid irritation of the prostate and neck of the bladder; enlargement of the prostate, etc. And this discharge will be kept up by sexual excesses, overexercise, constipation, masturbation, indulgence in saccharine substances or, in stimulating drinks, more especially beer, ale, and other fermented fluids; it will likewise be maintained by constitutional debility, as well as by a strumous, or rheumatic tendency. A bougie passed over the affected part almost invariably produces a painful sense of soreness, and may, when withdrawn, be found tinged with blood. By means of the endoscope the character and the exact seat of the disease may be seen, and the remedies be applied directly upon the morbid spot.

When gleet depends upon stricture, prostatic enlargement, growths in the urethra, or vesical irritation, the removal of these by the appropriate means will generally be followed by a disappearance of the discharge. When it is due to a granular condition, or granulous ulceration of some portion or portions of the canal, it may be cured by direct applications to the part, through the endoscope, or by one of the following measures: for injections or local applications, Nos. 1, 2, 3, or 4, referred to under injections for gonorrhea, may be used,—and for internal remedies one of the following may be administered:

1. Take of Extract of Nux Vomica twenty-four grains, Sulphate of Quinia, Extract of Hyoscyamus, each, forty-eight grains; mix, and divide into forty-eight pills, the dose of which is one or two pills three times a day, about an hour previous to each meal.

2. Take of Tincture of Blue Flag, Tincture of Mandrake, each, seven fluidrachms, Tincture of Nux Vomica two fluidrachms; mix. The dose is from ten to fifteen drops in water, repeated two or three times a day.

3. Bromide of Potassium internally, with Compound Tar Plaster to the perineum, has effected cures in obstinate cases depending upon prostatic malady or obstinate irritability of the neck of the bladder.

4. Tincture of Sheep Laurel Leaves in doses of ten or twenty drops, three times a day.

5. Take of Sulphate of Quinia twenty grains, Elixir Vitriol, one

fluidrachm; mix, and dissolve the quinia. Then add Tincture of Chloride of Iron one fluidounce. The dose is twenty drops, in water, to be repeated every four hours. Used in debilitated constitutions.

Where there are tender spots or ulcerations in the canal, the following applications have been found beneficial: 1. Take of Tincture of Chloride of Iron two fluidrachms, Wine of Opium half a fluidounce, Rose Water two fluidounces; inject into the urethra, so as to come in contact with the tender part, and retain it there five or ten minutes,—and repeat the injection several times a day.—2. Take of pulverized Opium one scruple, Chloride of Zinc five or ten grains, Spermaceti Ointment one ounce; mix. Apply along the whole course of the urethra every night, continuing its use until it causes no smarting, spasm, or reflex pain.—3. Take of Chloride of Zinc three grains, Chloride of Gold and Soda one grain and a half, Hydrochlorate of Morphia four grains, Distilled Water two to four fluidounces; mix. This will be found especially useful in those cases where an extremely painful and irritable ulcer exists in the neighborhood of the fossa navicularis or near the meatus, applying it two or three times a day, and, in some cases, aided by the daily introduction and retention for about five or ten minutes, of a steel bougie. Indeed, the careful introduction of a bougie, medicated or not, and whether stricture be present or absent, is often followed by a cure; the bougie should be of as large calibre as possible to pass without difficulty or great pain. Its use should be omitted if it increases the discharge.

Much irritability of the neck of the bladder in either gonorrhea or gleet, may be removed by a mixture of one drachm of Bicarbonate of Potassa, half a fluidounce of Tincture of Hyoscyamus, and two and a half fluidounces of Infusion of Marsh Mallow, to be taken in tablespoonful doses every three or four hours.—In many cases of gleet the preparation of Tinctures of Chloride of Iron and Cantharides, named under Gonorrhea, No. 3., may be administered with decided benefit.

In gonorrhea, the patient should keep as quiet as possible, the more so the better for him, and after the more active period has passed, his diet must be light, but nutritious and easy of digestion, avoiding high-seasoned food, acids, fats, coffee, asparagus, tomatoes, pepper, saccharine articles, too much salt, and all intoxicating drinks, especially the vinous and fermented. A suspensory bandage should be worn all the time, especially if he moves about much, the bowels must be kept regular, and coition be positively prohibited. If he be weak or anemic, tonics and preparations of

Iron should be given in conjunction with the other treatment; if he be scrofulous, Iodide of Iron, Iodide of Potassium, or the Bromides, etc., may be given; if he be rheumatic, Colehicum, Black Cohosh, Iodide of Potassium, etc., should be administered, omitting, however, the Iodide of Potassium whenever it increases the discharge. The same rules are applicable to gleet.

Balanitis is an inflamed, excoriated, or ulcerated condition of the mucous membrane covering the glans penis, or the prepuce, with a discharge upon the surface, or, curdy flakes of matter, and heat and itching. Sometimes the ulceration will extend quite deeply. It may be caused by long prepuce, uncleanness of the parts, matters from the vagina, gleet matter coming in contact with the parts, and secondary syphilitic matters. It may exist simple, or be complicated with phimosis or gonorrhea. It may be removed by cleanliness of the parts, and washing with a weak solution of Tincture of Chloride of Iron, Alum, Nitrate of Silver, Tannin, or Chlorate of Potassa. If phimosis be present, this must be removed by the appropriate means, injecting one of the above-named solutions between the glans and prepuce, three or four times a day. If gonorrhea, warty excrescences, gleet, or stricture be present, these must be treated by the usual means. When associated with, or due to a syphilitic taint, as from uterine discharges of a constitutional syphilitic nature coming in contact with the glans penis, constitutional treatment must be pursued.

Before closing my remarks on gonorrhea, I would state that in quite a number of instances I have observed the disease to be followed, in six or twelve months after its apparent cure, by one or all of the following symptoms, viz.; tenderness of the scalp, falling out of the hair, sore mouth and tongue, fissures in the mouth, balano-postitis, anal and nasal fissures, cutaneous eruptions, obstinate gleet discharge, stiffness of joints, tendency to orchitis, etc. In the majority of these cases I have satisfactorily ascertained that the females from whom the gonorrhea was derived, had no obvious syphilis, but were probably tainted with the disease from previous infections. Can it be that a syphilitic taint in the system can so far influence the gonorrheal or leucorrheal discharge from a female as to infect another party, in coitus, and give rise to the above symptoms? These cases are usually cured by Harlem Oil, in conjunction with the Iodide of Ammonium.

STRICTURE OF THE URETHRA.

Stricture of the Urethra is an abnormal contraction of some portion of the urethral canal, owing to organic deposit in or around the walls of the urethra (permanent or organic stricture); to local vascular inflammation or congestion (temporary inflammatory stricture); or to unwonted muscular action alone (spasmodic stricture). The last form may exist alone, or may complicate either of the two preceding ones.*

The *causes* of Organic stricture are various, the most common being a neglected or badly treated gonorrhea, in which it frequently exists as a cicatricial condition of the parts, following granular urethritis, or granular ulceration. However, stricture may follow inflammation of the urethral canal, whatever may be its cause, and is aggravated and occasionally caused by astringent injections during the period of active inflammation; the improper use of caustics; injuries to the parts; the forcible or improper introduction of foreign bodies into the urethra, as is often done by masturbators, unskillful or unqualified practitioners, etc.; riding on horseback; abuse of fermented liquors; a long continued irritation of the urethral walls, from acrid urine, presence of foreign bodies, growths, or deposits in the urethra, etc.

Inflammatory stricture may be occasioned by gonorrheal inflammation; exposures to cold and moisture; sitting upon cold or damp ground; or by whatever will occasion a vascular congestion of the urethra. This is due to a chronic inflammation of the spongy tissue, and may be located at any part of the canal where this tissue exists.—Spasmodic stricture may be caused by certain excitants when organic or inflammatory stricture is present; abrasion or ulceration of the mucous membrane at the part; rheumatic or gouty diathesis; cold; sexual excesses; horseback riding; violent exercise or straining; hemorrhoids; etc. It is more commonly met with among those who are laboring under permanent stricture, who have phosphatic deposits in the urine, or who have urethral irritability resulting from the use of acids, wines, fermented liquors, cantharides, exposures to cold and damp, improper use of injections, etc. Spasmodic stricture is generally located in that portion of the canal, nearly or entirely surrounded by the *acceleratores urinæ* and Wilson's muscles, that is, of the sphincters,

* In the description of stricture I am greatly indebted to the excellent work of H. Thompson on the *Pathology and Treatment of Stricture of the Urethra*, which should find a place in the library of every medical man. (K.)

internal sphincter or vesico-urethral orifice, and external sphincter or muscular portion,—and, from the resistance presented to the free and rapid advance of the bougie at these points, they have often been mistaken and treated for organic stricture; and in highly irritable urethras affected with spasmodic stricture, the mucous membrane may be so greatly engorged as to arrest the bougie even at two, three, or four inches from the meatus.

The *symptoms* of organic or permanent stricture may or may not be preceded by a gleet discharge, more commonly this discharge is present in greater or less quantity, as well as an uneasy sensation in the urethra, itchings, or pricking pains. The patient having, as he supposes, thoroughly emptied his bladder, observes a few drops to leak out and moisten his linen. Urination occurs somewhat more frequently than before, and the stream of urine becomes more or less flattened, divides into two or more streams, or passes in a twisted or spiral manner, and gradually diminishes in size; ultimately urination becomes difficult and painful; the patient strains and draws out the penis with considerable force, for the purpose of facilitating the escape of the urine, which in the advanced stage passes drop by drop. Associated with these symptoms are soreness or smarting about the neck of the bladder, a constant but faint desire to void urine, pain above and behind the pubes, dull aching pain in the back, loins, and glans penis, and sometimes severe shooting pain in one or both testicles. Nocturnal emissions are by no means infrequent; and coitus is often accompanied with pain. Gleet is a common accompanying symptom of stricture. Frequently the urine will be mingled with pus, and at times becomes very thick, and accompanying this condition, there will be more or less severe rigors. Sometimes the urine will be white or bloody, indicating a serious character of the disease. From the great straining effort to empty the bladder, in the advanced stage, hemorrhoids, prolapsus of the rectum, and even inguinal hernia have been produced. Impotency, or a partial or complete loss of the erectile power of the penis, is often observed.—If the stricture be allowed to go on, dilatation of that portion of the urethra located behind the strictured part will ensue; the prostate gland, the bladder, and even the kidneys become irritated and inflamed; thickening and ulceration of the vesical coat may occur; and finally chronic urinary abscesses are formed, with fistulous canals in and around the perineum, scrotum, and adjacent parts, and the patient is eventually destroyed. Death may also occur from rupture of the urethra, rupture of the bladder, uræmic poisoning, irritative fever, etc.

The symptoms of inflammatory stricture are, an unusual heat, sense of fullness and tenderness of the perineum, the stream of urine becoming much smaller, and accompanied with great burning pain. It finally passes in smaller and smaller jets, with much straining and tenesmus, until it finally ceases to pass at all. There is inflammation and swelling of the mucous and submucous tissues, with an exquisitely sensitive condition of the urethra. Irritating or astringent injections increase the severity of the symptoms.

The symptoms of spasmodic stricture usually come on suddenly, but without pain, the patient being unable to void his urine, or it may pass with difficulty; the bladder becomes distended, there is an anxiety of countenance, a hot skin, and a quick pulse. It may follow a voluntary retention of urine, excessive coitus, violent exercise, free use of wine or other liquors, the use of cantharides, turpentine, and other stimulants, derangements of the chylopoietic viscera, etc.

Dimensions, etc., of the Urethra. According to careful observations it has been ascertained that the length of the urethra during life is about seven and a half inches, and after death eight and a half or nine inches; these are the average and more constant measurements, which may, however, occasionally be found greater or less. The diameter of the canal varies according to the part, though it must be recollected that in the state of vacuity it presents no cavity, its walls being applied against each other. This cavity is only formed by the introduction of foreign bodies, and, notwithstanding the variations in the diameter, the urethral walls may be dilated or expanded according to the size of the instrument introduced and the degree of force employed. In the natural state the diameters at various points are about as follows: at the meatus, two and three-fourths to three and one-tenth lines; at the fossa navicularis, three and nine-tenths to four and three-tenths lines; directly behind the fossa, three and one-half lines; middle of the spongy portion, three and nine-tenths lines; cul-de-sac of the bulb, four and seven-tenths lines; membranous portion, three and one-half lines; commencement of the prostatic portion, three and nine-tenths lines; center of the prostate, five and nine-tenths lines; urethro-vesical orifice, four and three-tenths lines.

The urethral canal, in an operator's point, consists of an extrapubic, movable, or pendent portion, and an infra-pubic or slightly movable portion; the first comprises the spongy portion, which, however, is less movable in that part nearest the membranous region, and which, when the penis is flaccid, may be moved in almost any direction; the second, comprises the muscular or mem-

branous, and the prostatic regions.—The membranous region is about from eight to ten lines in length, and passes in a direction obliquely downward and backward, it connects anteriorly with the spongy portion, and posteriorly with the prostatic; at its posterior part it forms the bulbous part of the urethra, which, toward its termination and as far as the middle of the prostatic portion is very dilatable. The whole of the membranous portion is extensible by slow dilatation.—The prostatic region is from nine and two-thirds to eleven and one-third lines in length, passes subhorizontally, and a little obliquely upward and backward in the living body, owing to the contraction of the levator ani muscle. In this region is contained the veru montanum, prostatic and seminal ducts, and the sinus pocularis; this is the most capacious portion of the whole urethral canal.—The spongy region comprises all that portion of the canal between the meatus and the membranous region, and is more dilatable inferiorly than superiorly, because of the greater thickness of the spongy tissue in the first direction.

When the penis is in a flaccid condition, the urethra has two directions, forming a blunt angle with each other, that is vertical, from below upward, and horizontal from front backward, and yet, by bringing the first in the proper direction, the whole of the canal may be made equally horizontal so as to readily admit the passage of straight catheters, endoscope tubes, etc. In a state of erection of the penis, the urethra forms an angle of about 55° to 65° with the body, giving a curve to itself at its pubic portion, termed the subpubic curve, and which describes an arc of a circle three and one-quarter inches in diameter, the cord of the arc being two and three-quarter inches.

The different parts of the urethral canal, in a healthy state, furnish different sensations according to their degree of elasticity and extensibility, when a catheter or bougie is introduced; a bulbous bougie having a diameter of about two and a half lines is the best to use,—its arrest would indicate pathological conditions that a less diameter would not detect. The size of the bulbous part may be adapted to that of the meatus urinarius, as one that will readily pass the meatus can generally be introduced without trouble throughout the whole length of the canal.—In the spongy and prostatic portions a velvety sensation is imparted to the hand of the operator; in the fossa navicularis, the membranous region, and at the urethro-vesical orifice, a sensation of friction or rubbing, but not hard as in the case of strictures; and the muscular or membranous portion in particular gives a sensation of prehension. At the bottom of the cul-de-sac of the bulb, at the entrance of the

membranous portion, the instrument is often arrested, as if an obstacle existed there; there is also a slight arrest at the urethro-vesical orifice.

The person operated upon will experience a more or less sensitive condition of the mucous membrane of the fossa navicularis, so much so with some parties, that they faint or become convulsed as soon as the instrument enters this part. This sensibility becomes blunted after the catheter has passed beyond the fossa, but often re-appears at the subpubic curve, to be again lost as far as to the termination of the bulb. Upon entering the muscular portion, a special sensibility exists; the person experiences a desire to urinate, and throughout this portion he often experiences the same sensation as if he were urinating. These sensations are usually feeble in the normal state, but are increased in a pathological condition. The contact of an instrument with this portion often causes increased perspiration upon the surface of the body, a feeling of weakness, and even faintings; but this phenomenon is not exclusive to this region, being often experienced at the fossa navicularis. Pains in the infra-pubic portion are often reflected into the glans penis and the inferior surface of the fossa navicularis, where they occasion itchings or ticklings; on the contrary, these itchings in the glans may cause contraction of the perineal muscles. When the instrument has entered the bladder, all these sensations disappear.

A bougie may be arrested in its course through the urethra by the valvule at the posterior extremity of the superior wall of the fossa navicularis; at the termination or cul-de-sac of the bulb; and small instruments may likewise be arrested by entering one of the numerous openings along the inferior wall of the canal, the sinus pocularis, or one of the ejaculatory orifices. In such cases we slightly withdraw the instrument, and attempt its passage in another direction, in order to free it from the obstacle; in passing the cul-de-sac of the bulb it may become necessary to elevate the beak of the instrument a little, in order that it may pass, and which requires the introduction of a finger into the rectum.

Organic strictures of inflammatory origin commence insensibly, in such a manner that there exists between the healthy part and the maximum point of the stricture, an infundibulum that conducts to this point. Those of traumatic origin commence suddenly. The orifice of the strictured point may, in regard to diameter, run through the entire scale from the normal caliber of the canal to its complete obliteration; it may be central, or more or less eccentric, according as the band of indurated tissue completely or incompletely surrounds the urethra.

Strictures are generally quite short, (linear), but often multiple. The orifices of the successive strictures pursue the same directions, or else opposite directions, in zigzag, or rather in a sinuous form, as the infundibulum that precedes strictures of inflammatory origin gives rise, between two points more contracted, to a pipe or passage that is a little smaller and that gradually unites them; in other words, successive strictures with opposed orifices are not abrupt like those of traumatic origin.

Occasionally, however, strictures are very long, and may even affect the whole length of the spongy portion. When they have a certain length, either they are not uniform, presenting points successively more strictured, which give to the bougie a sensation of jerkings, or else they are uniform and result from an atrophy, probably from induration of the spongy body following chronic inflammation; the urethra is then reduced to a hard, ligamentous cord with a narrow canal.

Incomplete strictures are generally dilatable, the complete or circular are not if all the spongy tissue is invaded. The less the spongy tissue is affected the more dilatable will be the stricture. Callous strictures are seldom dilatable. Strictures at the bulbous portion are exceedingly dilatable. Strictures attended by a highly irritable condition of the urethra, that are seated at the meatus, or at the fossa navicula, and sometimes those located at the middle of the spongy portion are hardly dilatable, and may require incision or internal division, more especially those of a circular form at the meatus, and those at the fossa. Old and extensive strictures usually require either internal division or external urethrotomy; internal division being more applicable to strictures seated in the anterior part of the urethra.

Organic strictures exist only in the spongy portion, and not in the membranous, nor in the prostatic. They occur more frequently at the subpubic curvature, that is, at the junction between the spongy and membranous portions, especially at the posterior or bulbous part of the spongy portion,—are less common as the junction is approached,—and are exceedingly rare behind the junction. The next most frequent location is at the meatus urinaris and the fossa navicularis; and finally at the peno-scrotal angle or center of the spongy portion, as well as along this portion to the fossa.

Organic strictures are met with under various forms, according to their location, and the amount of fibrinous deposit producing them, and have been classified (*Thompson*) as follows:

1. *Linear Stricture*, (bridle stricture, valvular stricture). This is

a thin membranous diaphragm stretched across the urethral canal, with one or more perforations, and embracing the whole canal like a narrow ring, or only a part of it like a crescentic septum. The septum may extend directly across the canal, and sometimes it runs obliquely. Occasionally several of these linear strictures, in the form of small narrow bands stretching across the urethra, may be met with. Bridles or valvules are often constituted by the development of the mucous follicles, and open either in front, or behind.

2. *Annular Stricture* is when the narrowing caused by the thickening of the mucous membrane embraces a larger portion of the urethra, not exceeding the fourth or the third of an inch. The strictured part appears as if a cord had been tied round that portion of the canal.

3. *Indurated Annular Stricture*. In this form the indurated deposit involves more or less of the corpus spongiosum and may be of any length not exceeding half an inch, the center of this space being the most contracted part, giving an hour-glass or infundibuliform appearance to the affected portion. The induration is generally thicker on the lower than on the upper part of the canal, and is often appreciable by the finger from the external surface.

4. *Irregular or Tortuous Strictures*. In which the induration extends deeply into the surrounding tissues, often involving the entire thickness of the spongy body, forming hard masses appreciable by the finger; the contraction may be of any length from half an inch to an inch or more, may be regular or irregular, and the canal generally deviates more or less from its proper direction.

Strictures have also been pathologically classified (*Thompson*) as follows:

1. *Simple Stricture*, in which there is diminution in the size of the urinary stream, with frequent micturition and great variation in the amount passed.—2. *Irritable Stricture*, attended with chilliness, irregular circulation, rigors on very slight irritation; and the gentlest employment of instruments causes great pain, and sometimes hemorrhage.—3. *Contractile or Recurring Stricture*, in which there is a constant tendency to become narrower in the absence of treatment; and contraction rapidly recurs after dilatation has been applied.

Complete obliteration of the urethra, although very rare, may exist; but it is always accompanied with fistula behind, and results from traumatic causes as well as from urethritis.

Diagnosis of Stricture. Although we may know of the existence of a previous urethritis, or of an injury, preceding the symptoms

above named, yet we should not rely too much upon them in determining the presence of a stricture; in every case, therefore, the urethra should be carefully explored by bougies or sounds, using at first one of a medium size, and increasing or decreasing the caliber according as the instrument selected passes through the canal, or becomes arrested at one or more points. It must be borne in mind that a complete exploration can not always be made at first, from the peculiar sensitiveness of the urethra, and that, consequently, it frequently becomes necessary to accustom the canal to the contact of instruments, by passing wax or elastic bougies through to the bladder for six or eight days in succession. The object of the exploration is to ascertain the exact seat of the stricture, its diameter, extent, situation of its orifice, whether there are more than one, and whether any complications exist, as, false passages, foreign bodies, hyperæsthesia, prostatic disease, etc.

With regard to the introduction of the catheter or bougie for urethral exploration, the same rules are to be observed as named hereafter for dilating the stricture, carrying the instrument through the canal to the bladder. In introducing it for the first two inches, the beak of the instrument should be directed against the lower wall of the urethra in order to avoid its hitching in a large lacuna upon the upper wall. If the instrument passes readily onward until it reaches the subpubic curve, it may be arrested in its progress in this neighborhood without any stricture being present, but which may be overcome by gentle manipulation, as by withdrawing the instrument a little and then advancing it in another direction, and so proceeding carefully until it passes; it may also be arrested at the prostatic entrance, and after having advanced fifteen or twenty lines from this point, to the urethro-vesical orifice;—but by steadily and gently pressing the beak of the instrument against these parts, they will soon yield and the catheter will proceed until it enters the bladder, which may be known by the flow of urine, if a catheter be used.

The rules for the exploration are as follows: To avoid making a false passage, as well as to determine the existence of one if it exists, in order to avoid censure; to pass the instrument *gently*, using no force, lest a false passage be made; to pass the instrument beyond the sinus or cul-de-sac of the bulb, by gently withdrawing it a little, then with its beak resting on the upper wall to advance it, and, if necessary, stretching the penis by traction, or, perhaps elevating the beak by a finger placed underneath it; if stricture be present, a sensation of pain is developed at some part of the canal where none exists in a normal state, the beak pressing upon this

point; if we continue to advance the catheter when this pain is produced, it becomes increased, and the instrument is either arrested, or passes for a distance of from three to eleven lines, the usual length of a stricture, imparting a sensation of friction and as if going through a small, grasping orifice; if the instrument be arrested, it must be withdrawn and a smaller one be introduced, and so on until a size is obtained that will pass beyond the obstacle; after having passed the stricture the friction ceases, and we have the velvety sensation of the normal walls with cessation of the pain; the friction experienced as the instrument passes through the stricture, is of a rigid character, like penetrating a tube of parchment, and it is held tightly,—in a long stricture, the friction is irregular, giving inequalities, rugosities, jerkings, or as if the bougie were passing over granulations or sand; if several strictures exist and are more than three and a half lines from each other, they may readily be distinguished, but, if they are less than this distance there will be some difficulty in determining them by the olive bougie; in bringing the olive from behind forward, the resistance of the last stricture passed, and its compression can be clearly felt,—by continuing to draw, the ball suddenly penetrates, and we have the same sensations as before, but more distinct,—the extent of the stricture may be known by the distance at which the obstacle was observed from before backward, and that obtained from behind forward, being careful to subtract the length of the ball; the exploring catheter should be graduated, and the seat of the stricture will be known by the depth at which the instrument penetrates before causing pain, or before being arrested; its diameter may be known by comparing it with that of the instrument that will pass through it; their extent and number can only be determined when they are permeable, and may be better made out by bougies with olive-shaped extremity. These olive bougies should be carefully moved two or three times from before backward and from behind forward at the strictured point,—if the contraction commences and terminates by a funnel shape, which is peculiar to strictures of inflammatory origin, a certain increasing and decreasing friction will be experienced before the compression or arrest is felt, according as the instrument is carried from or toward the contracted part; if bridles exist, they will be indicated by the sudden jerk or jump the instrument undergoes at the part where they exist, and according as this jerk occurs from before backward or from behind forward will we know the direction in which the bridle is inclined.

The central or excentric situation of the orifice of the stricture

may be determined by impressions, except at the termination of the bulb where it is always excentric, even in the normal state. Wax bougies, or model (impression) bougies may be used for this purpose, allowing them to remain pressing upon the part for two or three minutes to obtain the impression of the stricture, its permeability or impermeability, and any false passage just anterior to it. A model bougie is formed by attaching to the beak of an ordinary bougie, a soft composition consisting of equal parts of bees-wax, diachylon, and shoemakers' wax, working this into a cylindrical shape.—The presence of ulcers, granulations, or strictures in the urethra, their peculiar characters, etc., may also be readily ascertained by means of the endoscope.—It may be remarked here that, provided urine flows in a stream, the urethral canal not being impermeable, it is not essentially necessary to determine the exact number of strictures present, as the posterior ones can be correctly diagnosed as we continue to dilate or cure the anterior ones, or, in other words, we perfect our diagnosis of the condition of the canal as we proceed in our treatment.

With regard to the detection of false passages, ulcers, foreign growths, etc., in the urethra, as well as to their treatment, we refer the reader to surgical works, and those which specially treat upon them, among which Thompson's is, at this day, the best.

The *post-mortem appearances* of stricture are, a loss of the redness of the mucous membrane of the urethra, which is thickened, indurated, rough, or corrugated, with a few transverse bands of whitish fibres beneath the mucous membrane, encircling and narrowing the canal, and, in severe cases, the meshes of the submucous cellular tissue, and even the erectile tissue, are filled with lymph deposit, forming a hard, inelastic, and more or less unyielding mass. The substance forming the deposit is observed, under the microscope, to be the same as that met with in other inflammatory infiltrations, and possessing similar histological elements, instances of which are met with in the interstitial deposit producing cirrhosis of the liver, and in the cicatrices of burns.

The *prognosis* of stricture depends much upon the attention paid to it by both the practitioner and the patient; bridle or valvular, incomplete, and recent strictures are more readily curable than others; while annular, or complete strictures, indurated, and those of long standing, are very tedious and difficult of cure. Strictures resulting from atrophy of the tissues around the urethra, are very difficult of cure. Complications often exist in advanced strictures which may render the prognosis doubtful as abscesses, fistulas, ex-

travasation of urine into the tissues, hernia, complete retention of urine requiring puncture of the bladder, etc.

In the *treatment* of strictures four methods are employed, viz., dilatation, cauterization, internal division, and external urethrotomy. The last three are usually performed in very difficult and obstinate cases, (excepting strictures at or near the meatus), and consequently belong more especially to the domain of surgery. In this work we will devote a few pages to the cure by dilatation, which is applicable to more recent and incomplete strictures, and to the major part of cases presented to the physician's notice, and which consists principally in the careful introduction of flexible or metallic bougies into the urethra, from time to time, in order to promote absorption of the morbid deposition. When the stricture is very small, or the urethra irritable, catgut or small elastic bougies may at first be employed. Experienced physicians, with the proper knowledge of the anatomy of the parts usually prefer metallic instruments, but in the hands of those of less experience and knowledge, the elastic ones are much safer. Before attempting the introduction, the patient should evacuate his bladder.

Having ascertained the size of the bougie required for the commencement of treatment, by the previous exploration, and the patient standing in front of the physician, or, which I prefer, lying upon his back with the shoulders slightly elevated, the medical man will proceed to pass the instrument. This should first be oiled, or anointed with some anodyne ointment, as, of Belladonna, Stramonium, Conium, etc., and in extremely difficult cases, it will also be advisable to freely oil the urethral walls by injecting some olive oil into the canal, and preventing it from passing out by compressing the meatus while the bougie is passed. I generally prefer castor oil in oiling the bougie; and the instrument should always be warmed to a temperature equal to that of the body, as a cold bougie will give rise to spasmodic contractions, and interfere with its advance through the urethra.

Holding the penis lightly between the fingers of the left hand, the bougie is to be passed slowly and gently along the urethra, almost allowing its own weight to carry it, until it comes to the strictured part; no force should be made to pass it, but holding it between the thumb and forefinger, gentle and continued pressure should be made in order that its extremity may enter the strictured orifice,—five, ten, or even fifteen minutes of this steady pressure may be required, when, if the stricture is permeable, it will be felt to yield, and the bougie will slowly pass through the part, and the same course is to be pursued with each obstacle encountered. If

too much pressure be made, the urethra may be torn through its walls, and a false passage be made, which is frequently done by careless or ignorant operators; when this happens, immediately withdraw the bougie, instruct the patient not to urinate for a few hours, and make no further attempts to pass a bougie until twelve or fourteen days have passed.

The signs of the production of a false passage are, 1. At the moment it is produced, both the patient and the physician experience a sensation of crackling, of tearing, and blood flows from the urethra; sometimes these signs are absent, or, if blood be present, it may proceed from another source, as, for instance, urethral fungosities.—2. Another sign is a deviation of the direction of the bougie from the median line; but this will not be observed when the false passage is parallel to the urethra.—3. When a false passage has commenced, the instrument advances with difficulty, and gives rugous frictions; but the same sensations are produced when the bougie is engaged in one or several strictures,—it is equally held tight by them, and passes only when some force is employed, after the beak has entered the orifice.—4. Some practitioners have carried the *catheter* through a false passage, nearly, if not quite, its whole length, without any suspicion of it. A want of the flow of urine should then be taken as an evidence. However, the catheter may be carried to the bladder without a flow of urine, either because its orifices have been closed by mucosities, or because they have entered above the surface of the fluid; an injection in the first instance, and a slow withdrawal of the instrument, in the second, will remove the difficulty.—5. If, notwithstanding these signs, the deviation of the route through the urethra has not been noticed, (which can hardly happen except when the catheter re-enters the urethra, or is in the bladder, and has permitted the urine to flow), we will become aware of the presence of a false passage by the consecutive symptoms. Complete false passages give rise to infiltration of urine, abscess, and urinary fistulas; incomplete, may remain for a long time without occasioning any symptoms,—their tract often becomes cicatrized. Model bougies may give an impression of them.

Having passed the bougie through the stricture, we must allow it to remain in a length of time according to the character of the contraction; if this allows the instrument to pass through it rather readily, from five to ten minutes will be sufficient; if the passage has been difficult, it may remain in for half an hour or an hour; if it has been extremely difficult, the orifice being quite small, it may remain in for eight or ten hours, or all night;—but in no case

must it be allowed to remain long enough to give rise to irritation at the part.—The next day, provided there be no irritation nor inflammation to prevent, or as soon as the irritation is removed, two bougies are to be introduced, commencing with one of the same size as that used the last time, and, after allowing it to remain a few minutes, withdrawing it, and immediately passing the other, which should be a size larger. Thus, on every session, using two bougies, always beginning with one of the same size as that with which the preceding operation had been finished, and concluding with one a size larger. The pressure of the bougie will generally occasion a mucous discharge in dilatable strictures; non-dilatable strictures give a dry bougie upon withdrawing it.—In all cases of difficult introduction, the patient should take a warm sitz bath immediately after the operation, for about half an hour each time, in order to prevent any great amount of irritation following; and should the urethra become very sensitive or irritable, this may be overcome by injecting as far as the irritable part, a small amount of a mixture of Extract of Belladonna half a drachm, Glycerin a fluidounce; repeating it, as required, two, three, or four times a day. Bruised Stramonium Leaves (recent) to the perineum, or around the penis, according to the location of the stricture or of the sensitiveness, will also exert a good effect.

It may be the case, that the orifice of the stricture may be ex-centric instead of centric, in this case, after a careful pressure for ten or fifteen minutes without the beak entering the orifice, we should withdraw the instrument an inch or two, and then, keeping the beak as much as possible against the side or wall of the canal, slide it along; thus trying consecutively every part of the surface of the canal until we have discovered the part or direction at which the orifice exists,—and when once ascertained, it should be recorded, in order not to forget it in subsequent operations.

The following rules, from an English writer, bearing in mind all that has been heretofore observed relative to the exploration of the canal, diagnosis, etc., will be found useful in the introduction of bougies;—1. Begin with one of a moderate size, or such as will pass the stricture, and increase it very gradually; sometimes, its passage will be greatly facilitated by curving it, previous to its introduction, so as to adapt it to the curvature of the urethra.—2. Employ no force in passing it along the canal; but where resistance is encountered, be content with merely causing its beak to press against the contracted orifice for a short time each day, with the hope, that by a perseverance in this plan, an entrance and a dilatation may ultimately be effected.—3. Never pass the bougie

into the bladder, except at the first exploration to ascertain the extent of the disease, but merely carry its beak at a short distance beyond the stricture or strictures.—4. If it is to remain in the canal any length of time, guard against its slipping into the bladder, by bending its end, and tying it with a cotton thread or tape fastened to the penis. I have found a better plan to be to cut the bougie to the required length, and then, by means of a small disc attached to its outer extremity, and which rests upon the glans around the meatus, it is retained in place.—5. Avoid all exercise during its presence in the urethra, and prevent, as much as possible, the penis from becoming erect.—6. In every case, even after the disappearance of the stricture, the bougie should be occasionally passed for a considerable length of time, at first every month, then once in every three months, and finally once in every six months; and should there be the least return of the obstruction, to which there is always a tendency, the dilatation should again be had recourse to. And on this account, the patient should always be taught to perform this operation for himself, as soon as the canal becomes sufficiently dilated to admit of the ready passage of a large sized bougie.

In addition to the means already stated, other means must be pursued in order to facilitate the cure, and render it permanent. In difficult cases, a poultice of bruised recent Stramonium Leaves, or, of dried Stramonium Leaves and Lobelia, should be applied around the penis, or to the perineum, according to the seat of the obstruction, and be allowed to remain on, each time, about half an hour or an hour previous to the introduction of the bougie; and two or three times a day, the surface immediately external to the stricture should be well rubbed with an ointment composed of Belladonna Ointment one ounce, Iodine ten grains, Strychnia, dissolved in sufficient Alcohol by means of a drop or two of Nitric Acid, two grains; mix, triturate the articles thoroughly together, and use but a small portion at a time, being careful not to let any of it come in contact with an abraded surface, the eyes, or the mouth. These means favor the ready passage of the bougie, and produce a condition of the parts in the neighborhood of the adventitious deposit, favorable to its more rapid absorption, when compressed by the bougie.

In some cases, the application of Mild Vegetable Caustic upon the stricture, by means of a proper instrument, will facilitate its softening and absorption; Alum, Sal Soda, and ointments containing small proportions of Chloride of Zinc, Sulphate of Zinc, etc., will also frequently answer a similar purpose, but great care

must be taken not to occasion too much irritation by these applications.

Not unfrequently, internal measures will greatly facilitate the cure, and I have found considerable benefit to follow the free use of an infusion of Horse-mint, Water Pepper, or Buchu, in conjunction with one of the following pills, repeated two or three times a day: Take of Digitalis, in powder, one scruple, Strychnia one grain, Extract of Stramonium five grains (or Extract of Belladonna four grains), Alcoholic Extract of Black Cohosh one scruple,—mix thoroughly together, and divide into twenty pills. The following has also proved serviceable: Take of Iodine one drachm, Strychnia two and a half grains, Podophyllin twenty-four grains, Alcoholic Extract of Black Cohosh three drachms, Leptandrin a sufficient quantity to form a pill-mass; divide into one hundred and eighty pills, the dose of which is one pill to be repeated three times a day.—Bromide of Potassium internally will be found very serviceable in cases of stricture attended with considerable irritation of the urethra and bladder, allaying the irritation so that a bougie can readily be passed.

The urine must be kept as free from acidity as possible, by the use of proper diet, mucilaginous diuretics, diaphoretics and bathings of the surface, as little exercise as possible, and, if required, the means heretofore named for acid and alkaline conditions of the urine. The bowels must also be kept regular, exposures to cold and damp be avoided, together with a plain, but nutritious and easily digestible diet, avoiding all stimulants.

The resilient and undilatable strictures met with at or near the meatus urinarius, and at the fossa navicularis, always require incision or division, after which, a large bougie should be passed, and be retained for a considerable time to prevent contraction occurring from cicatrization. Steel or silver instruments are the best to be employed in these cases.—The character and condition of a stricture, the ready introduction of a small bougie through its orifice, the internal division of an undilatable stricture, the direct application of agents to the strictured part, and consequently, a safer and far more efficacious treatment than has generally been pursued heretofore, is readily accomplished by the employment of the endoscope.

The treatment of *Spasmodic Stricture* consists in evacuating the bladder as soon as possible, by the introduction of a catheter, which may be readily effected by at first placing the patient in a warm bath. When the catheter reaches the strictured part, it should be held firmly but not forcibly, the same as named in the

preceding treatment for organic stricture, for some ten or fifteen minutes, when it will overcome the stricture and pass into the bladder. If, however, the stricture be very obstinate, a fomentation of recent Stramonium Leaves, bruised, or, of dried Stramonium and Lobelia Leaves may be applied to the perineum, and, if necessary, around the penis, and be kept there for some time, aided by nauseating and relaxing doses of some preparation of Lobelia; after which, the introduction of the catheter may be attempted.—Dr. Thomas says, “In spasmodic stricture, where the irritability of the urethra is so considerable as to forbid the introduction of a common bougie, this may be readily lessened by touching the point of the instrument slightly with Liquor Potassa, after it has been oiled, and is ready for introduction. The effect of potassa employed in this manner upon an irritable urethra is often astonishing, and a full-sized bougie may be thus easily passed into the bladder, which had been previously regarded as impracticable.” The above cataplasms of Stramonium, the injections of Belladonna and Glycerin into the urethra, and the use of anodyne and relaxing suppositories or injections into the rectum, will also facilitate the catheterism.

Spasmodic stricture is apt to return; in order, therefore, to permanently remove it, an after treatment should be pursued, consisting of temperance in all things, regularity of the bowels, and the use of a pill, repeated two or three times a day, composed of Sulphate of Quinia one grain, Extract of Belladonna one-eighth of a grain, and Eupurpurin two grains; mix for one pill. The Injection No. 2, under the treatment of Gonorrhea, will also be found beneficial. In obstinate cases, a liniment may be applied once or twice daily, to the perineum and along the course of the urethra, composed of Olive Oil, Oil of Amber, each, one fluidounce, Oil of Lobelia, Aconite Liniment, each, two fluidrachms; mix.

Inflammatory Stricture may be removed by anodyne poultices, spirit vapor bath, cathartics, warm fomentations, sedative injections into the urethra, anodyne suppositories, nauseants, sedatives, and other similar measures.

SPERMATORRHEA.*

Spermatorrhea is the term applied to a spontaneous discharge of semen, generally occurring at night, during sleep, and occasion-

* “Spermatorrhea” is an unfortunate name for the malady or maladies resulting from excessive venery or masturbation, as there are but very few instances

ally during the day. The night discharges are termed "nocturnal emissions," or "nocturnal pollutions." It may arise from several causes, but more commonly from sexual excesses, and especially from masturbation. Unfortunately, masturbation is a vice by no means uncommon among the youth of both sexes, and is frequently continued even into riper years; in the course of the last twenty-eight years, I have treated 2,751 males and 117 females, whose ailments were brought on by this habit; and, in addition to this, during the same length of time I have received communications from more than 4,000 persons, victims of self-pollution, who did not come under my treatment, either because I could not promise quick cures, or, for pecuniary or other reasons. I state this to show the prevalence of the vice, and its evil results, although denied by many practitioners, who ought to know better.

Although upon commencing the habit of self-pollution there may be no abnormal tendency of the system, yet, if the practice be persisted in, it eventually produces morbid condition of the spinal marrow and cerebellum, which, together with the accompanying symptoms, are of very difficult and tedious removal; and the more frequently the vice is indulged in, the greater will be the desire to continue it, from the prostration of the will—and mental powers,—so that, like the drunkard, the victim loses all moral power, and has no longer any control over his animal appetites, and the cessation of the habit becomes almost, and in some cases, quite an impossibility. Yet there are many instances in which mental and physical injury are not present, unless indeed, they unfortunately exist in the imagination of sensitive and timid persons, being either caused or aggravated by the exaggerated statements made in popular works by interested writers.

It must be constantly borne in mind that nocturnal emissions, of themselves, although annoying, are not dangerous; the danger exists in the reflex movements,—the functional or organic lesions of the brain and spinal marrow following their frequent repetition, and particularly when they are associated with the powerful mental efforts usually made by masturbators during the act, to conjure up the most libidinous, unnatural, and voluptuous—exciting ideas and images, and, as it were, to make a reality of them. Nocturnal emissions may occur with any man, as well as spontaneous nocturnal sexual orgasms with the female, and under the

of spontaneous seminal discharges except those that occur as "nocturnal emissions." The day discharges are more commonly of prostatic and not of seminal fluid. I employ the term here in its more popular (but erroneous) sense, as referring to the several abnormal conditions following the above-named vices.

influence of one or more of a multitude of causes, without constituting a disease; they may even occur as favorable crises among those who are continent. But when these pollutions occur frequently, and especially when they are followed by the symptoms hereafter named, the result of frequent nervous irritation, attended by reflex motions, they then become serious and demand prompt attention.

The practice of masturbation is almost always commenced in early life; among the many persons whom I have treated for maladies occasioned by this unnatural practice, I have met with but one who commenced it subsequent to the eighteenth year of age,—the others acknowledged that they first practiced it at an age varying from ten to fifteen, and some at so early a period as to have actually forgotten the initiative. But, however early may be the age at which persons first masturbate, the practice is not always confined to their youth, nor suspended when coition is to be had, but is frequently continued into riper years, and even by those who are married.—Among females, however, I have met with many who commenced the practice after their eighteenth and some even not until their twenty-fifth year; this may be owing to the fewer opportunities they have for gratifying the passion naturally, than males, and to their greater chances of detection, when they receive the embraces of the male.

To enumerate the multifarious symptoms accompanying spermatorrhea, would be almost a Herculean task; they vary according to the frequency of sexual excesses or masturbation, the stamina of constitution, the temperament, the condition of brain and nervous power, the age at which the habit was commenced, the predisposition to disease, and various other circumstances. Strumous, and delicate, weakly habits suffer the most. Some persons practice it moderately, for years, with perfect impunity; while with others the same course gives rise to symptoms of a grave character. More frequently, however, the severer symptoms and maladies produced by it are extremely rare, and are met with only among those who have carried their unnatural indulgence to a very great excess. And when the symptoms of spinal and cerebral disturbances manifest themselves, the pathological condition has already been in existence for a long time; many months, and even years may pass before they become manifested, and this tardiness in their development often leads to a mistake of their true cause.

When the habit is commenced in childhood, or previous to the twelfth or thirteenth year, before there is any semen formed in

boys, or ovarian manifestations in girls, no *symptoms* are observed until the nervous system suffers; and the loss of nervous energy is caused by the overexcitement produced, which exercises upon the brain and nervous system an effect similar to that caused by repeated convulsive shocks, or epileptic spasms, in consequence it often retards the growth, impairs the mental faculties, and brings on a premature old age, with debasement of the human soul, and the mind filled with obscenity and beastliness. The child loses its memory and brightness of intellect, and gradually becomes dull, stupid, and indolent; it moves about slowly and heavily; the face becomes pale, and emaciated or swollen; the lips grow paler; the eyes become hollow and encircled by a livid margin, and the pupils are much dilated; the disposition becomes more irritable and fretful; the appetite capricious, voracious, or diminished; in walking, the gait becomes stooping and tottering; all taste for play or exercise is lost; and solitude is sought for the purpose of reveling in voluptuous ideas and indulging in titillation of the sexual organ. Various symptoms indicative of cerebellar and spinal disturbance manifest themselves, as, noises in the ears, headache, dilated pupils, partial blindness, determination of blood to the head, with heat and redness of the face, forgetfulness, great languor and debility, trembling of the knees, perverted vision, etc. Stammering is also a frequent result of early masturbation, owing to the frequent shocks to the nervous centers, injuring them and impairing their functions; the cerebellum being kept in a constant state of abnormal irritation.

With many, symptoms of dyspepsia appear, with general emaciation; there will be a frequent desire to void urine, with more or less pain in accomplishing it; the bladder becomes irritable requiring to be evacuated often; the child becomes feverish, and should any acute disease attack it, this assumes a typhoid character, which is apt to prove rapidly fatal. If the child is disposed to chorea, epilepsy, spasms, pulmonary disease, etc., these are certain to be induced in time. If the unnatural practice be continued, although no semen is lost at first, yet, after a time, the continued excitement, probably from a rapid or forced development of the functions of the genital organs, will effect a discharge of prostatic fluid, and perhaps even semen, and which will be attended with increased pleasurable sensations. If the habit be not left off, insanity, idiotcy, paralysis, or some other incurable malady is brought on, which eventuates in death.

The symptoms, among those masturbators who have arrived at the age of puberty, or at an age when semen is secreted, are as various as those met with among children, and are due to the excessive

discharges of semen, the constant straining excitement of the brain, and the repeated spasmodic shocks experienced by the nervous centers; several of these symptoms will usually be found in individual cases; rarely will they all be found present in any one subject. One very common symptom, more especially among young females, is a disposition to solitude, to seclude themselves from society; and this is by no means unfrequent among male masturbators. Headache, wakefulness, uneasy and restless nights, pains in various parts of the body, indolence, inaptitude to study, forgetfulness, melancholy, hysteria, great mental despondency, suicidal thoughts, weakness in the back and in the reproductive organs, variable appetite, and a lack of confidence in one's own ability, are very usual symptoms. Cowardice is a striking peculiarity,—masturbators can not look a person in the face steadily, for they fancy their habit is known or at least suspected. Symptoms of dyspepsia, with cough, irritation of the throat, pains in the chest, costiveness, unrefreshing sleep, disturbed dreams, constant and annoying lascivious desires and thoughts, and a tendency to lie long in bed in the morning. Among females, we also find leucorrhea, prolapsus uteri, menstrual derangements, sterility, hysteria, chronic uterine or ovarian congestion resulting in uterine or ovarian tumors, catalepsy, nymphomania, and often unaccountable nervous symptoms.

But the more important and usual symptoms accompanying spermatorrhea, are those due to functional or organic lesions of the nervous centers, the principal of which are as follows: weakness of memory; an inability to concentrate the mind; a want of confidence; disposition to mental and physical indolence; disturbances of vision, as, spots, flashes, bright lights, etc.; ringing or roaring in the ears, dull pain in the occipital region, or along the vertebral column, and especially in the lumbar region,—at first, these pains are manifested only after the seminal emission, but eventually they become prolonged, and terminate by being constantly present; more frequently, this dull pain obliges the patient when sitting or standing to frequently change his position, and it becomes less marked or even disappears when he lies down; weakness in the small of the back; palpitations; formication; and in severe cases, there is weakness or trembling of the knees or hands, a tendency to profuse perspiration on the least exercise, and a staggering gait much like that of an intoxicated person—*tabes dorsalis* or *ataxie myelo-phthisis*. But it must be recollected that the more severe cases are rarely met with.

From want of nervous energy and nutrition, the penis, as well as the testes, gradually diminish in size and energy, and have more or

less coldness; sometimes the testes swell and become tender or painful, or hang very low; the spermatic vessels enlarge, feeling like a coiled up bundle of worms, (varicocele); priapism is sometimes present. There is a weakness at the root of the penis, when erect, with often a soft state of the glans penis; and although not completely impotent, yet as far as the female is concerned, the patient is wholly useless, from imperfect erections and premature emissions on attempting coition. One of the more common and serious results is an involuntary discharge of the prostatic fluid (*see Prostatorrhœa*), immediately after urinating or defecation, with seminal emissions during sleep, and either with or without erotic dreams, as well as with or without pleasure, according to the degree of normal nervous sensitiveness of the parts. The prostatorrhœa is frequently accompanied with an itching or tickling in the glans penis, and is a most obstinate disease to overcome; it has been commonly confounded with seminal discharges, and has been termed "diurnal emissions or pollutions,"—but day spontaneous emissions of semen are very rare. I have met with but two cases in my practice.

The nocturnal emissions may occur every night, once a week, or only twice a month, and, as already remarked, in some rare instances, they may come on in the day-time. Cauterization has been recommended for these emissions, but I do not believe a single permanent cure has ever been effected by it, notwithstanding what has been stated by writers.

A microscopic examination of the fluid discharged, will detect its seminal character, by the presence of the spermatic filaments; in very bad cases, more or less of these filaments will be found in an abnormal condition, as, the head of the filament without the tail, or the tails will be short, or else have no head, or, again the tail or the head will be deformed, or there may be but a few filaments visible, in the midst of a fluid, containing little granules and the debris of epithelial scales,—and small crystalline masses will also be noticed in most cases. But it must not be forgotten that when there is a complete obliteration of the spermatic ducts, the fluid ejected is principally prostatic and contains no spermatic filaments whatever.

Chronic irritation of the neck of the bladder is common, with a sense of weight and fullness in the part, a frequent call to urinate, and, in some cases, requiring the patient to get up during the night. There is also apt to be a morbid sensibility of the genital organs, as manifested by tenderness or pains, itchings, and a more or less constant half-erotic condition of them; and when alone,

especially at night, a masturbator is powerfully disposed to pollute himself, notwithstanding the terrible consequences which he knows must ensue from a persistence in the habit; this is due to morbid sexual excitement with loss of moral power and nervous energy. In cases where there is great excitement of the genital organs, or where there is a disposition to continue the habit of masturbation, certain agents have been administered to check or suspend sexual feeling; but however much this class of agents (antaphrodisiaes) may be desired, their continued, or too frequent use is often more harmful than beneficial. Moral power, strength of will, are the best antaphrodisiaes, and these should be well cultivated.

When there is an irritable condition of the seminal vesicles and ducts, the presence of semen in the vesicles always produces more or less excitement, which, in connection with the irritability of the surrounding parts, amounts to an unhealthy excitement; this, under favorable circumstances, as, in the presence of a woman, becomes very much augmented, and is apt to cause an intense sexual feeling, supposed by the patient to be an evidence of a naturally strong animal passion. This condition is likewise often caused by an irritable state of the cerebellum. If, under this mistaken supposition, coition be indulged in, and continued to any extent, the ultimate result will be an impotency difficult to cure, and which may either come on rapidly, or gradually manifest itself, not being complete until several years have passed. Persons laboring under this kind of irritability, will have the sexual desire aroused by any slight extra irritation, as, riding on horseback, in a coach or stage, and even upon a mere handling of the parts.

There is also apt to be a weakness of the walls of the urethra, in which, after urinating, a few drops leak out and moisten the linen; and the stream may be free, flat, twisting, or divided into two or more jets soon after leaving the urethra; this is also common to stricture. Crystals of oxalate of lime, or dumb-bells, are apt to be present in the urine, more especially when the gastro-hepatic organs become deranged.

From a deranged or perverted nervous excitability of the sexual organs, the semen is prematurely discharged on attempting coition; or else, coition can only be performed under certain peculiar circumstances; and, from defect of sexual nervous power with muscular debility, there will be a partial or complete impotency.* The

*Although many medical men of high reputation deny the existence of abnormal results from masturbation, and even go so far in their ignorance or prejudice, as to attribute many of the symptoms encountered to mental influence,

commencing signs of impotency are, a weakness at the root of the penis during erection; an inability to maintain an erection and complete the copulative act, without causing the imagination to dwell lasciviously upon other females; premature emissions; diminution or loss of sexual desire; and softness and flaccidity of the penis *immediately* after an emission. One or more of these symptoms are always present in approaching impotency. Permanent impotency may or may not be associated with great loss of memory, mental weakness, great depression of spirits, and, in very severe cases, some kind of eccentricity, or monomania.

The more common consequences of excessive masturbation are, various symptoms simulating those of lesions of the brain, spinal marrow, heart, lungs, liver, stomach, or kidneys, as, chorea, mental impairment, hypochondria, premature old age, epilepsy, insanity, apoplexy, paralysis, dyspepsia, nervous irritability, etc. The children of parents whose nervous centers have been impaired by masturbation, are seldom robust and vigorous; in infancy they are subject to convulsions, to epilepsy, to scrofula, to bad habits; in adult life their mental qualifications are never extraordinary, and they are apt to be diminutive in stature. Frequently, however, a proper course of training will overcome some of these results, if commenced at a sufficiently early age, and persisted in until the full period of puberty.

The *diagnosis* of spermatorrhea is readily made out by the history of the case, the symptoms present, and the microscopic examination of the fluid discharged; an absence of spermzoons in this fluid is indicative of an obliteration of the spermatic duct, or else that the fluid is prostatic; deformed or imperfect spermzoons indicate a lesion of the semen-forming organs, with impaired nutrition and defective nervous power; a thin watery semen is indicative of irritability and debility of the seminal vesicles and the prostate gland (functional impairment).

Some persons may masturbate moderately, present apparent indications of good health, and yet secretly suffer from some of its con-

yet I have seen and treated too many cases to be misled by their statements or reasonings; and I venture the assertion, that there are hundreds of married men now living, between the ages of thirty-five and fifty, who are secretly suffering from premature emissions and partial impotency, the result of former sexual excesses, and who make no efforts to obtain relief, either from a false modesty, or a want of confidence in the skill of the profession,—and who fear to fall into the hands of advertising and unprincipled impostors. It is time that medical men should drop their prejudices regarding this subject, and devote more attention to it,—a subject which is of vital importance to humanity.

sequences; it is by no means uncommon for men, apparently healthy in every other respect, to be laboring under a partial or complete impotency at a period of life when their virile powers should be in a state of full vigor. More generally, however, masturbators, and especially those who have carried the act to an excess, may be known by their paleness or sallowness of countenance; by the rough, dry, cracked, or pimpled condition of the skin; more or less emaciation; dark semicircle under the eyes, which are apt to be sunken and hollow; dilated pupils, and a languid aspect as if drowsy or indolent. There is also a desire for being alone, or, when in company they keep aloof, sheepishly regarding some of the opposite sex who may be present, mentally associating them with lascivious and beastly ideas. They are late risers, loving to lie in bed for hours in the morning; their propelling, moving power becomes diminished. There is a want of firmness, of decision, in their deeds and manner; they are easily agitated, irresolute, timid, are apt to be slow of comprehension, are inattentive, "absent-minded, sad, melancholy, easily frightened, easily discouraged, wanting in clearness and point of idea, less bright than formerly, and altogether depreciated in looks and talents compared with what they would have been, had this soul and body-destroying practice never been contracted." They can not look another person steadily in the eyes, at least without blushing, or manifesting an apparent feeling of guilt or shame. The flesh becomes soft and flabby, and there is apt to be a weakness of the joints, more especially in the knees. A peculiar, disagreeable, rank odor is very apt to be exhaled from the body of a masturbator. Females, in addition to the above, will manifest a retiring, diffident manner, and a peculiar reserve in answering the common questions relative to health. Not unfrequently, when the fingers are used to bring on the venereal orgasm, sores will be seen around the nails, or, one or more very rough and broad warts, most generally upon the index and second fingers.

The *prognosis* of spermatorrhea is generally favorable. But there are cases, in which the lesions of the nervous centers have become so severe that they are beyond the reach of art, and a fatal termination inevitably ensues sooner or later. A combination of the symptoms of impaired digestion, weakness of knees, dyspnœa, all the time, great exhaustion following emissions, palpitations on the least exercise, fornication, weak vision, mental weakness and confusion, and partial deafness, are unfavorable symptoms; and more decidedly so when, in addition, the patient frequently observes a blue spot before the eye, which enlarges in area, and then disappears. When symptoms of ataxie myelo-phthisis are developed, the case is doubt-

ful. Great care must be taken by the practitioner, to determine partial or complete impotency due to actual lesions, from those arising solely from the fears of the patient, who has become alarmed, perhaps from reading some advertisement or publication in which the more severe consequences are especially dwelt upon. These severer results, it must be recollected, are of much less frequent occurrence than the milder and more readily curable forms.

A quick cure in spermatorrhea with functional disturbance of the nervous centers is simply and absolutely impossible. Time is always required to restore the brain and spinal marrow to a healthy condition, *after which*, the sexual weaknesses, under proper treatment, will rapidly disappear. The danger lies in the lesions of the brain and spinal cord, and not in the emissions themselves, which when due to mere local irritation are readily curable either by treatment alone, or conjoined with marriage. Indeed, it can not be expected that a disease brought on by calling one of the most important functions of life into action before the system is fully matured for it, and that, too, in an unnatural manner, and continuing this unnatural excitement of the function and its organs for several years, carrying it to such an excess as to affect the nervous centers, and, as it were, undermining the very foundation, strength, and vitality of the constitution,—can be cured in a few weeks or months. We have, in these cases, not only the existing lesions to overcome, without which the emissions will not cease, but also the reflex influences of these emissions upon the nervous centers, kept up by the existing impairment of these centers. The shortest time in which a *certain* and *permanent* cure can be effected is from twelve to eighteen months; many cases require from three to five years. It will be found that the reported cures effected by cauterization or otherwise, in a few weeks or months, are always temporary and never permanent. I have known supposed cures of these kinds, followed by marriage, in which no spontaneous emissions occurred subsequently, or but seldom, to terminate in partial or complete impotency between the ages of thirty-five and fifty.

The *pathological conditions* in spermatorrhea are unnatural paleness of the urethral mucous membrane, a granular condition or ulceration of the prostatic mucous membrane, irritability of the prostatic urethra, of the neck of the bladder, and of the orifices of the ejaculatory ducts, dilatation and a patulous condition of the prostatic or ejaculatory ducts, morbid changes in the testes, and, in some instances, an obliteration of the vas deferens, the tail or globus minor of the epididymis, or of the seminiferous vessels of the testes.

In the more advanced and unfavorable cases there will exist organic lesions of the spinal cord and cerebellum.

In the *treatment* of spermatorrhea and its attending lesions, much will depend upon their character, their severity, their influences upon the patient, his temperament, predispositions, etc., for that which will be found applicable to one patient, will often prove of no utility to another.

Marriage has been unwisely and ignorantly recommended by some physicians, as a remedy in these difficulties; but the instances in which it has effected cures, are extremely rare—indeed, I have known of four cases in which marriage was advised, and the persons were not capable of coition; in one case, the man died from ataxie myelo-phthisis; in the other three, a cure was effected in two, and the wife of the third party left him and returned to her parents. The objections to marriage in these cases, are,—one is not able as a general rule to have healthy intercourse, either from feeble erections, premature emissions, or even total inability; or, it may be that, from irritation at the neck of the bladder, the patient may imagine his sexual propensities to be naturally strong, and thus be induced to cohabit frequently, thereby hastening impotency; it also retards a permanent cure by keeping up more or less irritation of the nervous centers; again, if offspring are born, they are apt to be delicate or strumous. Persons who marry, laboring under the conditions heretofore referred to, as accompanying spermatorrhea, may find a cessation of their spontaneous emissions as long as they cohabit regularly, and which is due to the fact that the discharges that would have passed spontaneously are now passed naturally, but, this substitution of one mode of emission for another does not remove the functional or organic lesions of the nervous centers, and, consequently, at the age of from forty to fifty, the very period when the parties should be in their prime, they usually become partially or completely impotent, unless a cure of the accompanying lesions has been effected. Married, as well as unmarried persons, who have endeavored to remove their difficulties by proper attention to diet, exercise, bathings, etc., more generally find, after several years, that their condition is improved up to a certain point by such measures, but here it stops,—they do not become cured—nor can the difficulties in these cases be permanently eradicated unless by an appropriate treatment addressed to the brain and spinal marrow.

When these lesions have been cured, if the seminal discharges still continue, local means should be pursued to stop them; if these fail, marriage may be advised only under the following

circumstances; the spontaneous emissions must not occur oftener than once or twice a month, and must not be followed by exhaustion or other unpleasant symptoms; there must be no prostaticorrhea present; and the patient must not only agree to pursue treatment, but, until cured permanently, also agree not to cohabit oftener than once or twice a month; in such cases, marriage, in which emissions occur in a healthy manner, and at proper and regular intervals, will aid materially in allaying prostatic and vesical irritation, and in curing the non-complicated spontaneous discharges. Yet it must not be forgotten, that it appears to be a natural tendency of the nervous centers when under the influence of disease for a long time, to develop some of the previous symptoms of the disease, often upon very slight exciting causes, and which susceptibility may exist even for many months after a cure of the disease has been effected.

The first and one of the most important points in the treatment, is, that the patient at once abandon the pernicious habit, for unless this be done, all our remedial means will be useless and ineffectual. This will frequently be found a very difficult task for the patient to accomplish, for, from the moral and physical debility already effected, he will relapse into the habit unconsciously; and, in many cases, it will require much firmness, patience, and perseverance on the part of the physician before he will be able to permanently overcome this vexatious obstacle to a cure. But he must not become discouraged, nor leave his patient to suffer the terrible consequences of this unnatural practice, without making the most powerful and oft repeated endeavors to persuade, convince, encourage, and strengthen his reason and resolution. To be restored to health, therefore, masturbation, as well as natural sexual contact must be positively and absolutely discontinued. It will be found that although the constant irritation and abuse of the reproductive organs enfeeble and irritate the spinal cord, yet, when means are employed that improve the condition of these organs, an invigorating and restorative reflex influence upon the cord almost invariably ensues.

I know, that, acting upon the maxim of choosing the least of two evils, physicians have advised masturbators to marry,—nay, even to have unmarried cohabitation, hoping thereby to ultimately effect a cure, both of the habit and its consequences. But unfortunately, however plausible such a course may appear, experience, as a general rule, does not sustain it; for those who act in accordance with such advice find to their cost that the remedy is worse than the disease. The only true course for the physician to pursue

is, to gain the confidence of his patient, and then explain to him exactly what must be done. It will not do for the physician to be lax with his patient upon this matter; he must not wink at any minor peccadilloes of an animal nature, nor indulge him in anything calculated to excite in the least, the sexual sense. If he sincerely desires to benefit his patient he must take the highest moral grounds with him—in no other way can he cure him. The sexual organs, the sexual sense *must be kept in a passive condition until the cure is effected*—no other course can be depended upon. If the patient be married, and can avoid cohabiting while under treatment, it would tend to facilitate his cure, and be greatly to his advantage; but in no case should he be permitted to perform this act oftener than once in every two or three months. If he can not do this, it will be almost useless for him to undertake treatment,—though there may be a few exceptions to this rule.*

Balls, parties, theaters, lewd women, lewd men, novels, obscene books, etc., and especially books upon the subject of masturbation which exaggerate its effects and unnecessarily alarm those suffering from this vice, must all be imperatively avoided. These by calling the mind to thoughts of a sexual character produce an increased secretion of semen, which, by stimulating the genital organs, exerts a renewed sexual influence upon the brain, giving rise to desires and passion of an almost uncontrollable character, and which drive the patient, in spite of his reason to commit the very acts which he most wishes to avoid; and this, more especially among those who have never been trained to mental and physical self-control. The mind of the patient should be constantly occupied with something useful or interesting, he must not be permitted to remain idle for a minute through the day,—he must exercise considerably, but with moderation,—and whenever, through the day or night, he finds sexual thoughts occupying his mind, he must at once fly to close study, or active physical exercise, even to fatigue, if necessary, for safety. Not only must all other external causes of irritation be avoided, including horseback riding, exercise or work that will strain the back, too long continued sitting, etc., but those that are local must likewise be removed by appropriate treatment, as hemorrhoids, warts around the anus, urethral stricture, irritable urethra or bladder, ascarides, constipation, etc.

*I refer here to married persons who have committed sexual excesses, or who previous to wedlock were masturbators. Such may have nocturnal emissions, but, more generally, prostatic discharge, premature emissions on attempting coition, partial impotency, and evidences of cerebral or spinal disorder to a greater or less extent.

The bowels of the patient should be kept regular without purging; the diet should be nutritious, easy of digestion, not disposed to cause any distress, weight, or heaviness at the the epigastrium, gastric acidity, flatulency, diarrhea, or constipation, and the food should be well and thoroughly masticated before swallowing it. All high-seasoned food, spices, liquors, or acidulous articles are to be avoided, and as little saccharine substances be used as possible. Hearty suppers should never be eaten; and the supper should always be taken at least two hours previous to going to bed, and should invariably be light, using no meats whatever. The patient must not give way to melancholy, low spirits, or despondency, feelings apt to be common among this class of persons,—but should strive resolutely and manfully against all such feelings; he should be as cheerful and confident as possible,—seek pleasant society, but avoid the lascivious,—and absolutely refrain from seeking solitude for the purpose of brooding over unpleasant and dangerous thoughts. The more lively he forces himself to be, the sooner will his nervous system recover strength and vigor. Gentle exercise in the open air should be taken on every fair day. He must also endeavor by every means in his power to overcome the habit of sleeping on his back, as this position almost invariably occasions emissions with those who are disposed to nocturnal discharges; and as a full bladder is also likely to effect the same result, he should be careful to evacuate it on going to bed, and on awakening during the night.

If there is a sore or tender spot in the urethra when a bougie is passed, this should receive attention, and be removed either by a regular daily introduction of the instrument, or by the action of sedative, anodyne, astringent, etc., lotions or ointments, as may be required. The character of the urine should be ascertained, and any unhealthy condition of it be removed by the appropriate measures. The skin should be attended to once a week, bathing with a warm, weak alkaline solution, and drying with friction. A cool douche to the perineum, for five or ten minutes, also to the back of the head and along the spinal column, every morning will almost always prove serviceable; and, in some cases, the addition of a tepid douche to the perineum and genitals before going to bed, will aid in allaying irritation of the parts. The patient should invariably sleep upon a hard bed, with as little covering as possible to keep up a comfortable degree of warmth.

The therapeutical measures will depend upon the condition present, and various means will be required according to circumstances. Where no great amount of debility has been produced,

the patient will generally recover under a stimulating and tonic treatment, thus: Take of Cinchona, in powder, two ounces, Chamomile flowers one ounce, good Port Wine one quart. Mix together, and allow it to stand for a few days, frequently shaking, when it will be fit for use. A wineglassful may be taken three or four times a day. The elixir containing soluble Pyrophosphate of Iron, (*see page 774*), will also be found advantageous in nearly all cases.—Should there be nervous exhaustion with sadness, no disposition to exertion, etc., the following may be given: Take of Chloroform, Tincture of Ginger, each, half a fluidounce, Aromatic Spirit of Ammonia two fluidrachms; mix. The dose is twenty-five drops in a wineglassful of milk or rice water, to be repeated three times a day.

When there is debility with a sense of lassitude, or indolence, one of the following preparations may be given: 1. Take of Acetate of Strychnia one grain, Acetic Acid twenty minims, Alcohol two fluidrachms, Distilled Water six fluidrachms; mix. The dose is ten drops, three times a day, each dose containing one-fiftieth of a grain of Strychnia.—2. Take of Sulphate of Quinia, Alcoholic Extract of Nux Vomica, each, twelve grains, Extract of Hyoscyamus twenty-four grains; mix, and divide into twenty-four pills, of which one may be given every three² or four hours.—3. In long-standing cases, with more or less anemia and virile weakness; take of Phosphate of Quinia, Superphosphate of Iron, each, twenty-four grains, Alcoholic Extract of Nux Vomica six grains, Aletridin twenty-four grains, powdered Colombo a sufficient quantity to form a pill-mass; mix them well together, and divide into twenty-four pills. The dose is one pill, to be repeated three times a day.—4. Take of Citrate of Iron with Strychnia sixteen grains, Citrate of Iron with Quinia twenty-four grains, Syrup six drachms, Water four ounces; mix; the dose is two or three teaspoonfuls, three times a day, in a wineglass of water. All preparations of Strychnia and Nux Vomica should be used with great care, as, improperly used, they will produce serious effects. The dose of either should rather be proportioned to their influence upon the system of the patient using them; and it will be found that in some individuals the one-fiftieth of a grain of Strychnia will produce powerful effects, and the dose will have to be lessened to the one-sixtieth, one-seventieth, or even one-eightieth of a grain; while in others, again, the twelfth or sixteenth of a grain will be found necessary to produce the desired effect.—Preparations of Iron administered internally often occasion a congested condition of the genital organs, and, consequently, their employment should be closely watched; if congestion and irritation

follow their use, especially among those who are much annoyed with nocturnal discharges, we must cease their further employment.

Severe pain in the back part of the head, or a constant, dull, disagreeable soreness in this region, requires counter-irritation over the part to produce pustulation, or a discharge; and stimulating applications along the spinal column will frequently be of advantage. In most cases, however, it is better to avoid very active counter-irritating measures.

Irritability in the neighborhood of the neck of the bladder and prostate, tending to obstinately keep up nocturnal discharges, may be allayed by internal means, as well as by local applications; and these means, when effectual, will also temporarily arrest the spermatorrhea. Among the internal means which have been found the most effectual, are the following: 1. Lupulin, in doses of from fifteen to thirty grains at bed-time, either with or without the addition of a grain or two of pulverized *Digitalis*.—2. Bromide of Potassium in doses of from ten to fifteen grains, repeated three times a day.—3. Tincture of Sheep Laurel two parts, and Tincture of Stavesacre (*Delphinium Staphysagria*) one part; mix,—the dose is from ten to fifteen drops in a tablespoonful of water, to be repeated three times a day.—4. A strong infusion of the aments or catkins of *Salix Nigra*, drank freely.—5. Opium, Belladonna, or Conium, have frequently been found useful, and, in many cases, the means named under the treatment of Irritable Bladder, and Chronic Prostatitis.

Among the local applications are suppositories, injections, and counter-irritants. Suppositories are generally made of Butter of Cacao six grains, with or without one grain of Spermaceti, with which is incorporated one or two grains of Opium; one or two grains of Opium with from three to six grains of Extract of Conium; one grain of Extract of Belladonna; four or five grains of the Iodide or Bromide of Potassium; or, from one-half to two-thirds of a grain of Morphia, etc. But the prolonged use of suppositories will generally be found not desirable, from the unhealthy influences they exert upon the rectum and neighboring tissues; they are more especially useful in obstinate irritability and spermatorrhea.

Urethral injections are for the purpose of allaying irritability of the canal and the parts at the prostate and vesical neck, to remove urethral granulations, promote healing of any existing ulcerations, and to impart healthful tone to the debilitated and patulous seminal and prostatic orifices and ducts. To be effectual they should be carried directly upon the parts, and even into the bladder. Some practitioners consider them injurious, more, I think from the trouble

they occasion, and the dislike many patients have in reference to them, than from sound reasoning. I have successfully prescribed them for many years, and have never found them to fix the attention of the patient upon his disease to a greater degree than does the employment of other measures, and have never found the peripheral irritation increased, nor the reflex excitability of the cord augmented thereby. The articles I generally employ, are, a solution of Tannin one drachm to a pint of Water; a solution of Tannin and soluble Golden Seal, one drachm of each, to a pint of Water; a solution of Chloride of Gold and Soda, and Chloride of Zinc, each, sixteen grains to a pint of Water; the injections named under Gonorrhea, Nos. 1 and 2; and, Geranium, Golden Seal, each, in powder, half an ounce, Sulphate of Zinc sixteen grains, Water, Glycerin, each, half a pint. These injections should always be employed immediately after urination, and be retained as long as possible; they may be repeated two or three times a day. At first, they may cause some irritation, but this will speedily cease.—Dr. Douglas, of Glasgow, states that he has derived benefit from an injection of the following: Take of Opium one grain, Acetate of Lead three grains, Mucilage one fluidounce; mix. But I detest the Lead.

Counter-irritants are occasionally required, as in cases where there is soreness or tenderness upon passing a bougie along the prostatic canal, with frequent emissions and persistent irritability of the parts. A Compound Tar Plaster may be applied to the perineum, and a discharge be kept up for some time. Indeed, I have known the continued use of such a plaster upon the perineum, with internal means for the nervous complications, to effect permanent cures of spermatorrhea in the course of ten or twelve months; but, from the painful soreness the plaster produces, and the difficulties attending its application, but few patients will persevere in its use. Sometimes, I have beneficially employed the following ointment to the perineum, instead of the plaster: Take of Strychnia twenty grains, Alcohol 70 per cent. half a fluidounce, Oil of Origanum one fluidrachm, Simple Cerate one ounce; mix, and apply a small portion night and morning, with friction. Or, the following may be used: Take of Strychnia twenty grains, Aconitina four grains, Oleic Acid two drachms, or a sufficient quantity to dissolve the Alkaloids,—then add Olive Oil, or Simple Cerate, one ounce, and form a liniment or ointment, to be used in the same manner as the preceding. These should be employed with carefulness, not being allowed to come in contact with abraded or ulcerated surfaces, wounds, etc. They are also useful for giving tone to the relaxed

and enfeebled muscles concerned in the function of erection, whose powers have been overworked.

The *treatment* for the spinal and cerebellar lesions, will be the same as named under these maladies in a previous part of the work, (and to which the reader is especially referred), consisting principally of the internal administration of the Iodide or Bromide of Potassium or of Ammonium, Camphor, Belladonna, Ergot, Strychnia, Citrate of Quinia with Strychnia, Citrate of Iron with Strychnia, etc. Among the compounds that have proved useful, are the following: 1. Take of Bromide of Potassium one drachm, Citrate of Iron with Strychnia forty-five grains, Fluid Extract of Ergot forty-five minims, Glycerin, Water, each, half a fluidounce; mix. The dose is thirty-six minims, or about half a teaspoonful three times a day. The above quantity contains only fifteen doses. After using it for a few weeks, the ergot should be discontinued, substituting for it Extract of Belladonna three grains,—alternating the use of these articles every five or six weeks. In those cases where there is a weakness in the inferior extremities, or a tendency to paraplegia, bromide of potassium should not be employed until these symptoms have disappeared. 2. Take of Boujean's Ergotin one drachm, Extract of Belladonna four grains and a half, Strychnia three grains, Alcoholic Extract of Black Cohosh one drachm, powdered Black Cohosh, a sufficient quantity to form a pill-mass; mix, and divide into sixty pills, of which one is a dose, to be repeated three times daily. It must be recollected that preparations of Strychnia are only useful in cases where the lesions of the nervous centers are reflex, and should not be used when these lesions are centric. 3. The following has also been highly recommended: Take of Oxide of Silver, Sulphate of Bebeerin, Alcoholic Extract of Black Cohosh, each, one drachm and a half, Camphor half a drachm, Extract of Belladonna twelve grains; mix, and divide into ninety pills. Dose, the same as the preceding. Of course, in all cases, functional lesions are much more yielding to treatment than organic.

There are several auxiliary measures that may be required during the treatment of spermatorrhea, to which I will now refer. Varicocele, as well as a painful condition of the testes, or, great irritability in the neighborhood of the prostate and vesical neck, will frequently be remedied by wearing a suspensory bandage.—Pains in the testes, as well as a sense of fullness about them, may be overcome by Nitrate of Potassa in doses of five or ten grains, three times a day.—Great aching pain and weakness in the spinal column, especially in the lumbo-sacral region may be relieved by wearing over the part, an Opium plaster with Camphor sprinkled on it; a

Belladonna plaster; or, by the daily application of the Dermabiotikon. Croton Oil Liniment will also be found useful in some instances. In these cases severe labor or exercise must be avoided.—An annoying pain at the epididymis shifting to the prostate; or, a sensation of formication in the urethra or vas deferens; a sensation of fluid passing through the urethra, but none to be observed; coldness of the scrotum and testes,—may all be relieved by the application of veratria ointment or liniment to the scrotum and perineum.

That sense of fullness, or coldness in the testes and scrotum, which is often the certain forerunner of an emission, may be allayed by Lupulin in large doses.—A powerful preparation to prevent troublesome night erections is a pill consisting of Lupulin one drachm and a half, Camphor ten grains, Extract of Conium one scruple; mix, and divide into twenty pills, of which one may be taken at bed-time, and, in bad cases, one likewise two or three hours before bed-time.

A morbid sensibility of the urethra may be overcome by introducing a bougie daily or every other day; the instrument should be anointed with Extract of Hyoseyamus, or Extract of Belladonna, half a drachm, Glycerin a fluidounce; mix. Or, it may be anointed with a mixture of Hydrochloric Acid twenty drops, Muriate of Morphia fifteen grains, Glycerin one ounce; let the bougie remain in for five or ten minutes at a time. Or, the following may be injected into the urethra: Take of Hydrochloric Acid ten or fifteen minims, Glycerin a fluidounce, mix; or, Extract of Belladonna four grains, Glycerin a fluidounce; mix. Also attend to the state of the urine.

Excessive nervous irritability may be overcome by the use of Ammoniated Tincture of Valerian; or, by a pill composed of Valerianate of Quinia half a drachm, Alcoholic Extract of Black Cohosh, Alcoholic Extract of Skullcap, each, one drachm, pulverized Pleurisy Root, a sufficient quantity to form a pill-mass; mix, divide into ninety pills of which one may be taken for a dose, and repeated three or four times a day. Some prefer Oxide of Zinc one drachm, to the Pleurisy Root.—Premature seminal discharges may be overcome, when unconnected with lesions of the nervous centers, by Opium suppositories, Bromide of Potassium ten or fifteen grains taken at bed-time, and the constant use of the inverse voltaic current by means of Pulvermacher's voltaic belt, which should be constantly worn in these cases.

Generally, impotency, not accompanied with lesions of the nervous centers, or remaining after these have been cured, will gradually disappear with the involuntary emissions; or, at all events will yield

to tonics, stimulating liniments, phosphoric acid, extract of cannabis indica, nux vomica, phosphorus, phosphate of manganese, galvanism, etc. Among the agents that have been given internally with success are the following: 1. Take of Phosphoretted Ether,* Tincture of Nux Vomica, Tincture of Cantharides, each, equal parts; mix,—the dose is twenty or thirty drops, three times a day.—2. Take of Phosphate of Quinia six grains, Dilute Phosphoric Acid half a fluidrachm, Glycerin, Water, each, two fluidounces, Essence of Lemon a few drops; mix; the dose is a tablespoonful three times a day.—3. Take of Tincture of Chloride of Iron, Tincture of Cantharides, each, one fluidrachm, Tincture of Nux Vomica half a fluidrachm; the dose is thirty or forty drops, three times a day.—4. Take of purified Extract of Indian Hemp twenty grains, Citrate of Quinia and Iron forty grains, Phosphate of Manganese one hundred and twenty grains, Alcoholic Extract of Aletris, a sufficient quantity to form a pill-mass; mix, and divide into forty pills. The dose is one pill three times a day.

Impotency when due to nervous exhaustion from over-indulgence, etc., must be overcome by rest, regimen, tonics, cold bathings, galvanism, etc.—It is often due to several old cicatrices of ulcers, lying along the floor of the urethra, at various sore, tender, or contracted spots. In some cases there may also be chronic congestion, with spasmodic stricture, and perhaps a neuralgia or pain in the testicle arising from reflex irritation. In these cases, if stricture be present it must first be cured, after which apply daily along the whole course of the urethra, from the bladder to the meatus, an ointment containing, powdered Opium one scruple, Chloride of Zinc ten grains, Spermaceti Ointment one ounce; mix. The application of this ointment should be continued until it causes no smarting, spasm or reflex pain, at which period the local disease will be cured and the general tone improved. Then, to reinduce the virile powers use a Pulvermacher's galvanic battery, applying the positive pole to the lower portion of the spine, and excite the parts generally, especially the glands, with the negative pole—also apply it, with a urethral conductor, to the prostate and vesicula seminales. (Pulvermacher's voltaic belt increases the tone of the parts; a battery current should be used occasionally; Opium, suppositories to allay any irritation; and minute doses of Cantharides to excite the parts.) (*H. Lobb.*)

Not unfrequently, impotency is due to certain mental causes, as

* Phosphoretted Ether is made by dissolving twenty-eight grains of phosphorus in four fluidounces of pure sulphuric ether.

fear, grief, anxiety, disgust, peculiar sensitiveness or imagination, or from apathy, etc.; such cases require a moral treatment adapted to their particular cases. It may also be due to close study, use of liquors, hypochondria, gastric difficulties, syphilitic affections, injuries of the head, etc., all of which must first be removed by proper treatment, and then, if the impotency persists, employ the means to overcome it, heretofore named.

Both spermatorrhea and impotence may be due to an excessive irritability of the urethra, which not only renders the person extremely liable to nocturnal emissions, but, with some, the mere act of urination will occasion a seminal emission. The treatment for this difficulty is Electricity, passing the currents in various directions, from the perineum to the glans, from the sacrum or lumbar region to the glans, through the rectum and penis by means of an instrument which conveys one pole into the urethra or into the rectum; urethral injections of Belladonna in Glycerin, Sulphate of Iron in Glycerin, Tannin in Glycerin, etc.; internal use of Tincture of Sheep Laurel, of Staphysagria, or of Chloride of Iron, etc. And for the cerebellar or spinal affection, which usually accompanies this variety, Bromide of Potassium may be used internally, and electrical shocks should be passed for a few minutes along the vertebral column from the occipital region to the glans, applying the negative pole to the glans, or perineum, and the positive to the spinal column, and repeating the operation daily, or every other day. I have found the constant electrical current more useful in allaying the cerebellar and spinal irritation, than the induction current, or Faradization.

Sometimes there will be a tardy ejaculation, requiring a lengthened period of coitus before an emission occurs; this is due to a debilitated condition of the reproductive organs, a want of normal excitation or irritation, and requires electricity, and local stimulations, as, urethral injections, or the introduction of bougies coated with Glycerin in which Sulphate of Iron, Sulphate of Zinc, etc., have been dissolved. The walls of the urethra should be placed in direct contact with the negative electrical pole, along its various points, and especially at the fossa navicularis, and at the prostatic region. In these cases, the penis is apt to be cold, pale, and relaxed, and the scrotum loose and pendent.

One point must be especially urged upon patients who have been cured of impotency, and that is moderation in coition; this should never be undertaken oftener than once or twice a month, in any case. A departure from this rule, will almost invariably effect a return of the impotency.

DIABETES.

The term "diabetes" was formerly applied to an excessive discharge of urine; but in later years investigations have led to the discovery that there may be an increased amount of urine passed, in some cases containing sugar, in others holding no saccharine substance whatever. The former has received the names of *diabetes mellitus*, *glucosuria*, *melituria*, and *glucohæmia*, the latter being the preferable term, as it implies a saccharine state of the blood. It is likewise subdivided into two classes: *a*, in which saccharine matter is present in the urine at longer or shorter intervals, and is due to certain physiological or pathological conditions, not strictly affiliated with true saccharine diabetes, and which has been called *incidental diabetes*; *b*, in which the saccharine condition of the urine is persistent, and is accompanied with grave symptoms. This last is diabetes proper, or true glucohæmia, and forms two groups;—one in which the saccharine substance varies in amount at different periods, and in which the symptoms are less severe, thirst and excessive emaciation being generally absent;—the other, in which all the symptoms are of a serious character, with constant thirst and excessive emaciation.

The *causes* of diabetes are merely conjectural; among the supposed exciting causes are, exposures to wet and cold, or to sudden changes of temperature; intemperance; excess in venery, or masturbation; immoderate evacuations; excessive use of saccharine and amylaceous articles of diet; sedentary habits; severe mental emotions; constant use of acid drinks, or crude, unwholesome diet; organic diseases of the brain and spinal cord; injuries to the brain and other parts; and indeed anything that will derange the digestive and biliary functions, impoverish the blood, and debilitate the system. Many of these causes have no doubt occasioned incidental diabetes, and may also be a starting point of the more serious and persistent variety of the disease. And the incidental variety, also termed *diabetes insipidus*, or *polyuria*, is often observed following epilepsy, asthma, whooping-cough, the inhalation of chloroform, etc.

This disease may occur in either sex, but is more common among male sin the proportion of two to one. It is seldom met with under five years of age or beyond sixty-five, is more common and more fatal among males between the ages of forty-five and fifty-five, and among females between twenty-five and thirty-five.

The ordinary duration of diabetes is from one to three years, though it may run a much more rapid course.

For convenience, I have considered diabetes at this place, which is, at present, as suitable as any other, because we do not positively know whether it is a renal, pulmonary, hepatic, nervous, gastric, or blood disease. Its *pathology* is but little understood, notwithstanding the multiplied researches of recent years. Thus, Bernard, after a series of elaborate investigations, came to the conclusion that the liver secreted a material, an amyloid substance (hepatic-dextrine), which, coming in contact with some peculiar ferment in the blood, was converted into sugar, which became decomposed and disappeared in the lungs under the influence of the inhaled atmospheric oxygen. But when, under certain morbid conditions, and especially that of nervous irritation, either an inordinate amount of sugar is formed from the liver-dextrine, or the decomposition of the sugar in the lungs is incomplete,—diabetes is the result. Dr. Harley rather sustains these views, though he considers respiration to be the exciting cause, during health, of the hepatic saccharine forming function; and, from his experiments, does not believe that any great amount of decomposition of the saccharine matter in the blood occurs in the lungs, but that this matter affords support to the system, disappearing, in health, from the larger blood-vessels, in its passage through the numerous capillaries of the body.

On the other hand, Dr. Pavy, who has also devoted considerable research to this subject, denies that any sugar is formed from the liver-dextrine during a state of health, or, that it exists in the circulation, and maintains, that if it is converted into sugar, or if sugar is found in the circulation, it is an abnormal condition, or, is the result of post-mortem changes. His view appears to be correct, as regards cold-blooded animals, and is gradually becoming the prevailing opinion as regards the warm-blooded.—So that, between the views thus briefly presented, nothing satisfactory has yet been made out, and the pathology of diabetes remains to be determined, though important knowledge toward this highly desirable object has been attained.

The *symptoms* of diabetes may manifest themselves rather suddenly, but more commonly they are gradually developed. After several weeks or months of indisposition, with some feverishness, and, perhaps, slight emaciation, but without any derangement of the digestive functions, the patient's attention is directed to the frequent calls to urinate during the day, and which also disturb his night's rest, as well as to the increased amount of urine passed,

which may vary from ten to even thirty pints per day. With this excessive discharge of urine, the patient experiences an unquenchable thirst, as well as inordinate appetite; the mouth is dry, the tongue either clammy and coated with a white creamy fur or mucus, or else red and preternaturally clean, and the saliva thick and viscid. The gums are frequently swollen and inflamed, bleeding upon the least touch; the breath has an odor similar to that of the urine, like that of hay, or ripe apples, and, in many instances, the body often exhales a similar odor; not unfrequently a sweet taste is experienced in the mouth; and the bowels become costive, with occasional colicky pains. The skin becomes harsh, dry, and scurfy; emaciation occurs, with a care-worn, dejected expression of the features; there are frequent attacks of dizziness and pain in the head, as well as a sense of lassitude, and fatigue; and, usually, the sexual appetite becomes more or less impaired. The patient becomes restless, dissatisfied, and the moral and intellectual faculties are gradually blunted.

As the disease advances, the emaciation and debility augment; pulmonary symptoms become developed, or else, an uncontrollable diarrhea, with hectic fever, and diminution in the quantity of urine, which may lose its saccharine character and become albuminous; and dropsical effusion occurs in the inferior extremities, continuing and progressing, until death from exhaustion, coma, convulsions, diarrhea, or other complication, ensues.

Persons laboring under diabetes are subject, in addition to the symptoms already named, to boils, carbuncles, eczema, psoriasis, and other cutaneous affections; to gastro-intestinal derangements; to diarrhea, sometimes of a dysenteric nature, and proving rapidly fatal; to pulmonary tubercle; to low and fatal types of pneumonia, pleuritis, or peritonitis; to gangrene of the lower extremities; to amblyopia; and to cataract. Diabetic cataract is generally of the soft kind, is rapid in its progress, and may attack one or both eyes,—more commonly both. I have met with this cataractous opacity in three cases, in each of which it disappeared in from five to eight weeks, under the influence of Nitrate of Ammonia.

Diabetes insipidus may be determined from glucohæmia, by the absence of sugar and albumen in the urine, and by the specific gravity of this fluid, which varies from 1033 to 1007. The accompanying symptoms are similar to those of diabetes mellitus, but are usually of less severity.

The most prominent feature in diabetes mellitus is the character of the urine; this is excessive in quantity, very clear, paler than natural, though sometimes having a green tinge, of a sweet taste,

an odor like hay or ripe apples, specific gravity varying from 1025 to 1055, and fermenting very readily. The presence of sugar in the urine, and its amount, may be determined by the methods made known on pages 122, 862, by means of Mitscherlich's polarizing apparatus, or, by the tests named in the author's *Am. Dispensatory*, 6th ed., pages 821, 822. Sometimes the grape sugar disappears from the urine, and in its place will be found inosite or muscle sugar, to detect which will require a different process from that pursued for grape sugar. (*See page 864.*)

The *prognosis* of diabetes will depend greatly upon its character; in diabetes insipidus it is less grave than in diabetes mellitus; yet, notwithstanding, it is frequently unyielding to treatment, and proves fatal, especially when due to organic disease of some of the more important organs,—indeed the seriousness of the prognosis will depend on the character of the accompanying disease, the severity of the symptoms, and their influence on the general system.

In diabetes mellitus, it must be remembered that it is only occasionally a cure is effected; by far the larger number of cases prove fatal. This may be owing to our ignorance of the correct pathology of the disease, and its consequent empirical treatment. The prognosis is much more unfavorable in young persons than in those of advanced years; as well as in persons of spare habits than in the corpulent. The more unfavorable symptoms are, abundance of urine, pulmonary symptoms, presence of cataract, or amblyopia, increased amount of sugar in the urine, diarrhea, and the presence of albumen in the urine.

The favorable symptoms, (which, if not indicative of recovery, are of a susceptibility to improvement and a prolongation of life), are, no unusual appetite or thirst; diuresis absent or very moderate; emaciation and debility not marked; sugar in moderate amount, appearing only temporarily or intermittently; abundance of uric acid deposits in the urine; and when the disease is due to mental anxiety, or to injuries that may terminate in permanent recovery. A gradual and finally a persistent disappearance of abnormal thirst, diuresis, and sugar, together with an increase in flesh and strength, are very favorable indications,—yet we must be aware that the disappearance of these symptoms may be followed sooner or later by their reappearance, and even in an aggravated form. Toward the termination of the disease, as well as in its later stages, when symptoms of phthisis or of severe dropsy occur, it is by no means uncommon for the sugar to disappear from the urine; but in these instances, there is no amelioration of any of the other symptoms. In all cases, however, those who labor under diabetes may be said

to hold their lives in their own hands; a strict attention to hygienical measures, and a thorough control of the passions and appetites, may greatly ameliorate their condition and prolong life for an indefinite period; but an inattention to these points, even a slight exposure to cold or moisture, or an increased amount of exercise, etc., may develop complications or an augmented intensity of the symptoms, which may rapidly and unexpectedly terminate life.

There are no *pathological appearances* peculiar to diabetes, or that throw any light upon its nature or its location. The liver, the kidneys, the lungs, the stomach, and the floor of the fourth ventricle, sometimes present more or less serious pathological changes, but these are not constant nor uniform, are often observed in cases where there has existed no diabetes, and appear to have no direct relation to the diabetes. Sugar is usually detected in the blood, and frequently in various other fluids of the system, as, in the saliva, tears, sweat, gastric juice, etc.

The *treatment* of diabetes, as heretofore remarked, is purely empirical, the principal objects being to diminish the amount of sugar in the blood, to decrease the diuresis, and to sustain the general nutrition and strength; the auxiliary measures are for the purpose of palliating or overcoming certain annoying symptoms that may be manifested from time to time, and for these several purposes both therapeutical and hygienical treatment is demanded.

The therapeutical means are complicated and uncertain, and consist of remedies and measures to influence supposed derangements of certain organs, as the blood, liver, and nervous centers, as well as of articles which have been asserted to exert a specific influence in this disease.

The bowels must be kept regular, by means of the Compound Powder of Rhubarb and Potassa, in small doses repeated three times a day, or, by minute doses of a mixture of Podophyllin one part, Leptandrin six parts. Active purgation must be avoided. Especial attention must be paid to the skin, bathing it daily with a stimulating liquid, and drying with considerable friction. Cold water douche to the back part of the head, and along the spinal column, will frequently be found very advantageous; it should be repeated every morning, or, every other morning. The Spirit Vapor Bath will also be found a very useful mode of exciting the skin to action; it may be repeated two or three times a week, as the strength of the patient will permit. Sometimes counter-irritation to the occiput, and along the vertebral column, will exert a very happy influence, as, by dry-cupping, firing, or by the use of the Dermabiotokon. And, as far as my own experience goes, I have

found excellent results follow these counter-irritating applications, when made in the hepatic region.

Among the various agents that have at times appeared to exert a special influence upon the disease, lessening the quantity of the urine, its specific gravity, and the amount of sugar contained in it, are the following:

1. Opium, which is often tolerated in large doses, even to four or five grains, without producing any unpleasant effects. It should be employed in conjunction with a restricted diet, and in doses sufficient to cause sleep; it appears to act by lessening the appetite and diminishing nervous excitability, but its effects are rarely permanent. Where opiates disagree, Belladonna may often be advantageously substituted. In cases where a tonic is required, Opium may be combined with Sulphate of Quinia, or with Alcoholic Extract of Aletis.

2. Alkalies, as the Bicarbonate of Potash, Carbonate of Ammonia, etc., have sometimes proved useful, while in other cases they have been of no service. The hypothetical view of their action by Mialhe is, that they increase the alkalinity of the blood, and thus favor the oxidation and destruction of the sugar contained in this fluid. As the too prolonged use of alkalies are apt to prove injurious, they should not be administered for more than twelve or fourteen days at a time, with intermissions of eight or ten days. Bicarbonate of Soda is given in the quantity of one drachm per day, gradually increased to three or four drachms. Carbonate of Ammonia is given in scruple doses three or four times a day. Camplin has recommended an effervescent Citrate of Ammonia. M. Guyot-Dannecey recommends half-drachm or drachm doses of Citrate of Soda, daily, as a remedy in diabetes. Its use may be prolonged for a greater period than the other alkaline salts, and is followed by a disappearance of sugar from the urine; when absorbed into the system, the acid is burned up in the respiratory process, and the system is then placed under the influence of an alkaline carbonate, which is eliminated by the urine.

3. Strychnia has in some cases appeared to exert a beneficial influence; though it will frequently be found to fail.

4. Permanganate of Potassa has been highly extolled, but has not sustained the eulogiums it at first received. And the same may be said of Ergot, Creosote, Iodide of Potassium, Tincture of Chloride of Iron, Rennet, Pepsine, etc., all of which have had their day of reputation.

I have treated four cases of diabetes mellitus successfully, by the internal administration of Nitrate of Ammonia in doses of from

ten to twenty grains, repeated three times a day, and given in solution. In two of these cases there was cataract in both eyes, which disappeared after having continued the use of the solution for five or six weeks. In conjunction with this agent, I also employed the following pills, alternating them every four weeks:—*a*, Take of Citrate of Iron and Strychnia, Sulphate of Quinia, each, forty-five grains, Opium from sixty to ninety grains; mix, divide into ninety pills, and give one pill for a dose, repeating it three or four times a day; *b*, Take of Bromide of Potassium two hundred and seventy grains, Extract of Conium Maculatum ninety grains, Extract of Aletris ninety grains; mix, divide into ninety pills, and administer the same as the preceding. Rennet wine was prescribed, to be taken after the breakfast and dinner meals, and the usual attentions bestowed upon the skin, kidneys, bowels, diet, etc.

The Nitrate of Uranium in doses of one-tenth of a grain, repeated three times a day, has produced some decidedly beneficial results, and is deserving of further investigation.

Dr. James Anton, who has had an experience in this disease, recommends the use of the cold wet bandage, applied around the body so as to cover the hepatic and renal regions, and then covering it with oil-silk or India rubber cloth, to prevent too rapid evaporation; it should be changed every night and morning, and its use be continued for several weeks. Any irritation, interfering with the sleep of the patient, he allays by a dose of Sulphate of Morphia at bed-time followed by a full dose of Tincture of Gelsemium, to prevent any unpleasant effects from the morphia, and to increase its anodyne influence.

A mixture of Phosphate of Lime fifty grains, Carbonate of Lime ten grains, Bicarbonate of Soda five grains, for a dose, taken in mucilage of Buckshorn Brake, and repeated three times a day, about an hour after each meal; in conjunction with a pill, taken also three times a day, about an hour before each meal, composed of Oxide of Silver one grain, Extract of Belladonna one-eighth of a grain, Sulphate of Quinia one grain, Extract of Black Cohosh one grain,—is stated to have proven very efficacious in the treatment of diabetes.

Dyspeptic symptoms should be treated according to their character and indications; an infusion of Aletris and Lycopus Virginicus, drank freely, will be found useful to restore tone to the digestive and biliary systems, and to diminish the urinary discharge. Pepsin, or Rennet Wine will sometimes be found to improve the appetite and the digestive powers. Pain, nervous irritability, and wakefulness, require anodynes. Anemia, debility, and emaciation,

are best overcome by Iron, Cod Liver Oil, wine, and proper diet; the soluble Pyrophosphate of Iron, will be found a useful tonic. To relieve an excessive craving for food, and the sinking sensation at the epigastric region, a pill may be given, whenever required, composed of Assafetida three grains, Sulphate of Quinia one grain, Sulphate of Morphia one-eighth of a grain; mix for a dose.

The hygienical treatment of diabetes constitutes as important a part, if not more so, than the therapeutical; more especially the dietetic measures. No half way course must be pursued; if the patient desires recovery or prolongation of life, he must not trifle with his malady, but must rigidly pursue the means pointed out,—he must gain absolute control over his appetites and cravings. The diet must be nutritious, but must contain no starchy or saccharine elements, or, at least, as little as possible of them; and, to prevent the stomach from rejecting it, the articles should be frequently changed. Meats, game, poultry, fish, eggs, cheese, salad oil, gelatin, cream, and butter may be used; and for vegetables, spinach, dandelion greens, water-cresses, turnip-tops, green lettuce, and sparingly of celery and radishes; also custard made without sugar, blanc-mange made with cream and not milk, and sparingly of various kinds of nuts. Bran bread, according to Camplin's plan, should be used instead of wheat, rye, corn, or oat-meal bread or cakes; or Pavy's almond rusk or bread may be taken.* For drink the patient may use tea, or coffee without milk or sugar, claret, spring water, dry sherry, plain brandy and water, weak beef tea or mutton broth, soda-water, and water acidulated with cream

*Almond rusk and biscuits are made by first freeing the almond powder from sugar, by washing with boiling water slightly acidulated with tartaric acid; then forming it into rusk or biscuits by means of eggs. When dry they are fit for use, and should be well masticated before swallowing.

Bran bread is made by washing the bran thoroughly, in water, until the water runs clear, then squeezing the bran in a cloth as dry as possible, exposing thin layers of it to the heat of a slow oven, until it becomes perfectly dry and crisp, and then finely grinding it. To three ounces of this bran powder, add three fresh eggs, an ounce and a half of butter, six ounces of cream; stir all thoroughly together, and flavor with nutmeg, ginger or other spice. Immediately before putting it into the oven, stir in the mixture, thirty-five grains of bicarbonate of soda, and then three drachms of dilute hydrochloric acid; put the basin containing the mixture at once into the oven, and bake for an hour or more. Biscuits may be made by omitting the soda and hydrochloric acid.

Another good biscuit may be made of fresh meat, pounded to a jelly, butter cream, gelatin, and prepared almond flour, mixed together and baked. This may be spiced to suit the taste, and will be much liked by the patients.

of tartar, tartaric, nitric, muriatic, or phosphoric acid, lime-water, infusion of *Lycopus* and *Aletris*, etc.; and he should be urged merely to sip at frequent intervals, rather than to indulge in large draughts at a time, which will augment the diuresis. As a general rule, no liquors whatever should be used, except required to sustain the strength.

Among the forbidden articles are oysters, crabs, lobsters, sugar, wheat, rye, corn or oat-meal cakes or bread, rice, arrow-root, sago, tapioca, maccaroni, vermicelli, potatoes, carrots, beets, turnips, parsnips, cabbage, cauliflower, peas, beans, pastry, puddings, and sweetened custards, apples, pears, peaches, gooseberries, strawberries, currants, plums, oranges, and sweet fruits of all kinds whether fresh or preserved, asparagus, etc.; also milk, ale, porter, beer, sweet and effervescent wines, port-wine, rum, gin, cider, cordials, etc.

Moderate exercise should be taken daily, in the open air; sudden changes of temperature must be avoided; the body should be kept well clothed; the feet especially must be protected from cold and damp; sleep should be limited to eight or nine hours per day; and all sexual indulgence be positively avoided. In many cases, travel and change of scenery will be useful, if the dietetic measures can be pursued at the same time. Similar measures may be pursued for diabetes insipidus; but, in all cases, any existing complication or etiological disease must be remedied by the appropriate treatment therefor.

CHRONIC DISEASES OF THE INTEGUMENTARY SYSTEM.

Chronic diseases of the skin may be purely local, depending upon want of cleanliness, irritation of the skin, the presence of parasites, etc.; or they may be due to some constitutional derangement, as, a rheumatic, scrofulous, or syphilitic affection. It must be borne in mind, however, by the practitioner, that these maladies do not always exist in an isolated form, but that cases are often presented to us in which two, and even three, different forms of skin disease co-exist in the same individual. Again, it must be recollected that a host of circumstances may be present which will greatly modify the character and severity of the affection, as well as its greater or less degree of susceptibility to treatment. Among these circumstances may be named age, sex, occupation, diet and manner of living, character of climate or of dwelling place, (in women uterine derangements), struma, anemia, gout, rheumatism, plethora, dyspepsia, syphilis, etc. And in estimating the diagnosis and the treatment of diseases of this system, the practitioner should pay great attention to such of these several conditions as may be present with any given case.

In order that cutaneous maladies might be more easily studied and understood, they have been grouped into classes; and there appears to have been presented to the profession nearly as many various classifications as there are authors, each one forming his system according to his own peculiar views regarding the cause and the especial characters of, as well as the structural changes attending, each particular affection. And as there is no classification at the present day that has been accepted by the medical profession as *the* system, the author will present such of these affections as he designs treating upon, under the divisions that appear to have met with the most favor in this country, and which are only modifi-

cations of the system of Willan and Bateman. Some of the affections commonly treated upon by writers under the head of skin diseases, are omitted at this place, having been previously described under other heads, as, Erysipelas, Purpura, Scorbutus, etc.

To correctly treat affections of the skin, we must first be enabled to form a correct diagnosis, for without this, we are much more likely to be unsuccessful than successful. The examination should be made by daylight in order that we may make no mistake as to the correct color of the affected parts. We must determine whether the affection is vesicular, pustular, papular, or tuberculous, etc.; if one of these, to which of the subdivisions does it belong. This may be arrived at by learning the history of the case, the patient's sensations and general health, the appearance of the skin, the condition of the pores, the color of the diseased part and its depth, the presence of excoriations, branny scales, or thick yellowish crusts, the appearances presented by the disease itself upon the surface of the body, as well as when a portion of it is examined under the microscope, etc. All of these several points must be carefully investigated, and, whenever there is any doubt, the whole surface of the patient's body must be examined thoroughly, should this be deemed necessary in order to a more perfect and satisfactory diagnosis.

ORDER I. EXANTHEMATA.

This order is characterized by superficial redness of greater or less intensity, as well as of variable size and form, which redness is due to an augmentation of blood in the small vessels, which almost or quite disappears under pressure, returning promptly however, when the pressure is removed, and which terminates in resolution or desquamation. No vesicles, or pustules are present in affections of this order, though there may be elevated points at certain parts of the skin, from a great accumulation of blood in such parts, and these may be known from papulæ by their temporary disappearance under pressure, which is not the case with papules. This order of maladies is often complicated with gastro-intestinal irritation, or disease of the brain, or lungs.

ERYTHEMA.

Erythema is a mild, non-contagious affection, characterized by a uniform redness manifesting itself in one or more superficial patches, of variable form and extent, and which is more commonly observed

on the face, chest, and extremities. Sometimes there will be an elevation or puffiness of the skin, which, however, soon subsides, leaving the redness behind. Febrile symptoms are rarely present, and there is generally but very little, if any heat, itching, or pain. One or two weeks is the general duration of the disease; on the disappearance of the redness a purplish or bluish tint remains for a few days, and, in all the varieties, desquamation is apt to take place.

Among the numerous varieties that have been named by authors, I may call attention to the following: 1. *Erythema fugax*, an evanescent affection, appearing and disappearing more or less suddenly, and generally on the face, arms, neck and breast, frequently with a degree of heat, tingling or itching, and perhaps some dryness and puffiness of the surface.—It is usually due to some gastro-intestinal derangement, or to mucous irritation of other parts, as, of the respiratory or urinary organs, and occasionally exists without any attributable cause.—2. *E. Marginatum*, in which the patches are rounded or circular, their borders are elevated and well defined, and the redness is deeper than in the preceding variety, but variable, the circular patches are from six to twelve lines in diameter, and the eruption is more commonly observed about the loins and external lateral parts of the limbs, though it may be seated on any part of the body. The affection occurs more especially among middle-aged persons and those of advanced years, and is ordinarily associated with some chronic disease of internal organs; its duration varies according to the character and curability of the accompanying chronic affection. This variety appears to be identical with *Herpes Circinatus*.—3. *E. Læve*, or erythema associated with œdema. This ordinarily attacks persons enfeebled by sedentary habits, intemperance, gastro-intestinal disease, anemia, and too much standing or walking; it usually occurs around the ankles and in the lower limbs, is attended with more or less redness, itching, a sense of tension, and a swelling which pits on pressure. It is often confounded with erysipelas, and may terminate in ulceration, or gangrene. In some cases, the cuticle gives way, and an ichorous fluid oozes out, forming a thin crust on becoming dried.—4. *E. Tuberosum* is more common among weakly females having derangement of menstruation. It consists of small circular patches, three or four lines in diameter, attended with or preceded by smarting or itching, bright red at first, but eventually becoming purplish, or resembling a bruise, and is sometimes mistaken for a mild form of purpura hemorrhagica. They occur principally upon the superior parts of the body, or the legs.—5. *E. Nodosum* greatly resembles *E. Tuberosum*; it is, however, attended with more active inflammation, is in oval patches

varying from six lines to three inches in diameter, is more commonly observed running on the forepart of the leg, in the course of the tibia, and is met with among debilitated or badly nourished constitutions.

6. *Erythema Chronicum* may present itself in the form of bright-red spots that come on very gradually, and then remain stationary, becoming paler or brighter according to the amount of gastrointestinal irritability present. Or, it may follow an acute form of erythema, being persistent and attacking parts where the skin forms folds, as, in the groins, behind the ears, in the joints, on the scalp, etc. The skin becomes red, the cutis more or less thickened, the epidermis exfoliates more or less, and the skin often chaps and cracks. There are three forms of *E. Chronicum*, viz.: *a. E. Pityriasis*,* or *branny tetter*, presenting dull-red or pinkish irregular patches, which may form on any part of the body, and are usually attended with more or less heat, itching, and tingling. Minute whitish scales are more or less rapidly thrown off from the light-colored patches, usually in abundance, and vary in size, being smaller and mealy-like in places where the skin is thin, and larger and branny-like where the skin is thick. The disease is not contagious, but is very persistent, and has been divided into several varieties of pityriasis.—*b. Pityriasis Vulgaris*, consisting of red patches, of greater or less extent, with more or less itching and tingling, especially when in bed, is common to those having a fair, delicate skin, usually occurs upon the parts more exposed to the air, and is attended with the exfoliation of more or less small scales. It is often observed along the sides of the chin, on the forehead, and around the mouth.—*c. P. Capitis* or *Dandruff*; attended with itching, an abundant exfoliation of scales, and is met with on the scalp and face, under the hair, eyebrows, and beard.

The *prognosis* of erythema is always favorable; the malady is readily yielding to proper treatment, and a removal of the exciting cause.

The *treatment* must be chiefly directed to the diseased conditions associated with or giving rise to the erythema. Keeping the bowels regular by laxatives; the kidneys by saline diuretics; the skin by slightly stimulating alkaline baths. Tonics, as Quinia, Hydrastin, etc., if there is much debility; Iron, if there is anemia, or Elixir of Cinchona and Iron. In several cases I have found much benefit from Bromide of Potassium; and in others, from the infusion of Maiden Hair, Elder Flowers, etc., named under Erysipelas.

* *Pityriasis*, from a Greek word, signifying "bran"—dandruff.

The external use of soap should be avoided in *E. Fugax*. As a local application Glycerin will be found very effectual; it may be combined with Tannin, Honey, Chlorate of Potassa, Muriate of Ammonia, Lobelia, or Iodine, etc. The Veratria Ointment will sometimes be useful in *E. Nodosum*. In œdematous erythema, *E. Læve*, astringent washes, and bandaging, may be used, in conjunction with the appropriate internal treatment; and if the serous infiltration be so great as to threaten ulceration or gangrene, the skin may be punctured here and there to allow the accumulated fluid to drain away.

URTICARIA.

Urticaria or Nettle Rash, is a non-contagious exanthematous affection of the skin, characterized by round, oval, or wheel-like elevations or wheals, (pomphi), which are either lighter or deeper-colored than the healthy skin, are of irregular shape, and generally surrounded by a red margin; it is accompanied with a burning, tingling, and itching sensation, and is rarely followed by desquamation. The disease attacks all ages and constitutions, and the chronic forms, are either persistent or intermittent, and often very unyielding to treatment.—Urticaria is occasioned by gastro-intestinal irritation, as well as by irritation of the pulmonary, genito-urinary, and other mucous membranes. Is more generally met with in warm weather, and appears to consist of an irritation of the nerves of the skin with consequent spasm of the muscular structure of the skin, due, probably, to a reflex action. Mental emotions, fatigue, exposures, improper diet, as well as certain kinds of food, dentition, etc., are frequently exciting causes of the appearance of the eruption.

1. *Urticaria Evanida* is characterized by the intermittent appearance of roundish wheals, white or with trifling redness, and which are accompanied with much itching and tingling, particularly when the body is very warm, or the patient is in bed. The spots look somewhat as if the patient had been whipped by a lash. Its appearance is usually connected with gastric irritation, disappearing when this is removed. When the eruption is persistent, it is called *U. Persistans*.—2. *U. Subcutanea* is a neurosis, which is accompanied at more or less distant intervals by a stinging and itching eruption, the tingling continuing during the intervals, as well as during the eruptions. At first, it may be confined to one spot, but subsequently extends over more or less surface of the limbs and body. Cutting or pricking pains are sometimes occasioned from slight causes, and there is usually more or less stiffness of the muscles of the affected part.

The loins and thighs, and sometimes the arms, are the parts more commonly affected. This variety of urticaria is described by Willan, and appears to have been some nervous malady, in which the occasional appearance of the eruption was a symptom.—3. *U. Tuberosa* is a rare form, characterized by large wheals which extend deeply into the subcutaneous cellular tissue, are painful, hot, and itching, when the patient is warm, and leave the patient weak and sore, as if he had undergone much fatigue. The wheals usually appear at night, and disappear in the morning.

The *diagnosis* of urticaria may be established upon the symptoms heretofore named. It somewhat resembles *lichen urticatus*, but this affection consists of small, hard, round pimples, which appear in successive crops, and eventually have a dark-colored scab to form upon them. However, urticaria may be complicated with other cutaneous eruptions.

The *prognosis* of chronic urticaria depends upon its exciting cause; the removal of this is generally followed by a disappearance of the eruption. If the eruption recedes, the internal disease is apt to be aggravated.

The *treatment* of urticaria must be directed to its cause, as, nervous debility, visceral derangement, mucous irritation, etc. The diet must be carefully regulated, avoiding all articles that appear to have an exciting action. Laxatives, saline or cooling vegetable diuretics, and frequent bathings of the whole body and limbs, must not be omitted. If there is a tendency to rheumatism, Colehicum, Black Cohosh, etc., may be used. When no indications of gastro-intestinal irritation, or other disorder is present, the eruption will often yield to the long-continued, or alternated employment of the following articles: Citrate of Iron; Tincture of Chloride of Iron; Sulphate of Quinia and Tincture or Extract of Black Cohosh; Belladonna Extract and Strychnia; and Bromide of Potassium, or of Ammonium. The intermittent form of urticaria must be treated by Quinia, Black Cohosh, Citrate of Iron and Strychnia, etc. The following has proved useful in obstinate cases, in conjunction with Bromide of Ammonium: Take of Oxide of Silver, Sulphate of Bebeerin, each, thirty grains, Extract of Belladonna four grains, Alcoholic Extract of Black Cohosh thirty grains. Mix, and divide into thirty pills, of which one is the dose, to be repeated three times a day.—Aconite has also been found successful.

To allay the tingling and itching, Glycerin in which Chlorate of Potassa, Belladonna, Morphia, or other narcotics are dissolved will often be of service; or, a mixture of one part of Acetic Acid with ten parts of Cologne; or, a mixture of two parts each of Chloro-

form and Laudanum, with sixteen parts of Water.—Vesication to the surface, or active rubefacients, with internal sudorifics will prevent or remove a retrocession of the eruption.

ORDER II. PAPULÆ.

Papulous or Lichenous affections are characterized by very small elevations of the cuticle, solid, acuminate, somewhat resembling enlarged papillæ of the skin, and of a color varying from dull white to bright red; pressure momentarily removes the color, but the pimple remains. They rarely contain any fluid, and usually terminate in resolution or in slight furfuraceous desquamation of the epidermis, and occasionally in a slight ulceration of the summits of the papulæ. They generally form slowly without any apparent cause, are apt to be preceded by itching, are seldom attended with fever, are non-contagious, may be manifested on any part of the body, and continue from a few days to many months.

LICHEN.

Lichen is a term employed to designate an eruption of minute, hard, conical papules, which are usually red or of the color of the skin, are attended with itching, prickling, or tingling, occur either in groups or isolated, are often obstinate and annoying, appearing in single or successive eruptions, and terminate generally in resolution, or in desquamation, rarely in superficial ulceration, and, which also tend to a thickening and roughness of the cutis. It is usually met with in warm seasons, and, although occurring in persons otherwise apparently healthy, is frequently connected with digestive derangements, overexertion, and exposures. Lichen frequently results from exposures to excessive or continued heat; from irritation of the skin; from depressing moral or physical causes; and *L. Agrius* is more common among persons during middle life, especially those who are dyspeptic, gouty, rheumatic, or laboring under mental anxiety. When met with in children and infants, it is popularly called "red gum" or "tooth rash," (*Strophulus*). There are several varieties of strophulus, requiring similar treatment, as, cleanliness, attention to diet, regularity of the bowels, chalybeates if anemia be present, alteratives if struma exist, tonics if there be debility, etc., and, if there be much itching, the application of powdered Starch, Oxide of Zinc, or a mixture of equal parts of Glycerin and Rose Water.

The following are the principal varieties of Lichen that may be encountered in a chronic form: 1. *Lichen Simplex*, presents minute papules, more commonly upon the extremities, but occasionally upon the face and body, they are usually less red than in the acute form, and are likewise attended with less itching. In eight or ten days desquamation ensues, but the eruption again appears and runs the same course, and this successive development of the disease may continue for months and even years, the affected parts of the skin gradually becoming thickened. In enfeebled systems the papules often present a bluish or dark appearance, and the affection is then termed *Lichen Lividus*. When the pimples appear at the points of the skin from which the hair proceeds, or, "at the roots of the hair," it is called *Lichen Pilaris*, and is accompanied with much itching and tingling; this variety is more common among intemperate persons, and those laboring under gastric derangement. Another variety of *L. Simplex* is *Lichen Circumscriptus*, in which the papules exist in irregularly oval or circular patches, with well-defined margins, the patches gradually increasing in diameter, and either healing in the center, thus forming rings, or, the center remaining red and scurfy. This has often been confounded with the vesicular affection, ringworm of the scalp or herpes circinatus; but it is more apt to be located on the external part of the fore-arm. When the ring, referred to above, is imperfect, or when several broken rings or circles are irregularly connected together, it has then been named *Lichen Gyrateus*.

2. *Lichen Urticatus* appears to be a combination of lichen and urticaria, the papules being larger than in the other lichenous affections, appearing in wheals and attended with a burning and itching; when these pass away there remains papulæ behind, frequently of a very obstinate character.

3. *Lichen Agrius*, like the preceding varieties may exist in an acute or a chronic form. The latter may follow the acute form, or it may be chronic from the commencement, and is characterized by a small cluster of papules, that are accompanied with considerable itching and smarting, and when removed by scratching or friction, they are succeeded by more pimples on the next day, and so on for many days, until finally the eruption forms a much larger and permanent patch. The itching is always increased by heat, stimulating food or drink, exercise, warmth of the bed, etc. Not unfrequently the affected skin becomes thickened, with deep cracks or fissures, and may be confounded with eczema, which disease, by the way, often co-exists with it. Occasionally some gastro-enteric derangement may also be present, but more commonly the patient

is apparently in good health. The parts more liable to be attacked are, the back of the hands, the arms, shoulders, legs, loins, and sometimes the face and chest. The grocer's, baker's, washer-woman's and brickmason's itch, are only varieties of this eruption occurring upon the back of the hands. The eruption frequently remains with obstinacy upon the inferior extremities of middle-aged persons.

Lichen may be *diagnosed* from *prurigo*, by its papules being smaller, more acuminate, and redder; from *scabies* by the itching being more of a tingling character, and the lichenous eruption more generally appears on the thicker parts of the skin; from *eczema*, by the eruption consisting of pimples and not vesicles, and by the absence of any fluid discharge from the pimples when they are broken.

The *prognosis* of lichen is not always favorable, at least as far as a prompt cure is concerned, for it often obstinately continues for years proving a source of great annoyance and discomfort to the patient.

The *treatment* of lichen will depend considerably upon the condition of the patient; if he be strumous, Bromide of Potassium, Iodide of Ammonium, Tincture of Chloride of Iron, and other antistrumous agents should be administered internally; if he be anemic, Tincture of Chloride of Iron, or other chalybeates; if he be dyspeptic, gouty, or rheumatic, the proper internal measures must be pursued for these maladies; gastric acidity especially must be removed; if he be debilitated, tonics will be needed; if residing in a malarial district, antiperiodics, etc. All known causes of the eruption should be carefully avoided, and a general attention be given to the hygiene of the patient. In weak, cachetic patients, a strong infusion of the leaves and stems of *Urtica Dioica*, in doses of a fluidounce or two, repeated three or four times a day, has been found very beneficial.

Various external applications have been recommended, among which I prefer the following,—though great care should be had not to continue the employment of any local application that has a tendency to irritate or inflame the skin:

1. Take of Carbolic Acid one drachm, Water, Glycerin, each, one fluidounce; mix. Apply to the eruption two or three times a day.—2. Take of Carbolic Acid one drachm, Pyroligneous Acid four fluidrachms, Water one fluidounce and a half; mix, and use as above.—3. Oxide of Zinc Ointment.—4. Take of Cherry Laurel Water one fluidounce, Glycerin two fluidounces; mix.—5. Take of Tincture of Chloride of Iron one fluidounce, Glycerin two or three fluidounces; mix.—6. Ointment of Iodide of Ammonium, one

draclim to the ounce of Simple Cerate.—7. Sometimes a Sulphur Vapor Bath every three or four days, will be of immense service.—8. Take of Iodide of Ammonium half an ounce, Camphor Water one pint; mix, and dissolve, and then add Chloroform four fluid-ounces. Shake this well together each time before using.

PRURIGO.

Prurigo is a chronic affection of the skin, characterized by the presence of non-contagious pimples or papules, and an intense, burning itching, which is greatly increased by overexercise, heat, or the warmth of the bed, and which varies greatly in intensity from the mildest to the most aggravated form. The papules are broader than in lichen, less acuminate, and are of the same color as the skin, and, from the scratching with the finger nails, they are torn and bleed, and then become covered with a small, thin, black crust or scab. In long-standing cases the skin eventually becomes thickened, indurated, and coarse. The *causes* of prurigo are various; it is often due to uncleanness, and sometimes to improper or innutritious diet, to the use of stimulants, to unhealthy atmosphere, to nervous irritability, to hepatic and gastro-enteric derangement, and to an impoverished condition of the blood; *Pruritus Senilis* appears more especially to owe its presence to the last-named cause. The affection has been divided into several varieties, according to its intensity and its location.

Prurigo mitis is the mildest form of the eruption, in which the papules are few, scattered, and attended with a moderate degree of itching; it may attack any part of the body, but is more commonly located on the posterior parts of the shoulders and body, and on the external parts of the extremities. It is worse in spring and autumn, and may remain for several weeks or months. *Prurigo formicans* is the term applied to the more severe form of the disease, in which there is not only intense itching, but more or less pain, and a sensation frequently compared to the creeping or stinging of insects, or to hot needles piercing the skin. The scratching often tears the skin, leaves marks of the nails, abrasions, and sometimes gives rise to pustules and small ulcers. The itching is often insupportable, occasioning much distress and mental irritation, or even despondency; and seriously affecting the general system. The disease terminates in a branny desquamation, leaving the skin dry and thickened. When the disease attacks aged persons, with incessant itching, and a greater disorganization of the skin, it is

termed *Prurigo Senilis*. Care, however, must be taken, that these symptoms be not due to the pediculus corporis or body louse.

The *diagnosis* of prurigo may generally be made out with the aid of a magnifying lens; the papules are broader and less elevated than in *lichen*, paler, and instead of being grouped in patches like lichen, they are isolated or more diffuse; there is also a greater morbid condition of the skin in prurigo, and the itching is intense. In *scabies* the itching is not of a burning, tingling nature, but is more constant and supportable, the eruption is located in the flexures of the joints, and may be at once determined by the presence of acari, and their minute furrows or canals,—in prurigo, the itching is more paroxysmal in its character, and the eruption is usually found on the outward surfaces of the limbs.

The *prognosis* of prurigo is not always favorable as to a cure, but is so in the majority of cases met with among the young, and those who have not passed beyond middle life. It seldom proves dangerous, except in the more severe and obstinate forms of *P. Senilis*.

The *treatment* of prurigo, like that of lichen, and to which it will be somewhat similar, will depend upon the circumstances present, and the peculiar conditions of the system. Food and drink of a stimulating or heating character must be avoided, using a light and cooling regimen, keeping the bowels and kidneys in as normal a condition as possible, and avoiding the several predisposing causes of the disease. Iodide of Ammonium, Bromide of Ammonium, Iodide of Iron, Tincture of Chloride of Iron, etc., will be required according to the tendency of the constitution. If hepatic disorder be present, Podophyllin, Leptandrin, or some of the other agents heretofore named for affections of the liver must be used. In all obstinate cases, the urinary and renal functions must be especially attended to.

In old and obstinate affections I have derived considerable benefit from the internal use of Aconite, either in the form of tincture or alcoholic extract; it may, likewise, be advantageously combined with Bitter Root, Leptandra, or Blue Flag. An infusion of Yellow Dock Root, drank freely, has proved very serviceable in *P. Senilis*. Among the agents said to have been useful, but which I have not used, are Nitro-muriatic Acid, Strychnia, and Stillingia.

In the severe forms of prurigo, the surface of the whole body should be washed daily with soap and water; the soap containing an excess of alkali; and once or twice a week the surface of the limbs and body should be exposed to the Sulphur Vapor Bath. If

the strength of the patient will allow, the Spirit Vapor Bath may be used every week or two, with great benefit.

The local applications are the same as those named for lichen; to which may be added the following: 1. A very dilute solution of Nitro-muriatic Acid.—2. An Acetous Tincture of Bloodroot.—3. Take of Chloroform one fluidrachm, Sulphate of Morphia one or two grains, Glycerin one fluidounce; mix.—4. Take of Oil of Bitter Almonds two drachms, Cyanide of Potassium twelve grains, Simple Cerate two ounces; mix.—Solution of Acetate of Ammonia; Extract of Belladonna and Glycerin; Solution of Muriate of Ammonia with the addition of Tinctures of Aconite and Poke, have also been found useful.

When the disease is seated upon the scrotum and root of the penis it is termed *Prurigo Scroti*, and is sometimes very distressing and unyielding. It may occur as a primary affection or be an extension of the preceding malady. When located upon the female organs, the labia or even extending into the vagina, it is named *Prurigo Pudendi Muliebris*, and is frequently so severe as to occasion nymphomania, and even give rise to the habit of self-pollution. When the affection is located on the perineum, or around the anus, it is called *Prurigo Podicis*, or *P. Ani*; in which the itching is apt to be very intense, the cuticle rough, and the parts covered with black crusts and furrows from scratching. Means similar to the above named must be used in these local affections. To allay the intense itching, in addition to what has already been named, a solution of Salt in water may be applied once or twice a day; or, the the Solution of Borax with Morphia; or, a mixture of Juniper Tar two parts, Glycerin thirty parts; mix and place over a fire, and while hot, stir in powdered Starch fifteen parts. A solution of Muriate of Ammonia in a dilute solution of Hydrochloric Acid, has also afforded prompt relief. The parts must be washed daily with soap and water. A solution of Borax one drachm in a cold infusion of Cleavers one fluidounce, will be found an excellent wash in nearly all of the lichenous, papular, and eczematous eruptions. And in many cases the solution of Sulphite of Soda in water and glycerin, named in the treatment for Favus, will be found decidedly efficacious.

ORDER III. VESICULÆ.

Vesicular or Eczematous affections are characterized by the presence of vesicles, containing a transparent or opaque fluid, serous or

sero-purulent. This fluid may become absorbed, and terminate in small, round, dry scales, or, it may be effused upon the surface giving rise to concrete laminated scabs or flakes. The eruption may be seated upon any part of the body, and is usually associated with a debilitated condition of the system.

ECZEMA.

Eczema is a very common non-contagious cutaneous malady, appearing both in an acute and a chronic form, and attacking either sex, and at all ages. It consists of an eruption of minute vesicles forming irregular patches upon various portions of the skin, and which, when ruptured form superficial, moist excoriations, which eventually dry and give rise to white, opaque, or yellowish, thin flaky crusts. One crop of vesicles is apt to be followed by another in rapid succession, the skin being more or less red, and eventually becoming thickened from infiltration of serum, into its tissues, and sometimes fissured, and even œdematous. Wilson states that "eczema is never present without lichen, and only becomes eczema when the vesicles are in excess over the papules." In the chronic form though there may still remain some redness of the skin, yet the more prominent characters are, the scaliness and desquamation, or, the cracked and fissured condition of the affected parts. According to the severity of the disease, there is more or less pain, smarting or burning, and itching, the itching being more severe in the chronic forms.

Various terms have been given to the disease, according to its peculiar appearances, as well as its location. Thus, *Eczema Erythematosum* when the predominant symptom is redness; *E. Papulosum*, when the cutaneous pores are in the form of papules or pimples; *E. Vesiculosum* when numerous vesicles are present; *E. Ichorosum* when a serous or colorless lymph is abundantly exuded; *E. Pustulosum*, when pustules and pus are present; *E. Squamosum*, when numerous scales are present; *E. Fissum*, when the skin is fissured; *E. Neurosum*, when severe pain attends, etc. And, as the eruption may manifest itself upon the scalp, the face, the ears, the lids, the mouth, in the axilla, on the breasts, hands, scrotum, etc., it has also received the names of *Eczema Capitis*; *E. Faciei* (crusta lactea); *E. Aurium*; *E. Palpebrarum*, etc., which designate not only the location, but frequently the variety of the eruption, as this, in most instances, presents one or other variety according to the part attacked. Thus, on the scalp, face, and ear, the eruption is at first

ichorous, and then scaly; on the back of the hand, it is papulous; on the palm of the hand it is scaly and the skin fissured, etc. When eczema is on the back of the hand, it has been popularly termed *grocer's itch*, *washer-woman's itch*, etc., "and it is often a point of nice distinction to determine whether to call a given eruption, eczema or lichen agrius, lichen eczematosis, as it might with great propriety be called."

Eczema Crurale is a very annoying and obstinate form of the disease which appears on the legs, giving rise to excoriations, crusts, or fissures, and even deep or superficial ulcers, and a serous or purulent discharge occasionally mixed with blood, and also to more or less infiltration of the skin. When deep, the fissures are red and raw-looking, and occasionally filled up by the small crusts formed by the discharge; the ulcers may be inflamed or indolent. It more frequently occurs in persons about middle-life or later, and is often associated with varicose veins, when it may require several years of treatment for a permanent cure.

All these varieties of eczema may assume a chronic form, *Eczema Chronicum*, or *Psoriasis*, in which the inflamed and swollen skin has deep cracks and fissures, from which, as well as from the excoriations present is secreted an ichorous and often unpleasantly-odorous discharge, which, when dry, forms thin, yellowish, laminated scabs, that fall off and are replaced by similar crusts successively deposited. Fresh returns of the disease, with redness, swelling, and discharge, may follow each other and perpetuate the disease for months and years. The skin may be morbidly charged, with a dense and infiltrated subcutaneous cellular tissue, and the eruption may be in circumscribed patches, callous and dense, thin and dry, thick, or horny and warty, and, frequently, there will be no ichorous exudation from these patches, or it may appear and disappear at certain periods. In chronic eczema the itching is frequently almost insupportable. The scabs often appear as if perforated with a number of pores through which the ichorous secretion exudes, and if any attempt be made to remove them before they are ready to fall off spontaneously, the parts beneath are thereby made to bleed.

The *causes* of eczema are generally somewhat obscure. The disease appears to be associated with general debility, or some constitutional disturbance, and may be excited into action by irritation of the skin, by general nervous irritability, induced by dentition, exposures, improper diet, derangements of the gastric, hepatic, or uterine functions, contact of certain irritating substances, etc. A strumous tendency also appears to be a predisposing cause, as well as rheumatism and gout. The disease is not contagious, though it is stated

that it has been transmitted by coition, and that the application of the discharge, when this is profuse, to healthy parts has occasionally developed the eruption.

In the *diagnosis* of eczema, it must be recollected that it is primarily vesicular, the vesicles containing a fluid that stiffens and discolors the linen, and that, unlike lichen, it prefers the internal aspect of the limbs. In *scabies* resembling eczema, the pustules contain pus from the first, and the itch insect may also be found. In *impetigo*, the pustules never contain lymph, are larger than those of eczema, are confined to a smaller extent of surface, and its crusts are dense, thick, and greenish-yellow or brown. As the chronic form of eczema bears some resemblance to lichen agrius, we must carefully endeavor to ascertain the previous history of the eruption; chronic thickening of the skin, dull redness, absence of papules or vesicles, scaly exfoliation of the epidermis, intense itching, an ichorous secretion, chaps or fissures, and, perhaps, œdema, are the characters of chronic eczema.

The *prognosis* of chronic eczema is generally favorable; but, in most cases, the disease requires many months before a cure can be effected, depending, however, upon its cause and the condition and circumstances of the patient.

The *treatment* of chronic eczema is both constitutional and local; in the constitutional measures we must be guided by the rules already given under the treatment of Lichen and Prurigo, carefully examining the patient to ascertain both constitutional and local derangements. The internal agents from which I have derived the greatest amount of benefit in this affection, are, Bromide of Potassium; Tincture of Chloride of Iron; Compound Syrup of Yellow Dock with Bromide of Potassium;—Bromide of Ammonium one ounce, Water one pint; mix, dissolve the salt, and add Solution of Perchloride of Iron an ounce and a half—the dose is a teaspoonful, three times a day; in some cases, the iron solution may be omitted, and two or four drachms of Citrate of Iron and Strychnia, be substituted therefor;—Iodine Pill; and in some cases, a combination of Sulphate of Quinia one drachm, Reduced Iron one drachm and a half, Strychnia three grains, Alcoholic Extract of Black Cohosh one drachm; mix, and divide into sixty pills, of which one is a dose, to be repeated three times daily. The preparation named in the Note on page 383, and also that in the treatment of Chronic Peritonitis, in which the Soluble Pyrophosphate of Iron enters, will be found exceedingly useful.

No general rules can be given for the selection or employment of these agents; the practitioner must be guided by all the circumstances of the case, as well as by the influence exerted by the

agent administered. The internal use of Cleavers, Hydrocotyle Asiatica, Steel Wine, Cod Liver Oil, etc., have been lauded, but I have not used them.—Of course, hygiene must be strictly attended to, especially regulating the condition of the stomach, the bowels, the kidneys, and the skin—and avoiding all stimulating and indigestible articles of diet.

As external applications, some one of those named for lichen and prurigo may often be used with advantage. Or one of the following may be employed, bearing in mind, that the disease is frequently very rebellious to local applications, which require to be often changed. 1. Take of equal parts of Suet and Sweet-gum; melt together; a small portion of this may be warmed, and rubbed in upon the part, there or four times a day.—2. Take of Red Oxide of Lead Plaster one ounce, Sweet Oil a sufficient quantity to make the two articles, when melted together and cooled, form a thin ointment. This may be used in the same manner as the preceding.—3. Compound Ointment of Bayberry.—4. Ointment of Oxide of Zinc.—5. Compound Ointment of Oxide of Zinc.—6. Paint the parts twice a day with a solution of Chloride of Zinc one drachm, Water, Glycerin, each, half an ounce.—7. Take of Prepared Tallow, Prepared Lard, each, six ounces, White Wax four ounces, Juniper Tar (pyroligneous oil of juniper, or huile de cade) one pound; mix together, by means of heat. To be used in the absence of moisture and itching, during desquamation.—8. Saturated Solution of Oxalic Acid.—9. Take of pulverized Sulphate of Zinc four ounces, Liquid Styrax four ounces, Lard one pound; mix, and boil gently together for some time, constantly stirring. Apply twice a day.—10. Mix together Iodide of Ammonium two drachms, Water and Glycerin, half an ounce of each; or, one ounce of Benzoated Lard or Oil may be substituted for the water and glycerin. Ointment of Iodide of Sulphur has sometimes proved efficacious; also the following: Take of Sulphuret of Potash, Carbonate of Soda, Hydrochlorate of Ammonia, each, in powder, three drachms; Lard two ounces; mix, by trituration. Many other preparations could be named, but the preceding will be found sufficient for all purposes. In all cases, the skin should be well washed with soap and water, each time before making an application; and when an ointment is used it should be softened by warming it, just previous to rubbing it upon the affected part.

In all cases, previous to applying any of the local remedies, the crusts formed must be removed, and which may be effected by first softening them with oil, and bread poultice. If there is any considerable infiltration of the skin, the application of alkalies is

indicated, as, alkaline Soft Soap, or Liquor Potassa carefully used; one of these may be applied once or twice daily, and it should never be so strong as to produce any destructive action upon the skin. In some cases the following will be found excellent: Take of Oil of Bitter Almonds one drachm, Oil of Sweet Almonds one ounce, Carbonate of Potassa four drachms, Camphor one ounce; mix.—When the infiltration and the itching have become moderated, a preparation has been highly recommended composed of Soft Soap, Alcohol, Oil of Cade, each, one ounce, Oil of Lavender an ounce and a half; mix. By means of a piece of flannel, rub some of this a little firmly over the eruption, night and morning, and allow it to dry upon the parts; before each re-application wash the parts as clean as possible. Petroleum Soap may be substituted for the Soft Soap, and Tar for the Oil of Cade.

The eczematous ulcers or fissures in *Eczema crurale* must be treated upon general principles, according to their inflamed or indolent condition. When there is much irritation or congestion, leeches around the parts will be found useful. The patient should be kept quiet, in the recumbent position for ten or fifteen days at a time, and the affected limbs be supported by a bandage evenly applied, and re-adjusted two or three times daily; in other respects the treatment will be similar to that heretofore named for the several varieties of eczema.

HERPES.

Herpes or Tetter is a common, transient, non-contagious, vesicular eruption, characterized by larger vesicles than those of eczema, globular, occurring in well-defined circular or irregular groups or clusters, seated on an inflamed base, and accompanied with an itching, pricking, smarting or burning sensation. The integument occupying the intervals between the clusters presents a healthy appearance. The clusters themselves vary considerably in size and shape. In from six to ten days, if the vesicles have not disappeared from absorption of their contents, they usually rupture, or dry up without rupture, and form thin pale-brownish scabs, which do not remain for any great length of time. The fluid in the vesicles is clear and colorless at first, and gradually becomes milky and opaque; when clear, it is of a neutral or slightly alkaline reaction, but never so alkaline as the fluid in eczema,—when opaque, it is neutral or slightly acid. The purplish or dark hue remaining after the scabs fall off, disappears in a few days.

There are several varieties of Herpes, as, *H. Phlyctenodes* which may occur on any part of the body, but more commonly upon the superior parts, and runs its course in from eight to fourteen days. *H. Labiales*, which is seated upon the lips or around the mouth, and lasts about eight or ten days. *H. Preputialis*, when seated upon the foreskin, and which sometimes forms a sore that has been mistaken for a chancre. *H. Pudendalis*, when the eruption occurs upon the labia majora, and which is often perpetuated by the irritating discharges from the vagina. *H. Zoster* or *Shingles*, which usually occurs on the abdomen, and is limited to one side of the median line; it may, however, affect the scalp, head, face, neck, back, chest, etc., and usually disappears on the tenth or twelfth day. *H. Iris* occurs in the form of circular patches, formed of concentric rings which present various tints of color, owing to their various degrees of development. The center of each patch consists of a solitary vesicle, with rings of vesicles surrounding it, and which run the usual course of herpetic vesicles. It is very rarely observed.

Herpes is essentially an acute disease being rarely met with in the chronic form; *H. Iris* is more liable to become chronic in elderly persons of debilitated or cachectic constitutions. The treatment of any chronic form of herpes will be the same as recommended for vesicular eruptions generally; including that for erythema, bullæ, etc., when the eruption assumes erythematous, bullar, etc., symptoms.

ORDER IV. PUSTULÆ.

Pustular or Impetiginous eruptions are characterized by pustules or elevations of the epidermis containing pus; these may be irregularly scattered, or united in clusters, and vary in their size and shape. Sometimes the purulent matter becomes absorbed, with accompanying desquamation; but more commonly the pustules terminate in ulcerations covered by crusts or scabs, or, by induration; permanent cicatrices are often left by the disease. The pustules may be seated upon any part of the body, and are usually associated with some constitutional derangement.

ECTHYMA.

Chronic Ecthyma is more frequently encountered than the acute form. It is a non-contagious affection, and is characterized by pustules occurring in succession for several months. They are

circular, of varying size, though usually rather large, and are apt to be indolent, passing through their various stages very slowly. When very large, they have a more or less inflamed areola around them, of a violet color, and hard. Some slight pain may also be present. In old persons, and those of impaired constitutions, the base of the pustule often presents a dingy violet or livid color, with more or less considerable inflammation. Eventually, the epidermis ruptures, and discharges a bloody sanious fluid, and the denuded surface becomes covered with hard, black, and usually very adherent crusts, which fall off after several weeks, leaving dark-red spots or cicatrices behind them. If these scabs be prematurely removed, they expose indolent ulcers with callous edges, secreting an ichorous fluid, and are of very difficult cure. In some cases, after an apparent tendency to suppuration, the pustules will gradually disappear with desquamation of the epidermis. When the disease occurs in infants it has been termed *Ecthyma Infantile*; and when in broken-down constitutions, *E. Luridum*, and *E. Cachecticum*.

The *causes* of ecthyma are various; the more common are, unhealthy and enfeebled constitutions, intemperance, gastro-intestinal disorder, and improper or insufficient food. It may also be occasioned by irritants applied to the skin, as observed among brick-layers, grocers, persons working among irritating powders, etc., by inhabiting moist, unhealthy residences, by improper exposures, and, sometimes, it follows as a sequela of measles, scarlet fever, etc. It is more common to adults in early life, and in the spring and autumn, and is frequently associated with other cutaneous affections, as, lichen, prurigo, scabies, etc. The seat of the disease appears to be between the cutis and cuticle, and not in an enlarged follicle.

The *diagnosis* of chronic ecthyma, requires that the history of the case, the symptoms, and the color of the skin around the pustules be taken into consideration. The pustules are large with a red or dark-colored areola around them, in which respect they differ from *acne* and *sycosis*, which present hard elevations without any areola. *Boils* are more painful than ecthyma and contain a "core;" the inflammation of boil is, at its commencement, deeper seated and thence extends to the surface, while, in ecthyma, the inflammation commences at the surface and spreads to the deeper-seated tissues.

The *prognosis* will depend very much upon the condition of the patient; a removal of any constitutional or local disorder will

usually be followed by a disappearance of the eruption. Of itself the disease is not dangerous, though frequently very obstinate.

The *treatment* of ecthyma is very similar to that recommended in the preceding forms of cutaneous eruption. A strict attention to hygiene; good nutritious food; tonics; alteratives; and warm baths. Constitutional or local diseases must be met by their appropriate treatment, and all external causes of the eruption must be entirely avoided. Sometimes, the Sulphur Vapor Bath, will be found beneficial. As local applications to the eruption, an alkaline wash may be used, as, a dilute Solution of Potassa; of Carbonate of Potassa; of Carbonate of Soda; of Hydrochlorate of Ammonia; of Iodide of Ammonium; or of Potassio-tartrate of Iron, etc. When there is much pain or irritation, anodyne and emollient applications only must be employed. The erythematous ulcers, when exposed, being of a very indolent character, usually require some stimulant application to cause them to heal kindly, as, touching their surfaces with Sulphate of Copper, Iodine, Compound Solution of Iodine, Turpentine, Sulphate of Zinc, Sesquicarbonate of Potassa, or Tincture of Chloride of Iron, etc.

IMPETIGO.

Impetigo (*Scall, Crusted Tetter, Running Tetter, Humid Tetter, etc.*), is characterized by an eruption of small, hemispheroidal, or flattened pustules, with but little inflammation at their base, and which may be scattered and distinct, or be collected into clusters of various extent, and fused one with another. These pustules are called "pyodracious," from their being small, hardly elevating the cuticle, not having much inflammation around them, and ending in a thick scab. They are attended with more or less itching, rapidly mature, rupture in the course of from one to four days, and discharge a quantity of thick purulent matter, which quickly dries, forming semi-transparent, thick, rough, greenish, or brownish-yellow, irregularly-shaped crusts. As the discharge often continues under these crusts, their thickness and size become greatly augmented, and the disease is prolonged. The purulent secretion exhales a very unpleasant odor, in most instances, which has been likened to that of valerianic acid, of spoiled cheese, or of rancid butter, more especially if the patient be kept in an uncleanly condition. Very often fresh pustules form around the parts originally affected, and thus cause the eruption to spread over a large surface. The crusts are

often slow and irregular in becoming detached, and when they do separate leave a red, shining, and very tender surface, which gradually disappears without leaving any cicatrix. The disease is divided into the following varieties:

1. *Impetigo Figurata*, (*Crusta Lactea*, *Porrigo Larvalis*), occurs more frequently upon the face, scalp, and neck, rarely on the limbs and trunk, and is often met with among infants during the period of teething. The small yellow pustules become developed upon one or more small patches of redness, and form distinct or confluent groups, of a circular or oval form, and the disease may be very mild, or be attended with more or less heat, itching, tension and pain. The cheeks, scalp, ears, lips, nose, and even the eyelids, may be affected. In a day or so these pustules burst, discharge a fluid, which forms crusts, as heretofore described, and which resemble a patch of dried honey; the disease may be prolonged by the formation of successive crops of pustules, with thickening and hardening of the integument, or, this may assume a morbid action, continuing to discharge an abundant semi-purulent fluid, which constantly keeps up the formation of crusts. When these crusts occurring on the limbs, become very thick, forming a sheath upon or around the limb, the disease has been termed *Impetigo Scabida*, and is often attended with severe ulceration. *Impetigo figurata* is the most common variety of impetigo met with; and notwithstanding the deep fissures and ulcerations of the skin caused by it, a permanent cicatrix is never produced. Sometimes constitutional symptoms may attend the disease, but they are usually mild. The eruption may be confined to a very limited space, or it may be very extensive, literally covering the face, like a mask; and it may appear periodically for several years in succession.

2. *Impetigo Sparsa* is more especially confined to the extremities, the legs in particular, and differs from the preceding variety in the irregular and scattered distribution of the pustules; these are usually attended with a more intolerable itching, and form thicker, more friable, and smaller crusts than the *I. figurata*. It is often conjoined with oedema, as well as severe ulceration; and the incrustation may spread to the ends of the fingers or toes, distorting or destroying the nails. It is always obstinate in its character, often continuing for years, notwithstanding every attention and treatment. *Impetigo Scabida* is a severe form of this variety.

When either *I. figurata*, or *I. sparsa* attacks the scalp, the disease is termed *Impetigo Capitis*, and is often accompanied with an enlargement of the lymphatic glands of the neck, sometimes followed by suppuration. Frequently, each pustule will be found traversed by

a hair, as if the disease had commenced in the hair-follicle. The hair is usually matted together by the secretions and crusts, and, if there is a want of attention to cleanliness, it will be full of pediculi. The disease is not contagious, and does not, as a general rule, injure the roots of the hair.—When the beard is the part affected, it is termed *Impetigo Sycosiformis*.—When there is much heat, tension, redness, and tumefaction, with fever and constitutional disorder, it is termed *Impetigo Erysipelatodes*, or *I. Erythematica*.

Impetigo may be occasionally caused by local irritation, but is more commonly referable to some constitutional predisposition, as, debility and the lymphatic temperament. Young persons are more liable to it than old, and it is more common in spring and autumn. Among the exciting causes may be named, bad food, unhealthy locations, intemperance, dentition, menstrual derangements, gastro-intestinal derangements, mental excitement, uncleanness, etc.

The *diagnosis* of impetigo may be readily made out by observing that it is seated between the cutis and the cuticle, and that its pustules are of small size, not much elevated, and with no induration around them. It may be determined from *favus*, by the bright-yellow, dry, cup-like crusts, through the center of each of which, one or more hairs pass, and which are readily pulled out; or, when these conditions are absent in *favus*, by the discoloration of the hair, and the patches of baldness. In case of doubt, the microscope will clear up the diagnosis by an examination of the hair, which may contain the parasite peculiar to *favus*, but which present their normal appearance in impetigo.

Impetigo may be discriminated from *sycosis*, in which the pustules are larger, more prominent, discrete, with darker-colored crusts, and attended with tubercular swelling and induration around the pustules; the microscope also reveals the parasite peculiar to *sycosis* either in the hairs or in the exfoliated debris; beside which, the disease commences differently, with elevated rosy circles, like those of *herpes circinatus*, and which increase in size circumferentially.—From *herpes tonsurans*, in which the hairs are diseased by a parasite.

The *prognosis* of chronic impetigo is usually favorable, though it frequently proves a very obstinate and troublesome disease. The duration of the eruption will depend greatly upon the constitution of the patient, the causes producing it, and the accompanying circumstances. When the scalp is affected, it is often of tedious cure.

The *treatment* of chronic impetigo is the same as advised in the preceding cutaneous affections, both as regards the hygiene, and

the local and constitutional measures ; much will depend upon the judgment and skill of the practitioner in selecting those means more especially adapted to each particular case. I prefer as a tonic and alterative, Bromide of Potassium, or, the alterative with soluble Pyrophosphate of Iron, given under Chronic Peritonitis. As external agents, the following will frequently prove useful: 1. Take of a saturated Solution of Oxalic Acid, Cologne, each, one fluidounce, Creosote twelve minims; mix, and apply twice a day. This will also destroy the lice.—2. Simmer the fresh leaves of Tricolored Violet (*Viola Tricolor*) in Cream and strain; a sufficient quantity of the leaves must be used, so as to form an ointment when finished. Use this three or four times a day.—To remove lice, Cologne may be used as a wash; or, an ointment, or infusion of Stavesacre; or, a very dilute solution of Carbolic Acid; the wash should be continued daily until all the “nits” have disappeared.

ORDER V. BULLÆ.

Bullous eruptions (blebs or bubbles), are, in reality, vesicular, but the vesicles are larger than in the Order Vesiculæ; indeed, when they exceed the size of a pea they may be termed bullæ. In some instances these blebs attain a diameter of six or seven inches; they may be round, oval, semi-circular, or polygonal, and contain a clear, transparent fluid, sometimes tinged with blood; a yellowish, opalescent fluid; or, a turbid, sero-puriform fluid. They are seated between the mucous and horny layers of the cuticle, and undergo the same changes as the Vesiculæ, speedily rupturing, and forming yellowish, or yellowish-brown scabs, as well as excoriations or superficial ulcerations. They may appear on any part of the body, but more commonly upon the extremities, especially the inferior. The disease may be partial or general, the bullæ appearing singly or in groups, occurring generally in successive crops, and continuing for several months or even years. It is apt to be associated with diseased or enfeebled constitutions, and sometimes gastro-enteric derangements.

PEMPHIGUS.

Pemphigus, sometimes termed *Pompholyx*, is more frequently met with as a chronic affection. It is characterized by the appearance of crops of bullæ, which rapidly and persistently succeed each other, and in so close a manner that they may be met with in all

stages at the same time—some appearing, and others passing away; frequently, before the first crop has run its course, the second, and even the third have made their appearance. Occasionally, the intervals between the crops of blebs are longer. Febrile symptoms sometimes precede each crop. Sometimes the bullæ are surrounded by reddish areolæ, and the first crop that appears is apt to be preceded by erythematous spots. A sensation of tingling and itching, or of smarting, accompanies the appearance of the blebs, which rapidly attain their full size, then burst, discharge their contents, giving rise to superficial excoriations, or, the fluid contained in them may decrease in quantity and dry up into thin, brownish, epidermic looking scabs, which cover red and tender surfaces, the cuticle surrounding them being wrinkled and thicker than natural. In this way the eruptions may continue to succeed each other for weeks, months, or years, occasioning a tedious and painful affection. More or less severe constitutional symptoms are apt to be present. The eruption may appear on any part of the surface, but more commonly on the fore-arms, and legs; and when on the face the bullæ are frequently confluent.

When the disease is attended with a most intense and insupportable itching, it is termed *Pemphigus Pruriginosus*. When the eruption consists of fine yellowish or grayish scales, usually commencing on the chest, and finally covering the whole surface so that there are no intervals of sound skin, it is called *Pemphigus Foliaceæ*. In the foliaceous variety the itching is usually moderate, there is no great infiltration of the skin, the scales and crusts resemble parchment, are turned in upon their margin, and are partly detached; beneath them are slight ulcerations with red surfaces, from which is discharged a somewhat plastic secretion. The skin usually exhales a nauseous, fetid kind of perspiration. When the bullæ present dark, livid spots, a purplish areola, and leave painful dark-colored ulcerations, secreting a fetid discharge, more or less constitutional disturbance being present, the disease is termed *Pemphigus Gangrænosus*, *P. Infantilis*, and *Rupia Escharotica*.

The causes of pemphigus are not well known; it appears to be associated with constitutional debility, disease of internal organs, depressing causes, want of nutrition, derangements of the hepatic, gastric, intestinal, and uterine organs, etc., and may occur at any period of life, the chronic form being, however, more frequent among persons advanced in years. It is a disease rarely met with.

The diagnosis of chronic pemphigus may be determined by the history of the disease from its commencement, the usual mildness of the constitutional symptoms, and its obstinacy and duration.

The bullæ of pemphigus leave behind them peculiar, dusky-red, isolated, irregularly-shaped marks, of various sizes, and from which there is a slight cuticular exfoliation from time to time. It may be determined from the following affections by the characters named: *ecthyma* consists of distinct pustules; *herpes* presents minute vesicles in clusters, and upon an inflamed patch; *eczema* consists of smaller vesicles, the skin becomes infiltrated and thickened, the scales and crusts are small, and the disease rarely manifests a tendency to appear upon the entire surface of the body at once; *erysipelas* presents more redness, swelling and inflammation, the redness disappears temporarily under pressure, the inflamed parts are swollen, and there is more constitutional febrile disturbance; *rupia* presents flat and less defined bullæ, isolated, more apt to be surrounded by a red margin, and thicker incrustations, beneath which is a more distinct ulceration.

Pemphigus being generally attended with debility or disease, does not afford a favorable *prognosis* for a rapid cure. Indeed, when complicated with disease or much constitutional disorder, the prognosis is unfavorable in proportion to the character and severity of the complication. It is very liable to relapse, and sometimes occasions diarrhea, emaciation, etc., which prove fatal. The pruriginous, foliaceous, and gangrenous varieties are very apt to prove fatal. When the system is about giving way, this eruption is often one of the unfavorable indications of such failure. When no serious complications are present, the prognosis is favorable, as the disease, in itself, is not of a serious character.

In the *treatment* of chronic pemphigus, tonics are the remedies usually prescribed, but we must be very careful in our examination of the patient in order to ascertain the existence of any local or constitutional disease, which, if present, will require its appropriate treatment in conjunction with the measures pursued for the pemphigus,—in such cases the cure of the eruption greatly depends upon that of the complication. I prefer as an internal agent in this affection, the following combination: Take of Bromide of Potassium one ounce, Citrate of Iron and Strychnia two drachms, Citrate of Iron and Quinia four drachms, Water one pint; mix, and dissolve the salts. The dose is a teaspoonful three times a day. Other tonics and alteratives may be used, however, especially some one of those named in the treatment of the preceding skin diseases. Cod Liver Oil, Quinia, and Nitro-hydrochloric Acid, etc., have also been advised as tonics; and Scrophularia, Rumex Crispus, Celastrus, and Helianthemum, as alteratives. If there is considerable irritation of the mucous lining of the air passages or

of the alimentary canal, Bromide of Ammonium; Infusion of White Indian Hemp, Solomon's Seal, and Yellow Dock; Infusion of Plenrisky Root and Ptelea; anodynes, etc., together with counter-irritation upon the surface of the chest or abdomen, will be required. Inhalations may also prove serviceable, when bronchial or laryngeal irritations are present. Other urgent symptoms will require means of relief according to their indications.

An attention to hygienic measures is of great importance; the skin should be frequently bathed with an alkaline solution, and also be at different intervals exposed to the action of a warm alkaline bath; the kidneys should be properly attended to, according to the character of the urine; the bowels should be kept regular without active purgation; the diet should be generous and nutritious but of easy digestion, and in old persons or in very weak systems a little wine or porter may be allowed; and the patient should be exposed as much as possible to a pure fresh air.

In the local management of the eruption it has been advised to open the blebs with a fine needle as soon as they form, and, after they have discharged their contents, to cover them with a mixture of equal parts, of Oxide of Zinc and starch, in fine powder. In many cases, an ointment of Stramonium and Lupulin will be of value to relieve pain and itching. When the excoriations or ulcerations are indolent, they may be touched daily or every other day with a drop or two of Spirits of Turpentine, and then be at once covered with Turner's Cerate, Benzoated Compound Zinc Ointment, or, with Mayer's Ointment,—as the Turpentine produces considerable pain shortly after its application, and which continues for some minutes. The detachment of the crusts may also be favored by the constant application of one of these ointments, or, of the Sweet Gum Ointment; they should never be torn off.

RUPIA.

Rupia is commonly described by authors, with Pemphigus, under the order Bullæ; it is characterized by an eruption of large, distinct, flattened bullæ, seated on very slightly raised bases, and surrounded by reddish-brown areolæ of an inflammatory nature. The bullæ contain a serous, sero-purulent, sanious, or dark-bloody fluid, which is discharged upon their rupture, and drying, forms thick dark or brownish, rough, prominent crusts, frequently of a conical shape, or resembling limpet shells or oyster shells, being thicker at the center than at the circumference, and looking as if formed of concentric layers projecting one beyond the other. These

crusts usually remain for some time before they fall off, and when this does occur, each detached crust exposes a circular, indolent, more or less deep, grayish ulcer, from which issues a profuse, ichorous, fetid fluid, and fresh scabs are readily reproduced upon the ulcer. The ulcers heal very slowly, requiring several weeks therefor, leaving a persistent dark-red or livid hue of the skin around the cicatrix. Not unfrequently rupia is attended with considerable disturbance of the general health, fever, etc. Three forms of rupia are usually described; but there is no material difference between the first two described below.

1. *Rupia Simplex* is the simplest form, the bullæ being circular, flattened, and about the size of a dime the crusts being thin, and the ulcers beneath them superficial; it more generally appears on the legs and inferior portions of the trunk, and is common among young children. It sometimes follows the exanthematous fevers, and is occasionally complicated with purpura hemorrhagica.—2. *Rupia Promineus* is characterized by larger bullæ, thicker crusts which are more projecting and conical, and a deeper and more troublesome ulcer, which is disposed to spread and increase its diameter. The crusts remain for some time before they become detached, and the exposed ulcer sometimes discharges a matter which gives rise to a new crust. The cicatrix formed continues of a dark or livid hue for many months. The bullæ may be few or many, may be developed slowly or rapidly, and may appear on the superior or inferior extremities, more commonly the latter.—3. *Rupia Escharotica* has already been referred to under Pempfigus.

The causes of rupia appear to be those that occasion debility or constitutional disease, as, intemperance, unhealthy food, impure air, uncleanness, etc., and the disease is frequently met with among scrofulous persons, and the children of drunken and dissipated parents; in most instances, it is associated with a syphilitic taint.

In the diagnosis, rupia must be distinguished from pemphigus and ecthyma. In *pemphigus* the bullæ are not flattened, usually occur in groups, with little or no redness around their bases, the fluid discharged is clear and transparent, the scabs are not so thick and conical, and beneath them there is only excoriation, or, at most, a very superficial ulceration.—In *ecthyma* the eruption is pustular from the first, has a harder and more elevated base, the crusts are flatter, and the ulcerations beneath them are not so deep as in rupia.

In itself, rupia is not a dangerous malady, although very obstinate and of tedious cure. The prognosis, however, will depend upon the size and number of the bullæ, their location, and the character and

nature of any co-existing diseases. A profuse eruption is unfavorable, and the atonic ulcers formed on the legs are often very intractable to treatment, requiring many months before they will heal. In the aged the disease sometimes proves fatal, especially among those whose systems have become impaired by disease, or irregular habits.

In the *treatment* of rupia, we must direct our means to the conditions of the system that are present. Any scrofulous or other taint or tendency of the system, will require the proper alteratives; and so of other maladies that may be present, the appropriate measures should be pursued the same as if no rupia had manifested itself. More commonly, tonics and alteratives will be required, together with a generous, nutritious diet, regularity of bowels, kidneys, and skin, and a pure fresh air.

The bullæ should be opened at an early period, and the fluid contents be permitted to escape, afterward painting the vesicles with the Tincture of Chloride of Iron. As the irritation is kept up by the morbid secretion from the ulcerations, the crusts should be softened and gently detached by applications of oil and poultices; and the surfaces of the exposed ulcerations should be stimulated so as to favor prompt healing, by applying Tincture of Chloride of Iron, either alone or combined with some Chlorate of Potassa;—a drop or two of Oil of Turpentine; Concentrated Nitric Acid, upon a soft wood porte-caustic; or Compound Tincture of Iodine may also be used. The healing of very obstinate ulcers on the legs may be greatly facilitated by passing strong electro-magnetic interrupted currents through them and the surrounding parts, daily; in such cases, a recumbent position, with the legs elevated, will be found useful.

With the exception of Rupia, and perhaps Herpes, the other varieties of cutaneous eruptions referred to in the preceding Orders, appear to be closely allied to each other, and indeed we frequently find two or more of them manifested simultaneously; beside which, the treatment is very nearly identical in each of them. Again, they are well known to be convertible into each other, and the erythema of to-day, may be an eczema, a lichen, or an impetigo to-morrow, and, subsequently, become a chronic ecthyma. These facts lead me to believe that in reality they are but one disease, under different modifications according to the exciting cause, the particular layer or tissue of skin affected, the peculiar conditions of the system, degree of original inflammatory action manifested, etc. But as authors generally describe them under distinct heads or orders, I have deemed it best to do the same.

During the last twenty years I have frequently been called upon to treat a very remarkable disease, which appears to be not only of a contagious character, but also to exist epidemically; it has received several names, as, *Indiana Itch*, *Illinois Itch*, *Prairie Itch*, *Seven-year Itch*, *Camp Itch*, *Army Itch*, etc. I have never seen a description of it, and consequently have no authorized name for it. It appears to be a prurigo, sometimes of an eczematous character, at others, presenting ecthymatous or impetiginous appearances; and frequently, it is associated with scabies.

It is characterized by a minute vesicular elevation of the skin, accompanied by a most intense and distressing itching, which is greatly augmented when the surface becomes heated, as, by exercise, heat of bed, etc. It appears upon the back of the hands, and between the fingers, more especially when complicated with scabies; also upon the arms, the trunk, and the legs. Any part of the body may, however, be attacked with it. Its duration varies from a few weeks to three or four years; but more commonly, under proper treatment it disappears in a month or two; sometimes it is very intractable to treatment.

The itching is of that intense character that the patient not only scratches, but actually tears the affected parts with his nails; and which, instead of allaying the itching, renders it more of a tingling, burning character. From the scratching, more or less imperfectly circular, rather indolent ulcers are produced, either large or small, superficial or deep-seated, and which become covered by thin scales or scabs of a dark color. In many instances there will be more or less redness around the margin of the ulcers, the surfaces of which bleed a little upon being scratched or rubbed hard, and the itching usually continues nearly as severe as at first, but scratching is apt to be more painful. In certain constitutions these ulcerations are more or less of an atonic character, with a dark color around them, and when healed leave a dark or livid cicatrization which continues for some time. In a few cases the eruption assumes a pustular or furuncular form, discharging a purulent fluid for many days.

I am not aware of its *causes*; it appears to attack all persons exposed to its action, without regard to age or sex; and those of weak or deranged systems are more liable to its severer forms. Uncleanliness, improper or innutritious food, and congregating persons together, as, in camps, etc., favor its appearance. The *prognosis* is generally favorable; but I have undoubtedly seen cases in which the disease having disappeared from the surface spontaneously, or from the influence of local (without internal) treatment, was subsequently followed by serious disease of internal organs; but whether

there was any positive relation between the two, or, whether they were mere coincidences, I am not prepared to say.

The *treatment* consists in the employment of the proper measures to overcome such abnormal conditions of the system as may be present,—the same as advised in the preceding skin affections; together with the necessary hygienic measures. And in all cases where the patients are in other respects apparently well, I invariably have them to take solution of Bromide of Potassium internally, as an alterative.

As to local applications, there are several that have been found useful, as—1. Bathing the whole surface of the body twice a day with warm water and an alkaline soft soap.—2. Take of Lard half a pound, Sulphur two ounces, Salt of Tartar one ounce; mix, and form an ointment; after bathing as above, apply this ointment every night.—3. Take of Sulphuric Acid two drachms, Sulphur half an ounce, Lard three ounces; mix, and apply as the preceding.—4. Take of Pyroligneous Acid two fluidounces, Pure Carbolic Acid four drachms, Water seven and a half fluidounces; mix the acids and then add the water. Apply to the affected parts once a day, by means of a pencil or sponge, thoroughly impregnating the skin with it. Nos. 2, 3, and 4, will especially be found useful in those cases associated with scabies.—5. Take of Iodide of Ammonium one drachm, Lard one ounce; mix. Apply three or four times a day, washing the surface every night with common soap and water. Twelve or fifteen minims of Chloroform added to this ointment, will aid in allaying the itching.—6. Take of Washed Sulphur, pulverized Carbonate of Ammonia, each, one part, Lard eight parts; mix. Thoroughly cleanse the person with soap and water, and apply the ointment; it may be applied once or twice daily.

For the ulcers, I have found that touching them two or three times a day with Tincture of Chloride of Iron, and then dressing them with Mayer's Ointment, or with the Red Oxide of Lead Plaster, exerts a decidedly beneficial influence.

FURUNCULUS.

Furunculus or Boil is a tumor varying in size from that of a pea to a hen egg, hard, prominent, conical, and usually quite tender and painful. The tumor presents a dark-red color, gradually increases in size, its base penetrating deeply, and more or less rapidly advances to maturity, the summit of the tumor becoming pointed and yellowish-white, bursts, and discharges a variable amount

of pus frequently mixed with blood. After the opening of the boil a sloughy piece of cellular membrane, or the *core*, will be seen occupying the purulent furuncular cavity, and which in the course of from four to fifteen days becomes loosened and is expelled. The pain now ceases, the swelling rapidly disappears, with the formation of granulations, and in a few days the part heals, leaving a transient, dusky redness, and a permanent cicatrix.

Boils may appear on any part of the body, but seldom in any great number, more commonly only one or two at a time, but they are liable to appear in succession, and thus annoy the patient for months and even years. In some cases, they are attended with constitutional febrile symptoms, depending, however, upon their location as well as their size. When seated in the neighborhood of sensitive nerves the pain is often intense. Young persons appear to be more liable to them, and they are due to gastro-hepatic disorder, constitutional debility, impure blood, etc., and sometimes exist as an epidemic.

Treatment is rarely required for boils except when they are very painful, or when they appear successively following each other. The progress of a boil may often be retarded and completely arrested by applying a cataplasm of pounded Ice to it; or by painting it frequently, with Oil of Turpentine, a saturated solution of Oxalic Acid, Compound Tincture of Iodine, Nitrate of Silver, or Iodized Oil of Juniper, etc. A poultice of Elm Bark, Flaxseed, Bread and Milk, or, of Hops and Lobelia Leaves, will hasten suppuration; and some Laudanum or Belladonna may be added to the poultice to allay pain. After the discharge of matter, should the cavity assume an indolent form, it may be touched with the Sesquicarbonate of Potassa, and be dressed with the Red Oxide of Lead Plaster.

When the reproduction of boils continues for weeks and months, moderate exercise, a generous diet, and the use of one of the following compounds will arrest their further appearance: 1. The preparation composed of Blue Flag, Black Cohosh, Soluble Pyrophosphate of Iron, Glycerin, etc., named in the treatment of Chronic Peritonitis; 2. Bromide of Potassium; 3. A decoction of Burdock Seed one ounce, Ground Centaury (*Polygala Nuttalli*) half an ounce; mix; 4. An infusion of equal parts of Burdock Seed, Sassafras Bark, and St. John's Wort.

When the furuncular disease appears as an epidemic, in addition to one of the above agents, the following powder should also be taken: Take of Bisulphite of Soda four hundred grains, Sulphate of Quinia ten grains, Sulphate of Iron twenty grains, Leptandrin

eighty grains; mix, and divide into twenty powders, of which one may be given for a dose every four or five hours.—Citrate of Ammonia, Yeast, and Porter have been found useful in the treatment of boils. I have known the following to permanently cure persons subject to constant and successive crops of numerous troublesome boils: Take of fresh Lemon-juice one pint, good French Brandy three fluidounces; mix. The dose is half a wineglassful, to be repeated three times a day. It should be taken in about an equal quantity of water, and its use be continued for three or four weeks.

ANTHRAX.

Anthrax or Carbuncle is a tumor of a malignant character, which is larger than a boil, and less conical. It usually commences with great heat and pain in the affected part, as well as more or less itching; a small pimple manifests itself, which, increasing in size, extends deeper and deeper into the cutaneous tissue, forming a circumscribed, flattened, deep-seated, hard, and dark-red or purplish tumor. And the disease is accompanied throughout its whole course by more or less severe throbbing and burning pain, irritative fever, and considerable constitutional disorder. When the tumor has reached its full size one or more small vesicles form on its summit, and which, when broken, discharge a thin, acrid, dark-colored fluid (sanious, ichorous, purulent), which excoriates the parts coming in contact with it. There may be one or many discharging orifices. These tumors vary in size from half an inch in diameter to six inches and upward, and they rapidly proceed to a gangrenous condition, grayish sloughs being detached from the healthy tissue. Carbuncles differ from boils in always being solitary.

The nape of the neck, the back, the buttocks, and the external surface of the limbs are more apt to be affected with them; and they are more frequent among middle-aged persons with constitutions impaired by dissipation, intemperance, etc. Bad food, residence in confined and damp places, mental depression, close study, trouble, etc., have been named among the exciting causes.

If granulations spring up, the abscess gradually healing, the *prognosis* is favorable. When the disease continues to progress, with great constitutional disturbance and typhoid symptoms, the *prognosis* is unfavorable. Death may occur from exhaustion, from pyæmia, or from the disease becoming extended to important tissues.

The *treatment* consists in applying potassa fusa freely to every part of the tumor, and especially within the apertures, having first benumbed sensibility by means of Richardson's anæsthizer; or by the application of pounded ice and salt to the part, for about five minutes. After this apply a poultice made of equal parts of powdered Marsh Mallow, Wild Indigo Leaves, and Charcoal, to which must be added some Carbolic Acid dissolved in Alcohol and Pyroligneous Acid; or Phenol Sodique may be substituted for the Carbolic Acid. Renew the poultice two or three times a day, and re-apply the caustic at each fresh dressing, until the parts slough off, and a healthy appearance is assumed, when the ulcer left may be healed the same as an ordinary ulcer. I have derived great benefit from the local application of a solution of Permanganate of Potassa (twenty to forty grains to the fluidounce of water); bathing the incised carbuncle with it daily, and also keeping it constantly applied by means of light compresses, covered with a fold or two of dry cloth.

Internally, the bowels, kidneys, and liver must be kept in as normal a condition as possible, being careful to avoid the production of diarrhea; tonics and alteratives should also be given, adapting them to the general condition of the patient. One of the agents named under Boils may be employed, or the following: Take of Cinchona one ounce, Ground Centaury half an ounce, Wine two pints; mix. The dose is a wineglassful three or four times a day. Tincture of Chloride of Iron, Chlorate of Potassa, Nitro-muriatic Acid, etc., have also been found useful. The diet should be nutritious, allowing ale, porter, wine, etc., as tonic stimulants. In case of diarrhea, Charcoal, the mineral acids, Perchloride of Iron, etc., may be used, or, some of the means named under Diarrhea. The following will frequently relieve the patient's sufferings: Take of Sulphate of Quinia eight grains, Sulphate of Morphia one grain, Elixir Vitriol two fluidrachms and forty minims, Tincture of Black Cohosh five fluidrachms and twenty minims; mix. The dose is a teaspoonful in some water or syrup.

ORDER VI. SQUAMÆ.

Squamous or Scaly diseases are characterized by their being of a chronic inflammatory, non-contagious nature, and consisting of a variable number of minute red papular elevations of the skin, or deep-red patches, which speedily become covered with particles of scurf or scales, the result of a morbid secretion of the epidermis. These scales are portions of the degenerated epidermis, and are

laminated, of a whitish or grayish-white color, often of a glistening micaceous appearance, dry, friable, of various thickness, and readily detached, leaving the skin from which they have fallen off, red, smooth, and shining; they are reproduced by successive desquamations for a long time; and are quite different from the scabs or crusts occasioned by the dessiccation of purulent and sero-purulent fluid upon the surfaces affected by the eruptions heretofore treated upon. The epidermis of the parts affected is altered in its qualities, being thickened, hard, dry, or otherwise degenerated. But little, if any, constitutional disturbance attends them; and the local heat and itching is not apt to occasion much inconvenience unless the epidermis becomes thickened and indurated; indeed these local symptoms are frequently unperceived. The unsightliness of the affection occasions the most uneasiness and annoyance.

Squamous affections are more apt to affect the outer sides of the limbs, and to avoid the flexures of the joints, but may occur in their vicinity, and often give rise to a sense of stiffness in the parts affected, to chaps, excoriations, and, when of long standing, to considerable induration and thickening of the diseased integuments. All persons are liable to these eruptions, without regard to sex, age, station, etc., and they may be transmitted hereditarily. The only squamous affection that I shall describe is *Lepra*. *Pityriasis*, *psoriasis*, and *ichthyosis* have been placed under this order, but I have considered the first under *Erythema*, the second under *Vesiculæ*, and the last under *Xerodermata*.

LEPRA.

Lepra (*scaly leprosy*, *dry tetter*, *branny tetter*, etc.), is one of the most persistent and difficultly-curable of skin diseases. It is a non-contagious chronic eruption, manifesting itself at first by the appearance of minute, thin, whitish scales upon dark-red elevated patches of various shapes and sizes, but usually of a roundish shape; this eruption may appear upon different parts of the body, but more frequently in the vicinity of the elbows and knees, and, like the pimples of lichen, is developed around the orifices of some of the cutaneous follicles. The scalp and face are also liable to the eruption. Instead of the affected surface presenting a bright or dull-red color, it is occasionally of a brownish or coppery tint, even when the system is free from any syphilitic taint. The patches may continue to increase in size, and as long as they exist the scales are formed, being detached and replaced by successive formations; the patches may also increase in number, and extend

from the points first affected to the trunk, and appear to be due to a congested condition of the skin around its pores. The constitutional symptoms are mild, if, indeed, any are present, and there may be a hardly appreciable itching, though occasionally this is troublesome at the commencement of the disease. The disease often lasts for years, sometimes appearing and disappearing at certain intervals; and its disappearance is manifested by the breaking of the circular patches which gradually become paler until the skin assumes its normal condition, while, at the same time, the elevations gradually sink to a level with the surface.

Lepra has been divided into several varieties according to its appearances, as well as its localities; most of those, however, based upon its appearances, are but different stages of the same eruption; those based upon its location have no other peculiar distinguishing marks. In the following list of these varieties, it must be recollected that several of them are described by some writers under the name of *Psoriasis*, which I have dropped under this Order, describing them under Lepra, as being the more correct affection.

1. *Lepra Punctata* is the early stage of the eruption, when it consists of minute, whitish, scattered patches, about the size of pin's heads.—
2. *Lepra Guttata* is the name given to the stage in which the patches have increased in size to that of from two to six lines in diameter, somewhat resembling drops of soft mortar.—
3. *L. Nummularis* or *Circumscripta*, is when the patches extending peripherally, unite together, and form round patches of the size of from one to three inches in diameter.—
4. When the patches thus fusing together form larger ones of irregular shape, the eruption being over a considerable extent of body, it is termed *L. Diffusa*.—
4. *L. Inveterata*, when the eruption is very extensive and troublesome.
5. *L. Universalis*, when the eruption covers the whole surface from head to foot, leaving no intervals of sound skin.—
6. *L. Vulgaris* where only a partial desquamation occurs in the middle of single circular patches.—
7. *L. Gyrate*, when the patches assume a serpentine, figure of 8, or other waved appearance; this is a declining stage of the eruption.—
8. *L. Circinata*, when the eruption disappears in the center of each patch, so that circles of eruption are left, enclosing healthy or nearly healthy skin.—
9. *L. Capitis*, when the scalp is affected.—
10. *L. Faciei*, when the face is the seat of the eruption.—
11. *L. Ungium* when the nails of the fingers and toes are invaded.—
12. *L. Nigricans*, a rare form of the disease, occurring in persons of enfeebled constitution, or those exposed to exposures and fatigue; it is charac-

terized by the parts having a dark livid color, and the scales being thin, and of a dull grayish hue. Sometimes a sero-sanguineous or serous fluid will be discharged from the exposed and excoriated surfaces, which hardens into an irregular and friable crust.—All these varieties are, however, but the one disease—*Lepra*.

Lepra Rupioidea is the name given to a variety regarded as a stage intervening between *L. Guttata* and *L. Nummularis*, in which there is an unusual accumulation of morbid epidermis, assuming the shape of large conical crusts marked by concentric rings, and projecting, somewhat resembling the crusts of *rupia*; when the surface beneath these prominent aggregations of scales is exposed, there is no ulceration, but merely a slightly-raised dark-red, rounded surface, which sometimes bleeds a little.

The *cause* of *lepra* is unknown. It appears to be capable of being transmitted hereditarily, though it is not invariably the case that the offspring are affected with it, because the parents are. It often appears in apparently sound constitutions, as well as among persons of strumous or scrofulous tendencies, and especially among those of sanguine-bilious temperament. Of its exciting causes we know nothing, although many circumstances have been named as such, as, long-continued mental fatigue, menstrual derangements, overstudy, anxiety, debility, intemperance in eating and drinking, etc. All climates, seasons, and races are liable to it. Anatomically, it is congestion and exudation into the upper layers of the cutis, with an increased production of epidermic cells. It is usually worse in winter and spring, and more commonly appears between the ages of twelve and thirty.

The *diagnosis* of *lepra*, as a general rule, may readily be made out; its prominent characters are the circular or circumscribed form of the dusky-red or coppery patches, the margins of which are elevated, while their centers are depressed,—the thin, dry, grayish-white, imbricated scales covering them,—the absence of moisture or of any discharge whatever,—and the appearance of the eruption near the elbows or knees, no matter wherever else they may be situated. The copper color may lead to an idea that the eruption is of a syphilitic nature, but the difference may be determined by an attention to the following points: *Syphilitic Lepra* is usually not very extensive, the patches are small and isolated, and prefer the inner rather than the outer aspect of the limbs, appearing likewise in the vicinity of the mouth and upon the palms of the hand and the soles of the feet, and have a more decided coppery tint than the non-syphilitic variety. The scales of the specific disease are thinner and less imbricated, not very white, but grayish

or quite dark, and rarely attended with itching,—sometimes there is a tendency to ulceration. The history of the disease, the presence of sore throat, headache in the temporal regions, crusts on the scalp, enlarged posterior cervical glands, condylomata, nodes, etc., will aid in determining its syphilitic character; beside which, syphilitic lepra is generally a second stage or degeneration of some other syphilitic eruption, either pustular, papular, tubercular, or ulcerating, and which is *never* the case with the non-syphilitic disease.

Lepra may be discriminated from chronic *Eczema* in which the color of the patches is brighter, the itching more marked, the scales are thin, not white, and less adherent, the eruption has no tendency to attack the elbows or knees, and at some period of the disease, there is always a serous exudation, which on the head mats the hair. Lepra is a dry eruption. From *Pityriasis*, in which the scales are more branny, and not imbricated, and there is no appreciable thickening or infiltration of the subjacent skin. From *Herpes Circinatus* which has no tendency to attack the knees or elbows, its scales being loosely attached and not of a shining grayish-white, the presence of the parasite as shown by the microscope, and its contagious character. From *Lupus Erythematosus*, which is more apt to attack the face and head, progresses much more slowly, the redness has a purplish tint and is greater near the circumference, the skin looks dry and shrunken, the scales are very thin not readily rubbed off, some of them distending the sebaceous follicles, and the disease leaves a glazed, slightly scarred appearance, as if the skin had been parched and seared by fire passing over it.

The *prognosis* of lepra, as far as the disease itself is concerned, may be considered favorable, as it rarely occasions any serious constitutional derangement, or proves fatal. The disease may become cured either spontaneously, or by treatment, but more commonly it remains through life, disappearing during warm seasons and re-appearing in cold. When it disappears, if the skin returns to its natural normal condition, its disappearance may be permanent, but any remaining abnormal condition of the skin will almost certainly be followed by a return of the eruption at a sooner or later period. First attacks appear to be much more amenable to treatment than subsequent ones. When the center of the patches heal, it is favorable as indicating a natural tendency toward a cure; but relapses are very common. The disease is, undoubtedly, often curable, under persevering and proper treatment.

The *treatment* of lepra does not yield much, if any, reputation to

the medical man; he may be successful, or he may not. A great amount of patience as well as untiring perseverance will be required on the part both of the patient and the practitioner. The closest attention is required to ascertain all the conditions and circumstances of the patient that may develop or perpetuate the disease. Is the patient very sedentary; does he overexercise, or does his business expose him to irritating vapors or dust, etc.; has he any mental anxiety; does his business require great and continued mental exertion; does he reside in an uncleanly, illy-ventilated, or damp location, or greatly secluded from the sun's rays; is he irregular in his habits, his meals, his sleep; are his bowels constipated or irregular; is his urine of an unhealthy character; is he intemperate; does he make use of improper diet; is he uncleanly in his person, etc.? If any of these circumstances are present, they must be removed or overcome by appropriate means. Indeed, in no disease, does a strict attention to the person's hygiene, in all respects, effect so much benefit as in the one under consideration.

A proper attention to diet, regular and moderate exercise in the open air, regular habits, regular hours for meals and sleep, cheerfulness of mind, absence of mental anxiety or severe mental occupations, attentions to the skin, bowels and kidneys and, if it can be had, change of air and scenery, are important essentials in the treatment. When it can be effected, a visit to the White Sulphur, or Salt Sulphur Springs, of Virginia, the Ballston Spa of New York, or other Saline or Sulphur Springs, and the use of the waters, will be found beneficial.

Again, the patient may be disposed to scrofula, rheumatism, gout, nervous irritability, uterine derangement, gastric, hepatic, splenic, renal, or enteric disorder, debility, cachexia, cutaneous torpidity, anemia, plethora, etc., any of which must be treated by the appropriate remedies independently of the cutaneous affection,—and this will be found very important, notwithstanding this affection often occurs in persons presenting, in every other respect, all the externals of health.

There is no specific internal remedy for lepra; arsenic and arsenical preparations have been highly lauded, but, beside being improper articles as medicines, I have known quite a number of instances in which they have proved unsuccessful. Fluid Extracts of bitter-sweet, nettles, mezereon, etc., have also been extolled, but they will be found unreliable; Tincture of Cantharides, however, has occasionally proved beneficial, but its action must be carefully watched, on account of its influence upon the kidneys and bladder.

It may be administered as follows: Take of Tincture of Cantharides one part, Tincture of Hyoscyamus two parts; mix,—the dose is half a fluidrachm in six fluid ounces of infusion of Elm Bark, repeated three times a day.

The best internal means that I have yet found in the treatment of lepra is the following: Take of the Compound Syrup of Yellow Dock one pint, Bromide of Ammonium one hundred and sixty grains; mix. The dose is one fluidounce three times a day, about an hour after each meal. In conjunction with which, one of the following pills must be taken three times a day, about an hour before each meal: Take of Citrate of Iron and Quinia sixty grains, Citrate of Iron and Strychnia thirty grains, Alcoholic Extract of Black Cohosh twenty grains, or more if required; mix, and divide into twenty pills. In some instances a mixture of the Tincture of Chloride of Iron, with a Solution of Chlorate of Potassa, may be substituted for the preceding named pills.—Carbolic Acid has been recommended as an internal agent, but I have not yet tested it in this disease.

External measures will be found as important as internal, and both should always be employed in conjunction. The skin requires attention; it should be bathed once or twice a week, or even oftener, with a soap-suds made of alkaline soft soap, to which some alcohol is added; and once in every week or two a Spirit Vapor Bath should be taken, or some Turkish baths, with thorough shampooing. This course is required to maintain the skin in as healthful condition as possible, as well as to aid in removing the scales, in order that the local medicinal applications may be made direct upon the patches and the skin. During the intervals between these bathings one of the following preparations should be applied to the eruption two or three times a day: 1. Take of Carbolic Acid one part, Pyroligneous Acid (8°), four parts, Water fifteen parts; mix. Apply by means of a sponge. In some instances, the amount of Carbolic Acid may be increased.—2. A mixture of Tincture of Muriate of Iron, Tincture of Cantharides, and Solution of Chlorate of Potassa.—3. Ointment of Oil of Cade.—4. Ointment of Iodide of Sulphur.—5. Ointment of Iodide of Ammonium. These should be thoroughly rubbed upon the patches as well as upon the healthy intervals between them, removing the greasy preparations every morning by means of soap and water. And an exposure of the naked surface every two or three days to the Sulphur and Iodine fume bath, will be found of great value and very efficacious.

ORDER VII. TUBERCULA.

Under this Order are included several affections very unlike each other, both anatomically and pathologically, and which have been described by some authors under the head of "Hypertrophies and Degenerations;" by others, as, "Cutaneous Diseases from Special Internal Causes," etc. The characteristics of this order of cutaneous diseases, are, primary, solid, circumscribed and persistent tumors of various sizes, considerably larger than papulæ, which may terminate in suppuration or ulceration. These affections are chronic in their nature, being generally developed very slowly, and being also very intractable to treatment, frequently requiring months and even years for their cure, and, sometimes, being absolutely incurable.

LUPUS.

Lupus commences with one or more circular or oval flattened elevations, tolerably firm, about a line or two in diameter, brownish-red or deep violet in color, and semi-transparent; these elevations remain indolent and stationary for a variable length of time, when they commence increasing in size and new tubercles become developed. The tubercles are generally grouped together, and assume an annular tendency. Sometimes the disease begins with the appearance of violet spots, on which are formed scabs, which being picked off are succeeded by other scabs, and so on, the disease in the meantime surely but gradually augmenting in area and depth. The parts more liable to be attacked are, the nose, and the cheeks, though it has been met with on other parts, as, the eyelid, chin, ear, arm, leg, etc. The tubercles may or may not ulcerate. Lupus may last ten, twenty, or thirty years, or more; but even when it has disappeared there is always a great tendency to its return. There are three varieties of lupus, as follows:

1. *Lupus Eredens* commences with the appearance of one or more small, smooth, dull-red, opaque tubercles, usually one, seated on the alæ or tip of the nose, and which, after a greater or less period of time, degenerates into one or more minute ulcers upon the summit of the tumor, covered each with a thin, brown, and adherent scab. Swelling and redness of the parts affected are generally present. Sometimes a dark livid spot, with slight swelling of the part is only observed, followed by the formation of a scab. The scab formed, in either case, being removed by scratching or otherwise, is followed by the discharge of an ichorous fluid, the drying of which gives rise

to another scab; and thus scab after scab may become successively formed, each one being thicker, and larger than the preceding, on account of the advancing ulceration and increased discharge of ichorous and purulent matter. The crusts are either rough and dark-colored, or smooth and yellow, are very adherent, consist of dried pus, blood, and sebaceous matter, and are being constantly formed upon the ulcers, whenever these are exposed; frequently, instead of being adherent, they will be undermined with the fluid discharged from the surface of the ulcers covered by them,—and sometimes they are blackish instead of a brownish color, especially in *L. Superficialis*. The ulcerations may extend in diameter, in depth, or both, and may rapidly destroy the nose, the lip, the lids, the cheeks, and even the bones, destroying all these in four or five weeks, or, it may progress very slowly, requiring several years for a part of the nose to be destroyed; the ulcers are concave, with uneven surfaces, grayish-red or yellow exudation of a fetid, ichorous and semi-purulent character, and their margins red, thickened, everted, or somewhat undermined; white patches of lymph will frequently be observed upon their surface,—and, at other times, small, brownish-red, unhealthy granulations. The superficial ulcerations are termed *Lupus Superficialis*; the rapidly destructive ones, *L. Vorax*; when the disease extends in circles or segments of circles, with unaffected skin in their centers, it is termed *L. Serpiginense*; and when it extends to the deeper-seated tissues it is termed *L. Exedens*. No itching or pain of any account accompanies this disease as a general rule, but touching the diseased spot frequently occasions pain. When the ulcer heals, the exudation becomes less in quantity, and thicker, the healing advances from without inwards, the part becomes paler, though it retains its unhealthy aspect for many years, and the cicatrix may be smooth, or may present white, corrugated bands, and give rise to deformities according to its situation. Sometimes cicatrization may be going on at one part, while fresh tubercles form at another.

2. *Lupus Non-exedens* is almost exclusively seated on the face, where it commences by one or more tubercles, of a dingy-red color, slightly elevated above the surface, not quite so hard as that of *L. Exedens*, indolent, semi-transparent, and about two lines in diameter. If but one tubercle exists, any improper, irritating applications will cause the eruption to spread more or less rapidly over the face, though this will ultimately occur, even if no irritants be applied. More commonly, however, the tubercles are developed simultaneously over a great portion of one or both cheeks, or of the forehead, and perhaps over the whole face; and the tubercles exist in groups,

assuming an annular disposition; as the disease progresses new tubercles continue to form around the original patch, whether the primary tubercles have disappeared or not, thus perpetuating the disease. They cause no constitutional disturbance, no inconvenience aside from their appearance, and may remain in a stationary, indolent condition for months.

The tubercles very rarely ulcerate, or become covered with adhering crusts, but their bases, after a time, gradually enlarge, the tubercles themselves become flattened, and accidental sores may appear at their circumference. With the enlargement of their bases, an indolent engorgement of the surrounding skin and subjacent cellular tissue occurs, which swell so as to fill up the spaces between the tubercles, and present a remarkable sort of puffiness. After a certain time, the affected parts will become studded with dark-red-dish points, which are tubercles not yet raised above the surface, and white points or scars may also be observed interspersed about; the scars having formed without incrustation or exfoliation. The tubercles in lupus non-exedens are rarely incrustated or ulcerated, though they are the seat of an insensible and constant desquamation, and when they disappear they leave cicatrized pits behind them. The swelling, the enlarged, puffy, flabby condition of the affected parts, and the yellowish-red and dingy tint, often present a repulsive appearance.

Sometimes a thin scale may be formed upon their tops, when these are scratched; and by a repetition of the scratching, scales may be produced in succession, each new formation being larger and thicker than the preceding. Occasionally, slight ulceration may be present, but it is insignificant; but at times, more especially upon the application of some improper agent, a considerable ulceration will occur, with more or less profuse ichorous discharge which forms a thick, laminated, yellowish-brown, and in some instances, apparently concentric incrustations, giving a very unsightly appearance to the features; this ulceration is not, however, corroding nor destructive, though it must be remembered that all the varieties of lupus may exist together in the same person.

This variety of lupus usually continues for a long time, and when it disappears, the skin never regains its natural condition and appearance; for a great length of time it presents a thin, smooth, shining appearance, with white cicatricial bands similar to those left by the preceding variety of the disease.

3. *Lupus Erythematosus* is more common among women, and attacks the face and head, especially the nose and cheeks. It may commence very insidiously, presenting a small pale spot surrounded

by a delicate purplish hue, and which slowly but gradually enlarges, while other spots of a similar character become developed around it, presenting after a time somewhat scalloped margins. More commonly, however, it appears in small, irregular, deep-red or violet-colored, slightly-raised patches or spots, circular or oval, and from two to twelve lines in diameter. The redness is greater near the margins than at the central portions, disappears momentarily from pressure, and becomes deeper from any exciting cause. The patches are frequently depressed in the center, the cuticle of which part presents a whitish opaque aspect, dries up into a thin, yellowish and horny layer, formed of small, branny adherent scales, which fall off from time to time. In some cases, instead of being covered with scales, the patches present a number of rough points, which when examined, will be found to be the orifices of the sebaceous glands distended with dry epithelial exuviae. The parts affected, look seared and parched, as if they had been acted upon by fire. When located upon the scalp, the hair follicles become permanently destroyed, and the hair falls out never to return.

The disease is of slow progress and appears to be an atrophy. When it is about disappearing, the cicatrization usually begins at the center and progresses toward the circumference of the patches; the healed parts become paler and paler, smooth, and leave a more or less distinct cicatrix.—The eruption occasionally appears on the limbs, fingers, and joints, and may be mistaken for chillblains; but its appearance in warm as well as in cold seasons will correct such an error in diagnosis. When the disease attacks the fingers, they look as if the parts had been burnt or scalded, and the atrophied skin contracts tightly upon the phalanges.

The *cause* of Lupus is not known. It appears, however, to be dependent upon a scrofulous or syphilitic taint of the system; the latter especially when it has been derived from progenitors. However, it has occurred in persons with whom there were no reasons for suspecting the presence of either of these taints. It affects children and adults, and young females especially in the first few years of puberty; males are as liable to its attacks as females. After the age of forty the disease rarely becomes developed. Bad food, impure air, want of exercise, and weak constitutions appear to be occasional predisposing causes. Country people are more liable to it than the inhabitants of cities. When the disease has once disappeared, it may re-appear at some future time. The disease involves the derma, causing interstitial absorption and atrophy of that tissue.

The diagnosis of lupus may be made out, from the violet or

dingy-red tubercles, their indolent progress, their subsequent dark-brown incrustation, desquamation, or ulceration, the seat of the disease, as, the nose, cheeks, lips, etc., and the pitted, unhealthy-appearing cicatrix left after the eruption has disappeared. It may, however, be confounded with some of the following affections: It may be determined from *acne*, which is limited to the sebaceous glands, is preceded by pustules which are red, and which leave behind circumscribed indurations surrounded by an erythematous areola, and the course of the disease is not so extremely slow as that of lupus.—From *cancer*, which generally manifests itself at a more advanced age, is attended with lancinating pains, more commonly prefers the lip as its location, presents a single tubercle only, which is hard, and surrounded by a firm base; after ulceration, cancer presents no dark-brown or blackish adhering crusts, its margins are callous and everted, and surrounded by an inflammatory areola, and its ulcerated surface is moist and of a fungous aspect. Lupus non-exedens, especially, may be discriminated from *Elephantiasis Græcorum* the tubercles of which are small, deformed, unequal, and of the same tawny color as the surface around them, which ulcerate, presenting black scabs here and there, and the ulcerations are more superficial than those of lupus, and have not the same tendency to spread; elephantiasis may also be developed upon other parts of the body at the same time or following its appearance on the face, and is eventually accompanied with severe constitutional symptoms.—From *impetigo* in which the crusts are prominent, rough, yellow, and not very adherent, while those of lupus are thick, dark-brown, and very adherent.—From *syphilitic tubercles*, which greatly resemble lupus, but differ from it in presenting larger, rounder, harder, and dusky copper-colored tubercles, which have less tendency to ulceration than those of lupus, and are less disposed to desquamate; the ulcerations that succeed the syphilitic tubercles, occur more rapidly than in lupus, are deep, have sharply-cut, well-defined, swollen, and copper-colored edges, a gray surface, and a greenish crust. Beside which, the history of the case, and the presence of other syphilitic symptoms, as, osteocopic pains, nodes, iritis, ulcers in the throat, etc., will assist in the diagnosis.

Lupus is an exceedingly intractable disease, and rarely yields to treatment until it has effected more or less destruction of parts, always leaving numerous, deformed, and indelible scars. Consequently, although the patient's life is not endangered, the *prognosis* of the disease is unfavorable. The earlier it is submitted to proper treatment, the less severe will be its results. The greater the

degree of swelling, of the parts affected by it, the more serious is the disease; likewise, when recently healed parts have their cicatrices destroyed by subsequent ulceration. When the cicatrices remain soft and of a bluish color, or are surrounded by the development of fresh tubercles, a renewal of the ulceration may be predicted.

The *treatment* of lupus is by no means so efficient as could be desired, and medical men have tried various means, but with only occasional success. Hygiene is very important in the management of this disease, as, pure air, cleanliness, healthy residence, good, nourishing, digestible diet, regular moderate exercise, regularity of bowels and kidneys, avoidance of crowded rooms, etc. Cod Liver Oil may be used with great advantage, both as an article of nourishment and a remedial means.

Internal treatment will be found of much greater value than local. The conditions of the patient as to a tendency to scrofula, the presence of anemia, scorbutus, gastric acidity, gastric debility hepatic disease, nervous irritability, etc., must be especially ascertained, and the proper course of treatment be accordingly pursued to overcome them. Among the internal agents that have been found useful in the treatment of lupus, are, Bisulphite of Lime; Bromide of Potassium; Bromide of Ammonium; Iodide of Iron; Phosphorated Cod Liver Oil, with soluble Pyrophosphate of Iron; Compound Syrup of Yellow Dock; Chloride of Gold and Soda; Carbolic Acid one part to Water one thousand parts, of which a teaspoonful may be taken in a glass of water twice a day, etc.

Among the local applications those that have been of the greatest benefit, are,—1. Carbolic Acid in Glycerin, or in Glacial Acetic Acid, and which has been found of service in each variety of the disease; it may be used in various proportions, as, one part of the Carbolic Acid to from twenty to forty parts of the other fluid.—2. Solution of Chloride of Gold and Soda one part of the gold salt to from sixty to one hundred parts of Water.—3. Tincture of Iodine.—4. In Lupus non-exedens, the Acetum Cantharidis, made with strong Acetic Acid.—5. In Lupus exedens, Chloride of Zinc; pure Nitric Acid; or Potassa fusa; to be carefully applied to the surface of the ulcer, subsequently dressing it with Compound Oxide of Zinc Ointment, in which a small quantity of Carbolic Acid has been incorporated.

During the recovery should there be a tendency to closure of the nostrils, from contraction of the cicatrices, they must be kept distended artificially, by gum-elastic tubing, sponge tents, etc. And any resulting deformities of the lip, eyelids, etc., should be rem-

edied by the necessary operations as promptly as possible.—I have never employed the Bisulphuret of Carbon, but would suggest it as a stimulating local application in lupus non-exedens, to be thrown upon the affected part in the form of spray.

ACNE.

Acne or Blotched Face, is a chronic affection of the cutaneous follicles, in which the sebaceous matter becomes morbidly accumulated; it may present a papular, pustular, or tubercular form. It is characterized by small isolated elevations or pustules, having a deep-red base, which rupture and discharge a small amount of sero-purulent fluid and some sebaceous matter, and are then succeeded by small, circumscribed, livid-red, hard, and indolent tumors, that very slowly disappear, leaving very minute scars behind them. It is common to both sexes, usually appears from the fifteenth to the fortieth year, but is more severe in the earlier years of puberty, and is ordinarily located upon the face; though the eruption may be seated on the neck, shoulders, breast, back of the arms, and back. There are several varieties of acne.

1. *Acne Simplex* is the mildest variety; it is met with on the forehead, temples, face, shoulders, and antero-superior part of the chest, and is more frequently observed in both sexes about the age of puberty. The pustules more commonly appear in succession, and in variable numbers, and each pustule passes through its several stages independently of the others. At first, small, deepish, indurated, more or less inflamed points will be observed, which enlarge to about the size of pins'-heads, become red and conoidal, finally present a pale-yellowish apex, rupture and discharge a small quantity of sero-purulent fluid, which, if allowed to dry forms a very delicate and slightly adherent crust. A dark, or livid-red, small, hard, very indolent tubercle or induration remains after the discharge of the fluid. The pustules generally run through their course in five or six days, without any pain or heat, unless they are developed near the filament of a sensitive nerve, when the pain may be severe. As new pustules are constantly forming, they may be seen in all their stages at the same time. A small, white, indelible cicatrix is often left behind.

When a small black circular point is observed in the center of the pustule, it indicates the external orifice of a hair follicle, and the presence of these black points gives rise to the variety termed *Acne Punctata*. When the pustule is larger and more indolent, suppurating very slowly, with deeper-seated inflammation of the

skin, it is termed *Acne Indurata*; this variety may be very mild and of trifling extent, or it may be very severe and present numerous eruptions, often leaving small, oblong, permanent cicatrices. It is often found associated with the two preceding forms, giving rise to a very considerable unsightliness of the features, from the livid-red tubercles, the thin scabs, the black points, and the swollen, red, shining, and greasy-looking skin. When acne indurata implicates the hairy instead of the non-hairy parts of the face, it is termed *Acne Sycosiformis*, or *Acne Mentagra*.

2. *Acne Rosacea*, (*Carbuncled Face*, *Grog Blossom*), more commonly manifests itself during adult life, from the thirty-fifth year and upward, though it may occur at a much earlier period. Its more usual seat is on the nose, though it may be developed upon, or extend to, the cheeks, forehead, chin, or even the whole face. The extremity of the nose (or in whatever other part the disease may first appear), become unusually red after a hearty meal, or after drinking some vinous, alcoholic, or other stimulating fluid. This redness gradually becomes persistent, with an enlargement of the veins of the part, and finally a few small yellow pustules make their appearance in the inflamed parts; the skin around them gets thickened and hypertrophied, and presents a rough, greasy aspect. The enlarged and red nose, covered with dark or purplish-red pustules or tumors, tortuous, varicose, bluish, cutaneous veins, and studded with more or less numerous yellow points, gives a very repulsive aspect to the features. Suppuration is never very decided, but appears to be, as it were, somewhat abortive; and the skin ultimately becomes permanently injected, indurated, rough, and granulated. Even should the disease be cured, the features never recover their natural condition and appearance. Occasionally, but rarely, itching and heat attend the eruption; and, sometimes, the disease disappears spontaneously.

The *causes* of acne are not well understood. It may appear in all persons, but more commonly among those of lymphatic temperament, rarely affecting children. Its presence may be due to whatever will induce a deranged condition of cutaneous innervation, as, torpid action of the capillary nerves and vessels, gastrointestinal derangement, cerebro-spinal irritation from masturbation or other causes, exposure to continued heat, etc. Intemperance is a very common cause of acne rosacea, but is not the only cause, as the eruption sometimes appears in persons of the most abstemious habits; this variety is often met with among females about the turn of life; with plethoric persons laboring under hemorrhoids; and not unfrequently is transmitted from parent to child.

The *diagnosis* of acne may be readily made out, from the preceding description. It may be determined, from *ecthyma*, which has larger, broader, and flat pustules, which are not as indolent as those of acne, are not accompanied with indurations or obstructed sebaceous follicles, are covered with thick and adherent scabs, prominent and laminated, and are not followed by tuberculated indurations. From *impetigo*, in which the pustules have no induration at their base, are usually confluent, and form, on rupturing, thickish, yellow crusts. From *eczema*, which is not limited to the face, is attended with much burning and itching, has a moist secretion at its commencing stages, and presents more decided desquamation at its closing stage. From *syphilitic tubercles*, which are always surrounded by a copper-colored areola, the tubercles being large, flat, shining, of a similar hue, and usually ulcerated on their tops; in addition to which there will be other syphilitic symptoms present.

The *prognosis* is favorable with all the varieties, except that of acne rosacea. *A. Simplex* usually disappears when the adult life is fully attained, or from marriage. *A. Indurata* is more obstinate, and is often very difficult of removal. *A. Rosacea* is seldom curable.

In the *treatment* of acne, the same course, as to the conditions, circumstances, hygiene, and constitutional tendencies of the patient must be observed as has been indicated in the preceding cutaneous maladies. All stimulants must be avoided, as well as intemperance in eating; and everything that may occasion gastro-intestinal derangement must be dispensed with. Tea and coffee should be avoided, and but little animal food be used. Exposures to the sun, to hot rooms, to sudden changes of temperature, are especially to be avoided, as well as mental and physical fatigue.

Among the internal therapeutical means that have been found the most effective, are the following, a proper selection from which for any given case, will depend upon the variety of the disease, and the judgment of the practitioner: 1. Cod Liver Oil.—2. Tincture of Chloride of Iron.—3. To four fluidounces of a strong infusion of Horse-radish Root, add thirty minims of Compound Spirit of Ammonia, and sweeten with Syrup of Ginger; this is to be taken in the course of the day, and repeated daily.—4. Iodide of Iron, in the indurated form.—5. In *A. Rosacea*, an acid solution of Iron made by dissolving Epsom Salts three ounces, Sulphate of Iron two drachms, in Infusion of Quassia one pint, to which has been added Dilute Sulphuric Acid half a fluidounce. The dose is half a fluidounce, three or four times a day.—6. Take of Solution of Bromide of Potassium (one ounce to the pint), one fluidrachm,

Citrate of Iron and Strychnia three grains; mix for a dose, to be repeated three times a day. It may be taken in some kind of alterative syrup, if required.

Among the external applications are the following: 1. By means of a camel's hair pencil apply a light layer of pure Carbolic Acid upon the pustules; they become whitish, then red, which gradually passes to a brown color, and at the same time the pustules sink and dry up. They then present the aspect of parchment, and an exfoliation removes the eschar from the parts. One application suffices in most cases to cure the pustules; those which contain no pus leave no cicatrices, but those which contain this product leave a small cicatrix after their cure by this cauterization. To prevent a subsequent return of pustules the parts should be painted once a day with a mixture of good wine Vinegar six parts, Carbolic Acid one part. In A. Rosacea, equal parts of Vinegar and Carbolic Acid may be employed.—2. A saturated Solution of Oxalic Acid may be applied to the pustules once or twice daily.—3. Take of Muriate of Ammonia two drachms, Tincture of Conium Maculatum one fluidounce, Distilled Water one fluidounce; mix. The parts may be washed with this mixture several times a day; if little or no irritation be present, the Conium may be omitted, and some stimulant be substituted, if required.—4. Ointment of Ioduret of Sulphur, has proved useful.—5. Iodized Oil of Juniper.—6. Spray of Sulphuret of Carbon, carefully applied once or twice a day.—7. Pure, concentrated Hydrochloric Acid; wet the pustules and skin around them with this, let it remain on about half a minute, and then wash it off first with water, and afterward with soap and water. If the skin be very sensitive the acid should be diluted with glycerin, as the patient can bear.—8. To eight fluidounces of Whisky add Bicarbonate of Potassa, and Hydrochlorate of Ammonia, each, half an ounce; bathe the indolent tumors with this, three or four times a day.

The Spirit Vapor Bath will be of service, taken every week or two; and an exposure to the Sulphur Vapor or Fume Bath, or, of Sulphur and Iodine together, and repeated twice a week, will be exceedingly advantageous. Of course, in these baths, the surface of the body and limbs, and not that of the face, are alone subjected to the influence of the fumes.—It has been recommended to puncture the pustules, and squeeze out the contents of the distended follicles as soon as they become perceptible; and this will prove very useful if, immediately after the operation, the emptied pustule be touched with a mixture of Carbolic Acid one part, Vinegar,

Water, each, five or ten parts.—*Acne mentagra* requires the same treatment as the other varieties.

FRAMBÆSIA.

Frambæsia, Yaws, or Sibbens, is a disorder supposed to have been imported from Africa, and which is common to the blacks on sugar plantations, especially in the West India Islands. The disease sometimes comes on without any premonitory symptoms, but generally, it is preceded by pains in the limbs, somewhat resembling rheumatism, and which are severe especially around the joints; languor and debility are usually present. After a time, more or less severe febrile symptoms manifest themselves, followed by an eruption of small red spots, similar to flea-bites, which are grouped around each other, and appear on various parts of the body, particularly the forehead, face, neck, arm-pits, etc. These gradually enlarge and give rise to papular, flattened, dull-red, firm and resisting papules, which become filled with an opaque, whitish or yellowish fluid, and which finally rupture, discharging a thick, glutinous matter, which on drying forms a somewhat thick scab. These pustules do not cover the whole body at any one time, nor do they appear in regular succession like the eruption of small-pox; but when one crop is passing away, a new one will be appearing in another place, each crop being attended with febrile symptoms. The pustules may attain the size of half an inch, and sometimes one or more will reach a diameter of an inch and a half or two inches. From the pustules being confined to a small space and connected by their bases, they present a rough, mulberry or raspberry-looking, fungoid-like appearance, from which is discharged an unhealthy matter, often of an offensive, acrid character, and which forms a scab around the edges of the excrescence. Cazenave and Schedel found these excrescences, in a patient under their notice, to be "constituted not of accidental tumors developed in the dermoid tissue, but by the skin itself in a state of hypertrophy, and divided into a multitude of vegetations," the epidermis being entirely destroyed.

The parts in the neighborhood of the eruption are hard and callos; and in hairy parts that are attacked, the hair gradually becomes white. The disease may, according to the condition of the system, last for several weeks or months, or even years; it is contagious, being, however, only communicable by direct contact with the matter discharged from the ulcers, and is stated to occur but once in a life-time. It may exist for a long period, occasioning no

great constitutional disturbance, except a severe itching; but it also gives rise to foul and sloughy ulcers of considerable extent, and even caries. Emaciation and debility often follow the disease, and also dropsy. The ulcers leave permanent cicatrices. The disease is rare among the whites; yet they sometimes become tainted with it, especially those who are frequently in attendance upon the diseased blacks.

Weak, feeble, scrofulous blacks, and especially those living in dirty, unhealthy, and damp huts, with poor nourishment, and uncleanly in person, appear to be more subject to this disease. Its cause is not known.

The *treatment* consists in first removing the diseased negro to some private, healthy location, where he can have no communication with those who have never had the affection, otherwise it may become spread over a whole plantation. In the early stage of the disease, before the eruption has fully appeared, sudorifics must be given, as the Compound Tincture of Virginia Snakeroot, aided by the Spirit Vapor Bath; the patient may likewise drink freely of a decoction of Sarsaparilla and Guaiac-wood, or of an infusion of Sassafras Bark and Elder Flowers. Occasional purgatives will also be required. The body should be bathed daily with a warm, weak alkaline bath; the diet should be nutritious, consisting principally of vegetables; the clothing should be warm and comfortable; and moderate exercise be taken daily; pursuing this course until the appearance of the second stage.

In the second stage, when the eruptions begin to dry up and disappear, mild purgatives should be given to keep the bowels regular; and for the purpose of preventing, if possible, a continuance of the disease, tonics and alteratives should be administered, as the Compound Syrups, of Sarsaparilla, of Stillingia, of Yellow Dock, etc., according to the constitution, predispositions, etc., of the patient, continuing their use until the disease has wholly disappeared. Ulcers may be frequently bathed with the Tincture of Chloride of Iron, and be dressed with the Compound Ointment of Oxide of Zinc; or an ointment composed of Citric Acid, Subcarbonate of Iron, and Lard. When the disease attacks the sole of the foot, the thick skin by confining the matter formed may occasion obstinate and extensive ulceration, rendering it painful to walk. In such cases, the best application is a poultice of the fresh Cassava Root, which is common to the West Indies; or, a dressing of Red Oxide of Lead Plaster, with a poultice of Elm and Poppy Leaves. Any hard swellings remaining upon the feet may be removed by bathing them in warm water until the swellings become somewhat soft, and then

touching them with Caustic Potassa, and keeping on Elm Poultices until the eschar falls off.

The other forms of disease that may be included in this order, are so rarely met with, and so intractable to treatment, that a very brief notice of them will be sufficient.

Molluscum, so called from its resemblance to the prominences that are observed on the bark of the maple tree, consists of numerous elevations developed within the cutis, varying in size from that of a hemp-seed to that of a grape, either rounded, or flattened and irregular, possessed of hardly any sensibility, usually with a broad base (*Molluscum Scssile*), though sometimes adhering by means of a narrow peduncle (*Molluscum Pendulum*.) These elevations often have a depression with a dark spot upon their apices, and occasionally present an indistinct lobulation. They are somewhat translucent, of the natural color of the skin, though sometimes brownish, enlarge very gradually, remaining unchanged in other respects, sometimes ulcerating and discharging their contents, or else, becoming inflamed and sloughing in mass, leaving behind either a pyriform warty appendage, or a permanent cicatrix. The contents of these tumors are, a white, waxy, or semi-fluid matter, oil globules, epidermal cells and granules, contained in a cyst sometimes consisting of several sacculi opening into a common cavity.

The *cause* of molluscum is unknown; it has been attributed to hypertrophy and alteration of the sebaceous glands; to an alteration of the structures concerned in the development of hair, especially of the cells at the base of the hair-follicle; and to alteration of the follicle itself, with hypertrophy of the subcutaneous areolar tissue. Its most common seat is on the body, the neck, the face, and the scrotum, and it is more common to children, though all ages are liable to it. No constitutional symptoms attend it.—The *treatment* is to open the tumors, and rub the inner parts with Nitrate of Silver, or touch them with pure Carbolic Acid, neutralizing the acid in a few seconds after its application by a drop or two of a solution of the Carbonate of Soda, of Potassa, or of Ammonia. If a pedicle be formed, cut it off with scissors, and then touch the exposed surface with one of the above-named agents.

Elephantiasis Græcorum. Greek Elephantiasis, or True Leprosy, is a terrible disease, now but rarely met with except in inter-trop-

ical climates. It appears to be a blood disease, and manifests itself by the deposition of an albuminous substance into and beneath the skin and mucous membranes; or, by exudation into the nervous structures producing anæsthesia and atrophy. It is a very chronic and intractable disease, is endemic in Lisbon and some other of the southern parts of Europe, in India, Africa, and also in some of the Polar countries. It may last for years becoming cured spontaneously, or terminating in death. The disease more commonly attacks males, and is more frequently observed between the ages of ten and thirty; it may be transmitted hereditarily, but is not contagious. In the countries where it prevails, the poorer classes suffer the most from it. According to the manner of manifestation, it has been divided into two varieties:

1. *Elephantiasis Tuberculosa*, is characterized by the presence of an eruption of dull-red or purplish erythematous patches, from six to twelve lines in diameter and somewhat hard; the patches are round or irregular in form, are sometimes more deeply colored in their centers, and at other times around their circumferences, and become of a brownish, tawny hue, and, in the negro, black. The skin in their vicinity generally becomes lessened in sensibility, though occasionally its sensibility has been augmented. These patches appear and re-appear, on different parts, the face being more generally affected, though the eruption may attack nearly all parts of the body; the patches are deeper-colored on their re-appearance, and have a tendency to become confluent. Finally, the patches become permanent, and in their midst are developed smooth, shining, dull-red or purplish, and very indolent tubercles, which eventually assume the bronzed color of the skin, or are whitish from deposition of albnmen. These tubercles are of various sizes, of irregular shape, and tend to suppurate and ulcerate, though they may remain unchanged for years, or disappear by resolution.—The hairs of the parts affected, become white and fall out. When the tubercles ulcerate they discharge a whitish, granulous, albuminous matter, and a yellowish-white, ichorous secretion, which upon drying forms thick, prominent, grayish-brown crusts. The ulcer is deep, with irregular, livid, callous and raised margins, and often painful. The disease is indefinitely prolonged by the constant and successive formation of ulcers, which, when they heal, leave white, hard, irregular, and projecting cicatrices. The constitutional irritation they produce often occasions death.

The disease may be confined to a very small district, or it may be very extensive; it is preceded by constitutional symptoms, as, lassitude, drowsiness, nausea, chills, depression, etc., which gradu-

ally subside as the eruption appears, and the severity of these symptoms is generally proportioned to the extent of the local disease. Mucous membranes are very liable to become attacked, as of the tongue, mouth, fauces, larynx, nose, conjunctiva, etc., and internal organs also frequently become involved, as the spleen, liver, kidneys, bladder, uterus, mesentery glands, etc., but this involvement occurs only in an advanced stage of the disease. "The parts affected are swollen or enlarged generally, the forehead is uneven and traversed by deep furrows, the eyebrows are tuberculated and overhanging, the nostrils sinuous and dilated, the ears pendulous and lobulated, the lips enormously thickened, the chin greatly increased in size, and the whole of the surfaces affected unctuous and tawny to the eye. In this state matters may continue for an indefinite length of time. But no long interval usually elapses before additional symptoms make their appearance: The tubercles are also apt to fall into a state of ulceration, when sores succeed, of an unhealthy aspect, and pouring out an ichorous fluid, which concretes into thinner or thicker, brownish or black-colored incrustations, under which cicatrices are slowly formed. The sense of smell becomes blunted; that of touch, too, is strangely affected; the voice grows husky, and is often entirely lost; the patient is affected with cough, quick pulse, and is singularly dejected in spirits, as well as weakened in his muscular power."

The *prognosis* is always unfavorable, and the *treatment* is based upon general principles; change of climate has been advised. M. Lemaire states that cures have been made by the internal and external use of Carbolic Acid. Commencing with two grains per day, internally, and gradually increasing the quantity to forty-five grains per day, diluting the acid well with water. The diseased parts were slightly canterized from time to time by Carbolic Acid mixed with an equal part of Alcohol, or of Vinegar; and upon the disappearance of the disease, a weaker solution was applied locally for some time. M. Bazin remarked, "Carbolic Acid is much preferable to anything I have ever employed to overcome this malady."

2. *Elephantiasis Anæsthetica* is the variety attended with exudation into the nerve-structures; it is slower and more insidious in its attack, and the constitutional symptoms are less severe, though there is much greater depression of spirits. Brownish or brown spots are followed by white patches and large bullæ, which suddenly arise from some slight irritation, or, spontaneously. These bullæ soon break, discharge a greenish-yellow or milky fluid, and leave inflamed and sometimes painful ulcers, over which thin, brownish crusts form, which falling off, are succeeded by others,

and so on; on healing, the ulcers leave cicatrices, with a white, smooth, depressed, partially-sensitive, and bald skin. Itching and pricking pains often accompany the disease; but in the advanced stage, when the anæsthesia produced by the disease is more complete, a fire may be applied to the skin, or the eye may be cut with a knife, without the patient being at all aware of it. The bullæ may be successively developed for several years, succeeded by the white patches, without further change. The parts affected are dry, while other parts perspire as usual. As with the preceding variety, any part of the system or of internal organs may be affected.

From atrophy of the glandular organs, the skin is left pale, insensible, dry, sordid, discolored, and like parchment; the countenance becomes emaciated and cadaverous, the features non-expressive, the conjunctivæ assume a dry, dull, and pale aspect, the lashes fall out, the lips become atrophied, the muscles of the limbs from atrophy become thin and insensible, and anæsthesia gradually but certainly comes on, being, as it progresses, attended with loss of appetite, thirst, chilliness, vomiting, torpor, drowsiness, and exhaustion of mental and physical powers,—when the eyeball is destroyed severe deep-seated pains in the orbit, and necrosis,—pains in the bones, pains and livid swellings around a toe or finger, followed by ulceration and loss of the toe or finger; caries, ulcers, diarrhea, perhaps anasarca and albuminous urine, tetanic spasms, or coma, and death.

But little can be done in the way of *treatment*. A nourishing diet, pure air, regularity of the bowels, and an observance of other hygienic conditions, together with diuretics, sudorifics, and alteratives, have sometimes been advantageous. Bromide of Potassium, Hydrocotyle Asiatica, Bromide of Ammonium, Cod Liver Oil, Nitric Acid, Iodine, Gold, etc., have all been recommended as internal remedies, in conjunction with local applications to the tubercles of stimulants, as, Nitric Acid, Sulphur and Iodine Fume Bath, Carbolic Acid, Sulphuret of Carbon, Chloroform, etc. Happily, these diseases are not met with in this country.

Elephantiasis Arabum, Arabian Elephantiasis, Bucnomia Tropica, Barbadoes Leg, etc., although of a similar name, with the preceding Greek disease, and referred to at this place, is a very different malady, having no affinity whatever with true elephantiasis, yet frequently confounded with it. Greek Elephantiasis consists of tubercles formed by the deposition of an albuminous substance in the

affected tissues, while Barbadoes or Elephant Leg is a simple hypertrophy of the skin and subcutaneous cellular tissue.

E. Arabum may attack any part of the body, but is more frequently observed upon the leg, the arm, the scrotum, or the breasts. Sometimes it commences without any premonitory symptoms; at other times it begins with active febrile symptoms and severe pains. A violent, deep-seated pain is felt in the affected part, which, together with a feeling of tension, extends along the principal superficial lymphatic vessels of the limb, in the course of which, and as high up as the groins or arm-pits, enlarged and painful lymphatic glands can be felt, and the superficial veins occasionally become hard and corded. In most cases a diffuse erythematous redness manifests itself, and the skin and subjacent cellular tissue commence enlarging and thickening. These attacks may disappear and occur again and again at irregular intervals, continuing thus for several months; but after each seizure the swelling not wholly subsiding, the limb gradually becomes harder and larger, ultimately acquiring an enormous size. Eventually, the febrile symptoms, local pain, and uneasiness pass entirely away, leaving the enlarged, unsightly limb. When the scrotum is attacked it may attain a size the weight of which may vary from fifty to one hundred pounds; and an affected leg may weigh nearly as much as the rest of the body.

The cuticle often remains unchanged, at other times it is thickened; the skin changes its pale, smooth, and shining appearance, enlarged vessels are seen permeating it; it becomes rough, hard, thickened, wrinkled, and covered with knotty or warty projections, and foul horny-looking scales or incrustations upon the epidermis, as in ichthyosis; or, it may crack in various directions, giving rise to deep and painful fissures. The hard and swollen lymphatic glands often inflame and suppurate, giving rise to abscesses which discharge a fetid matter; sometimes the glands slough. Cases, however, will be met with, in which the general health appears to be good, the only inconvenience being the enormous size of the swelling.

The disease is not contagious nor hereditary, though it is endemic in the tropics; it is more common among adults, and attacks rich and poor of both sexes indiscriminately, generally remaining for life. Its *causes* are unknown. Although not an immediately fatal disease, it undoubtedly tends to shorten life, and from its obstinacy to treatment, its *prognosis* may be considered unfavorable.

There is no successful *treatment* known for this disease; Iodine and its salts, friction, and kneading of the affected parts, regulated

pressure, repeated purgatives, and the local applications named in the treatment of the varieties of Greek elephantiasis, have been found useful. Soothing applications should be applied to fissures and excoriations. When the scrotum is greatly enlarged, its removal has been followed by success, so has the amputation of the affected leg or foot, when of enormous size; ligature of the femoral artery is also stated to have been of benefit.

Kelis, *Keloid*, or *Cheloidea* was first described by Alibert. Its precise nature is not known, though supposed to be due to some poison in the blood. It first manifests itself by a slight swelling of the affected part of the skin which increases in size and prominence, giving rise to small, hard, shining tubercles, oval, roundish, or quadrilateral, of a dusky or dark-red color, hard and resisting to the touch, and ordinarily accompanied with itching, pricking, shooting, or dragging pain in the part. Sometimes the tubercles are isolated and single; but when two or more are together they are apt to coalesce, and form an elevated, flattened mass, sometimes of considerable extent, and usually depressed in the center, giving to the thin and wrinkled skin covering them an appearance of the cicatrix of a deep burn. Usually, but one patch or mass is formed, but at times, several may exist at the same time on different parts of the body. The tumor varies in size from a few lines to two inches in diameter, and remains stationary for life, after having attained a certain size; or else very gradually increases in size, extending by small tapering claw-like processes, which give rise to a puckering of the skin. Sometimes it is accompanied with heat, puffiness, but no redness of surrounding parts, and, perhaps, considerable pain. The disease may, occasionally, disappear spontaneously, leaving a white and firm cicatrix; it never ulcerates. The anterior surface of the chest is more liable to it, but it may appear on the neck, arms, or any other part of the body. It generally occurs between the fourteenth and fortieth year, and is common to both sexes. It is frequently developed upon an old scar, or bruise, as well as upon the sound skin. When developed upon sound skin it is termed *Kelis Vera*; when upon the cicatrix of a burn, scrofulous ulcer, etc., it is named *Kelis Spuria*.

The affection is not contagious, nor is it a dangerous malady, as it does not appear to interfere with the patient's general health. It is, however, troublesome and annoying from the local inconveniences. No *treatment* for its cure is known; when removed by

caustic or the knife it re-appears. Sulphur fumes, Compound Iodine Ointment, Sulphuret of Carbon, Iodide of Ammonium Ointment, as local applications, have seemed to favor resolution.

ORDER VIII. XERODERMATA.

This Order is characterized by roughness, dryness, and loss of elasticity of the skin, without any eruption.

ICHTHYOSIS.

Ichthyosis, or Fish-skin disease is characterized by a morbid condition of the skin, which appears thickened in various degrees, with the development of hard, dry, somewhat fish-like scales of different sizes, and unattended by inflammation, heat, pain, or itching, but attended with a morbid alteration of the subjacent cutaneous layers. It is divided into the following varieties:

1. *Ichthyosis Vera*, *I. Simplex*, or *Xeroderma Ichthyoides*, is characterized by a defective nutrition of the skin, as manifested by its dry, rough condition, and the formation of grayish-white and thin, or dark-colored, green, brownish, or even blackish particles or scales of epidermis, with ragged edges, which are firmly adherent, and are marked by deep lines or furrows, dividing the surface into quadrangular, roundish, or irregular-shaped segments, greatly resembling the outer bark of a tree. When the scales are removed they soon form again, and the exposed surface is never red. The roughness is like that of the surface of a coarse file when the hand is passed over it. The skin may be thinner or thicker than natural, and soft, or hard and stiff like leather; dry, wrinkled, and mealy, with an absence of cutaneous fat; and that of the face may present a peculiar coppery redness, and an oily polish. The pores of the follicles are prominent from an accumulation of a dry, hard substance within them, and the hair is dry and brittle, broken off, or altogether wanting.

Ichthyosis vera is a general disease, though modified in appearance in different parts of the body; it appears to avoid the palms of the hands, the soles of the feet, the axillæ, the flexures of the arms, and the popliteal spaces, in most instances. It is due to malnutrition, and is commonly congenital, though sometimes accidental, when it may be confined to one region, particularly the limbs. When congenital, the disease is not strongly marked at birth, though the skin presents a dry, thick, rough aspect, but its

characters become more fully developed, presenting different appearances, as the child grows. The disease is rarely curable, though considerable benefit may be derived from a palliative treatment. It is not contagious, and is not, as a general rule, accompanied with any constitutional symptoms.

2. *Ichthyosis cornea* is the term applied to a more aggravated form of the disease, in which the hardened sebaceous secretion forms darker-colored squamous layers, or rough, almost horny prominences or spiculæ, so as to resemble a serpent or the integument of a porcupine. The spines may become three or four lines in length, and, as well as the scales, drop off after a time, and re-accumulate. The enlarged orifices of the sebaceous glands may be seen when the scales or horny concretions are removed.

The *treatment* consists of tonics and alteratives internally, together with nutritious diet, and general observance of hygiene measures. Cod Liver Oil, Bromide of Ammonium, diluted Carbolie Acid, Tincture of Chloride of Iron, etc., may be employed internally. As local external applications to arouse the skin and to remove the scales covering it, as well as to render it more supple and soft, warm alkaline baths, strong alkaline soap baths, vapor baths, etc., may be used, together with frictions; and applications of Oil, Glycerin, diluted Carbolie Acid, diluted Sulphuret of Carbon, etc., should be well rubbed into the skin. The Sulphur Fume Bath may also be found of service.

ORDER IX. MACULÆ.

The affections of this Order are characterized by a change in the color of the surface affected, from too much, too little, or altered pigment in the parts; thus, there may be a white, gray, yellow, red, blue, brown, or black color, and the spots may vary in size from that of a point to four or five inches in diameter. The seat of these alterations is the rete mucosum and papillary layer of the derma.

With many persons an exposure to heat and light, increases the cutaneous pigment, and gives rise to small, yellow, yellowish-brown, or greenish-yellow, round or irregular spots or patches, *Lentigo* or *Ephelis Lentigo*, popularly termed "freckles." Sometimes they occur, even from the period of birth, when the persons are not exposed to the sun's rays or its reflection. They are more abundant in childhood and youth, and are peculiar to persons of light hair and fair complexion, and especially to those with red hair. They are generally observed on the face, neck, hands, and other parts exposed to the light, but are also frequently seen on

other parts covered by the dress. When due to the action of the sun, they frequently disappear in the winter.

Treatment will not always remove these spots, although they have been occasionally removed by the persevering and continued use of local applications, as, a dilute solution of Citric Acid in Infusion of Roses; a liniment of Lime-water and Oil, to which a small quantity of Liquor Ammonia has been added; a mixture of three parts of Cologne to one of a saturated solution of Oxalic Acid; a weak solution of Lactic Acid; a mixture of ten parts of Carbolic Acid, ten parts of Vinegar, forty parts of Cologne, and one or two hundred parts of water, etc.; or, the following: Take of Lobelia Seed, Beef Gall, each, half an ounce, Guaiac Resin, Bicarbonate of Potassa, each, one drachm, Oil of Turpentine one fluidrachm, Spirits half a pint; mix. Allow the articles to macerate for ten or twelve days, frequently shaking, and apply to the spots two or three times a day.

There are several other affections belonging to this order, among which may be named *Vitiligo*, white or colorless spots or patches of the skin, and *Nigrities* or *Melanopathia*, in which certain parts of the skin or the entire surface becomes darker colored, presenting brown or black spots, a mottled appearance of the skin, a bronzed appearance, etc. The former disease is of no consequence, and is not benefited by treatment; the latter is only of serious import, as an indication of some disease of the system, for instance of the supra-renal capsules, etc., and only requires treatment for the malady of which it is a manifestation, when this can be ascertained.*

* ERYSIPELAS.

Erysipelas, or St. Anthony's Fire, is an inflammatory affection which the chronicist will sometimes be called upon to treat, especially by those in whom it frequently manifests itself, appearing and disappearing at regular or irregular intervals, and with various degrees of severity; and as the disease has been omitted in its proper place, a few remarks in relation to it will be made here.

The nature of the *cause* of erysipelas is not satisfactorily understood, though the disease may be considered a humoral and constitutional inflammatory disease, induced by a vitiated condition of the blood, which is present in all cases, whether they be epidemic or sporadic. Some particular atmospheric condition is also undoubtedly present when the disease appears as an epidemic. With some persons there exists a *predisposition* to the disease, an "erysipelatos diathesis," the disease appearing and disappearing frequently without any attributable exciting cause. Strumous-anemic persons are often subject to erysipelatos attacks, either during certain seasons, or from other very slight exciting causes.

Among the exciting causes may be named intemperance in eating or drinking, unhealthy or indigestible food, depressing mental emotions, fatigue or over-exercise, intestinal, menstrual, renal, or hepatic derangements, injuries or wounds,

ORDER X. SYPHILIDES.

Syphilides or Syphilodermata are cutaneous diseases that are associated with or due to the presence of the syphilitic poison in

etc. It is often the case that a meal consisting of improper food, or, of healthy food eaten in excess, will be followed by a more or less severe attack of erysipelas, among those predisposed to the disease; while on the other hand, a strict attention to diet will lessen the severity of the disease, and often entirely prevent its re-appearance.

Every part of the body is liable to erysipelatous inflammation, but it more generally appears on the face, legs, and feet, when manifested externally. The disease is not confined to any particular age, sex, or constitution, though young and elderly persons appear to be more liable to it than the middle-aged. Females appear to be more subject to it than males, especially those of sanguine and irritable habits, as well as those who are intemperate, or who suffer under some derangements of the reproductive organs. Pregnant women, especially those about to be confined, are very liable to puerperal peritonitis, after an exposure to the poison of erysipelas. There is no doubt in my mind that erysipelas, which is observed as comparatively confining itself to the true skin, very frequently attacks internal organs, causing sudden and unexpected loss of life; and this may be the result of its recession or metastasis from the surface, or, it may primarily attack an internal organ, as in puerperal peritonitis.

The *symptoms* of erysipelas are chills, loss of appetite, nausea, constipation, and other febrile symptoms, at the commencement, and which are succeeded in three or four days by an inflammatory condition of some parts of the external surface, attended with more or less pain, burning heat, pricking or stinging sensations, a remarkable florid redness, with a well-defined margin, and swelling of the skin, and which is characterized by a momentary disappearance of the redness upon slight pressure, a white spot remaining until the redness reappears. In the milder forms of the disease the commencing symptoms are rarely observed; in the severe forms, typhoid symptoms are by no means uncommon.

In the mild cases, there will be heat, roughness, and redness of the skin, perhaps slight febrile symptoms, which cease in a few days; the surface of the affected part becomes yellow, and desquamation ensues, the disease terminating in resolution. In the severe forms, the inflammatory symptoms will be more or less intense, with pains in the head and back, great heat, thirst, restlessness, small and frequent pulse, and the disease terminates in resolution and desquamation, or in suppuration, forming disagreeable, indolent, ill-conditioned ulcers, and very rarely, in gangrene.—The fluid contained in the vesicles is colorless, or yellowish, containing a free acid, and becoming thicker and more opaque.

There are three forms of erysipelas, viz.; *simple* or *idiopathic*, in which the inflammation is superficial; *phlegmonous*, in which the deeper-seated tissues are involved and the redness is less vivid than in the simple form of the disease; and *traumatic*, or that which follows wounds or injuries. Simple erysipelas is subdivided into. 1. *Erysipelas Erraticum*, in which the disease spreads and increases in extent, or suddenly leaves one part to appear at another more distant.—2. *E. Metastaticum*, in which the disease suddenly leaves the surface, and affects some internal organ, as, the brain, pulmonary mucous membrane, stomach, intestines, etc.—3. *E. Miliare*, in which the eruption appears in the form of crops of minute

the system, and which have certain features in common that distinguish them from non-syphilitic cutaneous eruptions. They

vesicles, containing fluid.—4. *E. Phlyctenodes*, a common form of the disease, in which the vesicles or bullæ are quite large, discrete or confluent, and of irregular form; they contain a colorless limpid fluid, which becomes yellowish, sometimes opaque, and, in unfavorable cases, purplish.—5. *E. Œdematodes*, which occurs in debilitated systems, and among lymphatic persons; the redness is not so bright as in the other varieties, and the parts attacked, usually the inferior extremities, are more or less œdematous.—6. *E. Gangrenosum* is that form of phlegmonous erysipelas in which the disease terminates in gangrene.

Erysipelas has also been named according to its seat, thus: 1. *E. Faciei*, its more usual form, viz., on the face. It may be of various degrees, from a very mild to a very intense attack. In the more severe attacks, it often commences with stupor, more or less delirium, full and frequent pulse, and high inflammatory symptoms. The face swells, becomes red or purplish-red, the eyelids tumid, the cheeks enlarged, and the features hardly recognizable; respiration is difficult; the fauces and nose very dry, and the disease may terminate in resolution, abscesses in the neck, or fatally, by metastasis to the brain.

2. *E. Capitis*, when the scalp is affected, and which is generally the consequence of a wound or injury. The inflammation partakes more of the œdematous variety and may terminate in resolution, suppuration, gangrene, or by extension to the brain.

3. *E. Mammæ*, when the breasts are affected; they swell and become very hard and painful, with frequently a severe pain in the axillary glands. The disease assumes the phlegmonous character, and may terminate in resolution, extensive suppuration, or gangrene.

4. *E. Umbilicæ*, when, as in the case of infants, the disease locates itself in the umbilical region, from which it may extend to the neighboring parts. It may terminate by resolution, or by gangrene and death.

Erysipelas is frequently complicated with diseases of internal organs, which are either idiopathic or secondary; in the latter case being due to the erysipelas (metastasis). In either instance, the internal affection is rendered more severe and unyielding to treatment, requiring us to address our therapeutical measures more especially to the erysipelatous disorder. Among the organs more generally met with in this association, are, the nerves, the brain, the respiratory organs, the heart, the stomach, the liver, the intestines, the kidneys, the bladder, the uterus, the peritoneum, etc., and the character of the malady may vary from a mild to a very severe one.

The *diagnosis* of erysipelas may be readily made out by the inflammation and swelling or vesiculated character of the inflamed part, and its uniform redness; the great tendency to spread; the burning or stinging of the parts; the more or less febrile disturbance present; and the momentary disappearance of the redness upon pressure. In the phlegmonous variety the local and constitutional symptoms are more severe, the tumefaction extends more deeply, and the redness soon becomes less vivid.

The *prognosis* of erysipelas in the milder forms is favorable. The more extensive the disease, and the more severe the local and constitutional symptoms, the more unfavorable will be the prognosis; more especially when coma, delirium, or typhoid symptoms are present. It is also more unfavorable among the aged, the intemperate, those of enfeebled constitutions, and where a metastasis or exten-

present themselves in nearly all the orders of maladies of the skin, heretofore referred to, and may, consequently, be exanthematous, vesicular, bullous, pustular, papular, squamous, and tubercular.

sion to important internal organs takes place. When occurring in cases of dropsy, diabetes, or renal disease with albuminaria, it is very apt to prove fatal. Death may also occur from serous effusion closing the chink of the glottis, in those cases complicated with disease of the larynx.

In calling attention to the *treatment* of this disease, I shall not notice its more severe forms; the means I employ for these will be found in my American Physician, page 232. I shall merely refer to the treatment for the milder varieties, and for those cases where the erysipelas is complicated with chronic affection of some internal organ.

When the disease attacks the face or other part, the bowels must be kept regular, and any gastric acidity be removed by the Compound Powder of Charcoal. At the same time, to remove the erysipelas, the patient should drink freely of an infusion of equal parts of Maiden Hair, Elder Flowers, White Indian Hemp, and Burdock Seed; about a pint and a half should be used daily. In some instances, Cleavers may be substituted for the White Indian Hemp. To allay the burning, stinging sensation, the following should be applied to the affected parts several times a day: Take of Hydrochlorate of Ammonia four drachms, Water two fluidounces; mix, dissolve the Ammonia, and then add Tincture of Lobelia one and a half fluidounces, Tincture of Poison Hemlock one fluidounce. These measures should be perseveringly pursued; relief occurs in a short time, followed by a disappearance of the eruption in five or six days.

Ulcers following erysipelas, should be touched daily, with a drop or two of Oil of Turpentine, and, when the pain thereby produced has passed away, dress them with Indigo-weed Ointment, or, Red Oxide of Lead Plaster. As soon as the ulcer assumes a healthy aspect, the Turpentine should be omitted, but be re-applied whenever it tends to become indolent. The Turpentine should be placed upon the center of the ulcer, and not be allowed to come in contact with its borders, or with the surrounding skin.

Patients who are subject to frequent attacks of erysipelas, occurring with but little constitutional derangement, may effect a permanent cure, by a continued and persistent use of the above-named infusion; of the preparation of Blue Flag, and soluble Pyrophosphate of Iron, etc., with Glycerin and Water, on page 774; or of the following preparation: Take of Ground Centaury (*Polygala Nuttallii*) four ounces, Beech Drops, Burdock Seed, each, two ounces, Water, Glycerin, No. 2, each, three pints; mix, and form an infusion. The dose is a wineglassful three times a day.

In erysipelas complicated with some internal chronic disease, in addition to the measures employed for the chronic affection, one of the preceding preparations should also be constantly used; or, they may be employed alternately, using first one for a certain length of time, then the other, and so on, until the cure is effected.

The bowels must be kept regular, the skin and kidneys in as healthy a condition as possible, and gastro-intestinal acidity, or derangement, be promptly remedied. An especial attention must be given to the diet, avoiding everything that will cause flatulency, acidity, irritation, constipation, diarrhea, or other disorder of the alimentary canal. Means to give tone and nutrition to the system are especially valuable; all depressing or debilitating measures must be avoided.

It may be important to refer here to the peculiarities of these syphilitic eruptions. In some instances they may exist for a longer or shorter time without presenting any, or but very few of the symptoms about to be stated; but in the majority of cases, several or all of the following general symptoms will be present: There will be a deep-seated change in the system, a derangement of the functions of various organs, and all the tissues and organs will suffer more or less from being supplied with blood contaminated with a poisonous material. The brain loses its energy, and becomes, as it were, torpid, giving rise to lassitude, weakness, indolence, despondency, inquietude, and apprehension; the nervous system becomes more or less prostrated, and nocturnal neuralgic pains are common; the tongue becomes pale, coated white, broad, and indented by the teeth; the pulse more rapid; the fauces more or less congested, with swelling of the tonsils and soft palate; the larynx irritated, with mucous cough, and sometimes nausea; the bowels more or less deranged, as well as the urine; the conjunctiva congested and muddy, and the whole skin presenting a yellowish, dirty appearance. (*Wilson.*) The more the system becomes tainted with the syphilitic poison, and the greater the debility and constitutional derangement, the more severe, extensive, and obstinate will be the accompanying syphilide.

In the *diagnosis* of syphilitic eruptions, there are antecedents for the practitioner to gain a knowledge of, as, a prior inoculation with the syphilitic virus and the existence of chancres, and buboes, which, having passed away leave behind cicatrices, indurations, and discolorations upon the penis and in the groin; there may have been, and may even still be ulcerations in the throat, osteoscopic pains, loss of hair, nodes, etc., though it must be recollected that the syphilitic virus may be communicated in a secondary or tertiary form, without any primary disease whatever, as is frequently observed among females who have been thus infected by their husbands who were, perhaps unconsciously, laboring under the constitutional form of the disease.

Syphilitic eruptions may appear suddenly, like an exanthema, and may disappear and appear in the same individual at different times; they may likewise present themselves from time to time under different manifestations, so that at one time the same patient may have vesicles, at another pustules or tubercles, etc., and even several different kinds, as papules, pustules, scales, etc., may exist at the same time upon a patient; and this *polymorphism* is a peculiar character of these eruptions. These eruptions may appear upon any part of the body and limbs, but their favorite locations are,

upon the face, the vicinity of the alæ of the nose, the angles of the mouth, near the roots of the hair upon the forehead, and the back of the neck, the inner angles of the eyes, the center of the chest, the inner surfaces of the limbs, and in the vicinity of the axillæ and groins.

Itching and *pain* are, as a general rule, absent, though there are some exceptions, as, when the scalp is affected, and in the early stage of some eruptions, there may be more or less itching; and in the softening period of tubercles, there may be some pain and tenderness. When itching is present, care should be taken to determine that it is not due to pediculi.

These diseases always present a *circular*, *oval*, or *crescentic* form, but which is likewise met with in some of the non-syphilitic eruptions; they likewise have a tendency to extend peripherally. The confluence of two or more patches, may, however, prevent or destroy this circular appearance, often giving rise to forms of figures of eight. The *scaly eruptions* usually consist of small circular spots, with thin, frequently very fine, gray, and few scales, with a circumscribed whitish borders, the result of the separation of the epidermis from the cutis around the diseased patch. The *vesicles* are flattish and do not readily rupture. The *crusts* formed are thick, hard, uneven, firmly adherent to the skin, having a stratified surface and presenting eminences and depressions; they have a peculiar dark-green or black tint. The *ulcers* have rounded, sharply-cut, perpendicular edges, their surfaces are ashy-gray, covered with a pultaceous substance, and discharging a sanious and plastic pus, and around their borders may frequently be seen the characteristic copper color. Ulceration is a common feature of these eruptions. The *cicatrices* are circular or crescentic, at first violet-brown, then tawny-brown, and then whitish and reticulated, more or less depressed in their centers, with the skin wrinkled, or even and fine.

One feature upon which much stress has been placed, is the *color* of the eruptions, but it has been overrated, as it occasionally appears with non-syphilitic eruptions, and is by no means a constant and certain diagnostic sign; it is described as *copper-colored*. The decided coppery tint is not apparent at first, but is dull-red or violet, and becomes dull reddish-brown or coppery after a certain length of time; and as the eruptions disappear, a dull-red or dirty-yellowish discoloration remains for a longer or shorter period. When *any* eruption presents the several features just pointed out, they will greatly aid the practitioner in forming a correct diagnosis as to its syphilitic or non-syphilitic character.

A brief reference to the several forms assumed by the syphilides may be of service, and I will treat upon them in the order heretofore given of non-syphilitic eruptions.

Roseola Syphilitica, an *exanthema*, is one of the simplest and earliest forms of constitutional syphilis, and may be ushered in with febrile symptoms. It usually appears in from six to sixteen weeks after the primary disease; and may come on gradually or suddenly, affecting almost the whole surface of the body, or extending from the chest to the abdomen and extremities; rarely on the face and neck. Scabs on the hairy scalp are very frequent concomitants. The patches are irregularly rounded, frequently confluent, but slightly elevated, and of various sizes, closely resembling, at first, the eruption of measles, or ordinary roseola. They have a rose color at first, which gradually becomes pale copper-colored or dingy red, and, as they fade away, grayish. These patches may present a mottled redness, or assume the form of circular blotches, or congested rings. Sometimes itching may attend the eruption; the affection disappears, generally without desquamation, in the course of four or five weeks. The erythematous roseola occasioned by *copaiba* and *cubebæ*, is not syphilitic, and is attended with pruritus.

Lichen Syphiliticus, a *papular* eruption, sometimes manifests itself in an acute form, the same as *Roseola*, and the lichenous papules may accompany or follow the latter affection. The papules are small, numerous, distinctly elevated, may be isolated or in clusters, present a tint similar to that of *Roseola*, and terminate by a fine furfuraceous desquamation. They may appear on any part of the surface, but principally on the face, and continue for several days, or longer. The hair follicles are often involved, the hair of the affected follicle soon falling out. In the more chronic form of the disease, which lasts for many weeks, the papulæ are larger, from three to six lines in diameter, circular, less elevated, and of a decided coppery color, they are also less numerous, are slowly and successively developed, rarely have a red areola surrounding them, and appear on the forehead, the scalp, the back, the shoulders, and also on the limbs, in the same situations as the non-syphilitic papules of lichen. They end in resolution, with a pellicular and frequently repeated desquamation, leaving dingy-red discolorations behind them.—The transition from the papular to the squamous

form is natural and easy, the scales becoming thicker, laminated, and successively renewed.

Eczema Syphiliticum, a *vesicular* disease, may be distinguished from the non-specific eruption by the vesicles being larger, fewer, and less confluent, occurring in groups, or irregularly distributed; there is hardly any irritation, the secretion is not very profuse, and the vesicles are each surrounded by a copper-colored areola, and remain unruptured for a long time, or, their contents may be absorbed without rupture. The disease is seldom observed on the face, and runs a chronic course; it is very apt to be accompanied with erythema, papules, or pustules. The affection is a rare one, and usually appears quite early after the primary syphilitic disease. The eruption is principally located at the hair follicles, and numbers of them may be observed with a hair passing through them.

Ecthyma Syphiliticum is a *pustular* eruption, greatly resembling that of the non syphilitic variety of ecthyma, but differs from it in having a copper-colored areola, and thick, hard, greenish-brown crusts larger than the pustule itself, sometimes depressed at the center, and of concentric appearance, and which, upon becoming detached, leave deep ulcers, that are followed by pitted or depressed scars, frequently permanent. The pustules are seldom in great number at a time, and usually occur on the inferior extremities, the body, and the scalp, frequently with baldness; syphilitic roseola or papules upon the body, may co-exist at the same time. This is a very common form of the pustular syphilides.

Impetigo, of a syphilitic character is likewise met with, and usually appears at an early period after the primary disease, isolated, or in groups. It may occur on any part of the body, but more commonly on the scalp, or face, and is generally accompanied either with an exanthematous or papular rash. The pustules are small, flat, superficial, soon dry up, and form somewhat thickish, brown, grayish, or greenish-yellow crusts, having a copper-colored border, and leaving discolorations of the same tint, after healing. The ulcers are generally superficial unless the syphilitic taint is of long-standing, when they are deeper and more extensive.

Rupia Syphilitica, sometimes termed a pustular syphilis, is, according to the preceding arrangement, a *bullous*, or bullo-pustular

eruption, of very frequent occurrence, and usually observed upon the legs, arms, and lower parts of the body, though sometimes on other parts. It is only met with in adults who have become infected with the venereal poison. It is characterized by an eruption of a few small purulent bullæ, or large pustules, of circular form, flattened on their summits, about six or nine lines in diameter, which ultimately contain a purulent fluid, which after a few days is discharged, and forms upon drying, broad, circularly-wrinkled, thick, dark-greenish or blackish, very hard, and firmly-adherent crusts, and which, from the gradual discharge of purulent matter, slowly increase both in thickness and in extent. The bullæ or pustules are developed on a livid or dingy-red blotch, rather tender under pressure, and the crust is surrounded with a copper-colored areola. When the scabs are removed they expose more or less deep, foul, indolent ulcers, presenting the peculiarities already pointed out of such ulcers, and upon which new crusts rapidly form. The cicatrix presents the characters heretofore indicated, being abruptly depressed and indelible. When the eruption is not very severe, the crusts not very thick, and the inferior parts of the body and legs are its usual seat, it is termed *Rupia Simplex*. When it is more extensive, with larger pustules, more prominent and conical crusts, resembling those of non-syphilitic rupia, very deep and obstinate ulcers, and usually seated upon the forehead, face, or limbs, it is termed *Rupia Prominens*. Syphilitic rupia is a very obstinate and intractable disease, is late in its appearance, manifesting itself only when the system has become greatly impaired and debilitated by the syphilitic poison.

Syphilitic Pemphigus generally manifests itself as the result of hereditary syphilis, and may be met with among infants at birth or soon after, and is rarely observed in the adult as a consequence of acquired syphilis. It presents a violet-colored patch upon which bullæ are formed, from six to twelve lines in diameter, flattened, not much raised above the surface, which contain a fluid of a purulent character, or sero-purulent, and which is discharged when the pustule ruptures. The disease is usually observed upon the palms of the hands, and soles of the feet, though it may be seated on other parts, as, the arms, chest, abdomen, etc. The eruption terminates either in desquamation, or in ulceration, and its prognosis is more serious in the hereditary cases.

Lepra Syphilitica (Psoriasis Syphilitica), is a *squamous* syphilide, which is usually developed in the later stages of the disease, and

may follow an eruption of erythema, papules, pustules, or tubercles, assuming a variety of characters, which, however, may present one or more of the features of the different forms of non-syphilitic lepra. Like *Rupia* it is more common among impaired and anemic persons, and almost invariably adults, and ordinarily prefers the inner aspect of the limbs, the soles of the feet, and the palms of the hands, sometimes it may be observed on the face and body, but rarely or never on the elbows and knees. Generally, the eruption is not very extensive, is in circular patches not over an inch in diameter, sometimes, in very small circles or segments of circles, the borders more elevated than the centers, and presenting a distinct coppery color after it has become chronic, but occasionally very dark, or black. The scales are thinner and less laminated or imbricated than in the non-syphilitic disease, are often of a grayish color, adherent, and the disease is seldom attended with itching. When the scales are removed they expose a smooth, soft, dingy copper-colored, and shining surface, and on disappearing altogether, they occasionally leave a slightly depressed cicatrix, the result of interstitial absorption of the tissues. This affection is very chronic in its course, and ends in resolution and repeated desquamation, never in ulceration. It is often exceedingly intractable to treatment.

Lupus Syphiliticus, is one of the *tubercular* syphilides, and which is sometimes difficult to distinguish from ordinary *lupus non-exedens*. There are two forms of the disease, one terminating in desquamation or resolution; the other in suppuration and ulceration. In the first form, *Syphilitic Lupus Non-exedens*, there are small, hard, shining, round, dusky-red, somewhat purplish tubercles, from one to six or eight lines in diameter, but slightly elevated above the surface, their bases occupying the entire thickness of the skin, and encircled with a copper-colored areola; these tubercles are arranged in circular or crescentic groups, and sometimes the skin in the center of the group is of a leaden-gray color. Each tubercle frequently, though not always, becomes covered with a hard, dry, and grayish scale, and is not attended with itching. The tubercles are commonly isolated, rarely confluent, and extend concentrically from the circumference of the first formed group. They usually occur on the face, end of the nose, forehead, or neck, rarely on the arms and thighs, or body; are very indolent, often persisting for many years; rarely end in ulceration; and leave dusky or livid-red discolorations.

Syphilitic Lupus Exedens, is the term applied to the pustular or tubercular syphilides when followed by ulceration, and which occurs at an advanced period of the syphilitic disease, usually in connection with tertiary symptoms. The ulcers are of two varieties:—1. *Serpiginous*, when they extend circumferentially; they usually appear in the vicinity of the larger joints, and often on the back, chest, shoulders, and even on the face, with a rather thin, greenish-yellow crust, and leaving a pitted cicatrix of the depth of the ulceration. The disease is very slow in its progress, is apt to be accompanied with itching and pain, and the ulcers have a great tendency to become extended.—2. *Perforating* ulcers are those to which the term *S. Lupus Exedens* is more especially applied; they generally follow the tubercular syphilides, and are seated on the nose, lips, or face. A few moderately-sized, flattened tubercles appear, their apices become red, then soften, ulcerate, and discharge an offensive matter, which forms a thick, rough, dark-colored crust. Generally but one eroding ulcer is formed. This ulcer extends in depth, even destroying the cartilages and bones, has a grayish surface, and when one crust is removed from it, another is speedily formed by the plastic sanious, offensive pus discharged. The disease is of a very grave character, progressing very slowly, being more unyielding to treatment than the preceding variety, and causing great and extensive destruction and deformity. It is usually associated with great constitutional impairment and cachexia. When the ulceration heals, coppery-red or brown cicatrices are left, which are marked with depressions, are either smooth or bridled by bands of inodular tissue, are of circular or irregular outline, and which eventually become dull white. It may be *diagnosed* from *caneroid ulceration*, which presents prominent everted edges, and is accompanied by lancinating pains. (See *Lupus Exedens*.)

Acne Syphilitica is not a common syphilitic eruption, and usually appears upon the face, forehead, neck, and upper part of the trunk, though it may extend to, and even be confined to the legs. The tubercles are very small, isolated, conical or acuminate, with an inflamed, red, but subsequently, copper-colored base. Each tumor requires three or four weeks for its development, when it ruptures, and the discharged matter upon drying forms a small, dry, grayish, or yellowish-brown crust. When the crust falls off a slight desquamation of the exposed surface may ensue, occasionally a very superficial ulceration exists. On healing, or when the eruption disappears, a slight depression of a dark color remains,

which sometimes forms a persistent, white, rounded cicatrix. The disease occurs as a tertiary affection, or rather at the period between the secondary and tertiary symptoms. It lasts several weeks, but may be prolonged by the development of successive crops of the eruption. It strongly resembles *Aene Indurata*, which, however, is of a more lively red color, and does not occur on the legs.

The above are the principal varieties of syphilides met with in practice; others may occasionally be observed, but they all require exactly the same *treatment*, viz., that heretofore named for Constitutional Syphilis, *which see*. It speaks but little for the judgment, skill, or knowledge of any medical practitioner whatever, who administers mercurials or arsenicals for the cure of this disease—it is a strong indication, either that he is behind the age, is a prejudiced servant to these minerals, or both.

It may be proper to state that in the treatment of these syphilides, when anemia, or great debility are present, they must be met by chalybeates, tonics, nutritious diet, moderate exercise, etc.—I have frequently derived much benefit in the Syphilides from the following preparation, applied to the exposed surface or to the ulcer after the crust has been removed: Take of Chloride of Gold and Soda six grains, Hydrochloric Acid twelve minims, Nitric Acid three minims, Lard one ounce; mix together in a glass mortar, gradually adding to it very finely pulverized Hydrochlorate of Ammonia half a drachm. If too strong it may be weakened by the addition of more Lard. This ointment will also be found useful in several varieties of non-syphilitic cutaneous affections.

ORDER XI. PARASITICI.

This Order includes all eruptions of the skin in which a vegetable or animal parasite is developed. These parasites may always be detected under the microscope; in the epiphytic diseases, some of the hairs, the crusts, the dusty scales or exfoliated debris, should be removed, placed upon a glass slide, moistened with a dilute solution of potassa or ammonia, to remove fatty matters, etc., be covered with a thin glass cover, and then be subjected to the microscopic examination. A microscope having a magnifying power of from three hundred to four hundred diameters will be sufficient for these examinations.

There has been some doubts expressed by many writers whether

the parasites were the causes or the result of the eruption; but it must be recollected that unless the peculiar parasite common to the eruption is present, there is no eruption; and again, the contact of these parasites alone has produced their particular malady. It is almost impossible for these parasites to become developed upon *perfectly healthy* skin, yet, it is not always necessary that any constitutional disorder should be present in order that they may become developed,—a suitable soil for their production will result from neglect of cleanliness, filth, moistures, atmospheric changes, deficient exercise, bad hygiene, and contagion; the languid, unhealthy condition of many strumous children appears to be accompanied with a condition of the skin very favorable to parasitic growth.

Dr. T. Fox believes that vegetable fungi act, 1, directly upon the skin, either *mechanically*, by invading, irritating and destroying the cells of the tissues and the hair shafts, and living upon their juices, as in tinea; or, by inducing local *chemical change* leading to fatty degeneration of the tissues, as in favus,—the result of a process of oxidation in which the fungi absorbs oxygen and gives out carbonic acid. 2. Indirectly, by bringing about changes in substances out of the body, which are brought to influence the latter, as by *conveying the noxious poison* of certain diseases upon the skin or into the air passages; or, by setting up a kind of fermentative action in part due to the oxidation consequent upon the nutritive changes in the plant, or by giving rise to products having an acute or a chronic action,—or in other words, by *developing a poison*. I think he is correct in these views.—These fungi, or rather their germs, exist everywhere, and are constantly floating in the atmosphere, and as soon as they find a nidus, a congenial soil for their germination, they fasten themselves and grow. This has been verified so many times that it is useless to do more than to refer to it here. In the human system a peculiar abnormal condition of the skin forms the soil for them; air, heat and moisture favor their vitality and development.

It is not yet positively settled whether the fungi observed in the various parasitic cutaneous maladies are distinct species, or only varieties of one species. Dr. Lowe believes the Tricophyton Tonsurans to be only the sporula form of Achorion Schonleinii, and this latter again to be, in its fully developed state, the yeast fungus, Aspergillus Glaucus; and it has also been satisfactorily ascertained that various fungi may produce skin diseases in every respect resembling the several kinds hereafter referred to.

VEGETABLE PARASITES, OR EPIPHYTES.

FAVUS.

This cutaneous disease has been known under many names, as, *Scall Head*, *Honeycomb Ringworm*, *Porrijo Lupinosa*, *Porrijo Favosa*, *Tinea Vera*, *Porrijo-phyte*, *Tinea Favosa*, etc. The disease is due to the presence of the fungus *Achorion Schonleinii*, and is rarely observed among cleanly persons. It attacks the orifices of the hair follicles, the epidermis, and the nails, and is more generally observed on the scalp, though it may be developed on any part of the body. It is characterized by the presence of very minute, rounded, bright-yellow or sulphur-colored dry crusts, depressed in the center, and through which one or more hairs pass. At first, each crust is smooth on its inner aspect, and somewhat below the level of the surface, but as it gradually increases in size, even to three or four lines in diameter, it rises above the level of the skin, and its cup-shape or central depression becomes more distinctly marked, and presents a series of marks in the form of concentric circles. The crusts adhere firmly to the skin, and can scarcely be removed in the dry state without being followed by a little bleeding; but when carefully removed, they expose, each, a shining red, circular depression covered by a very thin layer of epidermis, which depression is due to compression of the crust, and which soon fills up when the crust is detached. But, unless means are taken to prevent it, a new cup-like crust becomes quickly developed in the place of the detached one. As the crust grows older, the cup-like depression gradually disappears, the crust becomes whitish, more dry and brittle, and ultimately breaks up.

When the disease attacks the hair follicles it is termed *Favus Pilaris*; when the crusts are scattered and isolated, it is termed *Favus Lupinosa* or *F. Dispersus*; when the crusts are numerous, thickly set together, blending and becoming united on their edges, so as to form a continuous irregular incrustation, it is termed *Favus Scutulata* or *F. Confertus*. And when the crusts, at an advanced period, lose their circular or oval form, their cup-like depression, their sulphur-yellow color, assuming a dirty whitish tint, and readily falling off, the disease is termed *Favus Squarrosa*. These, however, are not different varieties, but different stages of the same disease.

If left to themselves, the crusts remain adherent to the surface for months and even years; and fresh accumulations from the hair follicles go on producing additional crusts, until the entire scalp becomes covered by one dense and uniform crust. This, however, rarely happens, for the constant itching causes the patient to tear or rub them off in his efforts to obtain relief by scratching. And the disease may be propagated to other parts of the body by the fungus thus carried beneath the nails by the scratching. The itching is often accompanied by an erythematous condition of the skin. If the crusts are allowed to collect to any extent, the chronic inflammation of the integument which is set up, will continue until the whole of the tissues of the scalp down to the bones of the cranium are involved in the morbid action. In severe or neglected cases, there is frequently an enlargement of the lymphatic glands in the neighborhood, and in some rare cases, the tongue presents vesicles and patches. If the disease be seated near the eyes, a troublesome ophthalmia, *tinca ciliaris*, will be produced, with an œdematous state of the lachrymal puncta. Secondary impetiginous eruptions frequently appear when there is great irritation present.

The hairs lose their glossy character, become dull, dry, whitish or ash-gray colored, very brittle, are often split longitudinally, and are easily pulled out. If permitted, the hair will become matted and in a very filthy condition, readily falling out, even at an early period of the disease. When the disease has lasted a long time, the hair follicles become destroyed, and patches of incurable baldness remain, the skin of the bald part being pale, smooth, glossy, very dry, and somewhat resembling parchment. Should the hair grow again, after an arrest of the disease by treatment, it will be flaxen or woolly, weak, thin, of a lighter color, and often gray.—The odor exhaled from the parts diseased is very offensive, and has been likened to that of mice or cat's urine. Pediculi are very apt to be engendered, often in large numbers, more especially if there be a want of cleanliness, and thus add to the irritation.

Favus of the epidermis, and of the nails, are less frequently encountered than the above variety. The disease, as with other varieties of parasitica, is contagious; one of its most active predisposing *causes* being uncleanness, and especially in a scrofulous or badly nourished constitution.

By observing the characteristics of favus as just described, its *diagnosis* will be easy. When the crusts have been removed by parents or guardians before presenting the children for treatment, the scalp will manifest at the points from which the crusts were detached, a deep redness, a depression, and a distinctly-circum-

scribed surface, with a thin shining epidermis, and a few scattered pustules may also be observed.

In *impetigo* of the scalp, the color of the scalp is light red, diffused; the hairs are not altered, there are no patches of baldness, although hairs may fall out here and there.—In *lepra* of the scalp, the crusts are whiter, and much more adherent, and the whitish-silvery scales of *lepra* may be detected on the elbows, knees, and other parts of the body; beside, there is no change in the condition of the hair, no baldness, and but little, if any odor.—In cases of doubt, the hairs or the crusts may be examined under the *microscope*, when, if the case be *favus*, the parasitical fungus will be detected, and the roots of the hair will be found split up.

Achorion Schœnleinii under the microscope, presents the following characters, viz.,—isolated spores, or filaments composed of them in chain-like forms. The *spores* are minute, numerous, oval or rounded bodies, from the one eighth-thousandth to the one three-thousandth of an inch in diameter, with clear, well-defined margins, and containing in many instances granules in constant motion, when water is added to the specimen under examination. The spores are not affected by water and acetic acid, and their contents are strongly refractive and homogeneous. Numerous *receptacles* or *spore-tubes* will also be observed, analogous to those of the mycelium, but usually less flexuous, empty throughout a great part of their length, and containing throughout the rest small granules, varying in diameter from the nine ten-thousandth to the one three-thousandth of a line. Other tubes may also be seen containing granules nearer to each other but not touching, and others, again, full of spores of various sizes. The enveloping tube is not always visible. All these tubes vary in length from the one five-hundredth to the one one-hundred and twenty-fifth of an inch, and in diameter from the one twenty-five thousandth to the one five-thousandth of an inch. The *mycelium* is formed of flexuous cylindrical, simple, branched, inarticulate tubes or filaments, of uniform thickness throughout, about one eight-thousandth of an inch. The cavity of these tubes frequently communicates with that of the ramifications; while these appear simply applied against this tube and separated from its cavity by a partition. The margins of the tubes are simple, clear, of dark color, and their cavity is transparent without any internal granulations. This fungus appears to grow between the epithelial layers just at the orifice of the hair follicle; from this point, it may spread downward between the hair and its capsule, and upward around and even in the substance of the hair.

When a vertical section is made of a favus crust, and examined under the microscope, it presents the following characters: The outer periphery consists of a granular crust about the one one-hundred and fiftieth of an inch in diameter, the stroma, apparently a hardened exudation from the surrounding parts; this is lined by the mycelium passing in from it; next the mycelium, proceeding inward, come the receptacles and the spores. The bulbs of the hairs will also be found covered with chains and masses of spores around them, and also between the laminae of the split and broken up roots.

The *prognosis* is favorable, as the disease can always be cured by appropriate treatment.

In the *treatment* of favus, it is very important that we remove the crusts and expose the affected parts so that they may be reached by our parasitocides. This may be accomplished by cutting the hair close to the head, and then applying Flaxseed or Elm poultices; or else freely scrubbing the hair with soap and water, having some hours previously thoroughly oiled the parts,—and repeating this operation once or twice every day. Epilation, or the careful removal of the hairs from the affected parts by a properly made pair of forceps, will aid materially in effecting a rapid and thorough cure, and should be pursued in very obstinate cases, though not absolutely necessary in every case. It is not, however, a very practicable operation; and it must be recollected that the disease itself is the best depilatory.

Immediately after the removal of the crusts, or of the hairs, the parasiticide should be applied, not merely superficially, but it must be well rubbed in, if it be an oil or liniment; or, the parts should be well impregnated with it, if it be a lotion.—Although constitutional measures are not always required, yet where the patients are strumous, or of delicate, weakly, or anemic habits, it will be found advantageous to administer remedies internally, with a view to effect beneficial constitutional influences, and bring about a more healthy action of the skin and its functions. For this purpose, the long-continued use of Bromide of Potassium will frequently be found useful; or, Tincture of Chloride of Iron; vegetable tonics and alteratives; together with pure air, moderate exercise, cleanliness, nutritious and digestible diet, etc.

The best parasiticidal agents are the following: 1. Take of Sulphite of Soda one drachm, Distilled Water three fluidrachms, Glycerin one ounce and a half; mix. This should be applied frequently, and will be found especially useful in those skin diseases due to a vegetable parasite.

2. Take of pure Carbolic Acid one fluidrachm, Pyroligneous

Acid, of 8°, four fluidrachms, Distilled Water fifteen fluidrachms; mix the two acids, and then add the water. By means of a brush this liquid should be applied upon the affected parts, thoroughly impregnating them with it. It should be applied once or twice a day, and be continued for some time after all traces of the disease have disappeared; also being careful to cleanse the clothing, etc., and impregnate them in the same manner. This is useful for both vegetable and animal parasites.

3. Take of Sulphurous Acid one part, Water, Glycerin, each, one and a half parts; mix. Applied similar to the preceding; or, it may be kept constantly applied, over the part, on lint moistened with it, and then covered with oil-silk.

4. Ointment of Pyroligneous Oil of Juniper, rubbed in two or three times a day; or the Oil of Cade alone.

5. A saturated solution of Oxalic Acid, to one fluidounce of which, add thirty minims of Creosote. Apply once or twice a day.—Phenol Sodique has also proved serviceable.

When it is desired to cleanse the scalp from ointment or greasy applications, it may be readily accomplished by means of benzole on lint; this will also aid in removing crusts that have been previously softened by oil or ointment.

TINEA TONSURANS.

This disease, also known by the names of *Trichosis Tonsurans*, *Trichosis Furfuracea*, *Porrigo Scutulata*, *Pityriasis Decalvans*, *Common or Scurfy Ringworm*, *Tinea Capitis*, *Herpes Tonsurans*, *Ringworm of the Scalp*, etc, is due to the presence of the fungus *Trichophyton Tonsurans*. There are three varieties of it, as follows:

1. *Tinea Tonsurans* commences with an itching, mostly experienced at night, and which varies in degree; at the same time, circular or oval patches of a dry, scaly inflammation will be observed on different parts of the head. This eruption may appear as an erythematous slightly elevated or papillated ring, or it may present very small vesicles, which rupture at an early period. The patches are quite small at the onset, but gradually increase in diameter. A change also occurs in the hairs, they become dry, dull, twisted, and easily extracted, and acquire a reddish, or ash-gray color; and as the disease progresses they become very brittle, and even spontaneously break off within a line or two of the skin, giving the appearance of bareness or seeming baldness of the parts, and are sometimes matted together in small bundles. The hairs also be-

come covered with grayish-white dust, the surrounding skin puffy and slightly elevated, with little prominences, and when the head is kept clean, the skin of the patches looks parched, of a grayish, yellowish, or reddish color in blondes, and bluish or slate-colored in brunettes.

As the disease advances, pustules and yellowish crusts may be formed. It may last for an indefinite time, or may spontaneously terminate, either in a thorough recovery, or permanent baldness from destruction of the hair follicles.—When the itching is severe, the irritation resulting from scratching will increase the inflammation, giving rise to sores, ichorous and purulent discharge, and enlargement of the lymphatic glands of the neck.—The disease is not confined, like favus, to the poorer classes of society, but is also met with among the wealthy, and is often very obstinate to remedial agents. It may be conveyed by using the combs, brushes, towels, wearing apparel, etc., of affected persons, or by direct contact, especially by sleeping with them. Children are more subject to the disease, it being very rarely met with among adults.

Tinea tonsurans is not difficult of *diagnosis*. In its first stage, the itching, the *circular* or oval red patches, with or without vesicles, pustules, papules, or scales, the dull, dry, reddish, or grayish appearance of the hairs, their tendency frequently to become twisted, or to break off near the surface of the skin, will determine its nature; and, in the second stage, the erythematous rings, the broken off hairs, and their tow-like appearance, the grayish-white parasitic dust on them, the slight swelling, and the darker hue of the integuments. In the third stage pus is formed, which destroys the fungus, so that it can no longer be seen, the hair follicles often become destroyed, and permanent baldness results; this is more generally observed, however, when the disease is seated upon the chin, *Sycosis*. The crusts formed are usually small, of a gray or yellow color, and when they become large, the movements of the scalp breaks them up into somewhat angular fragments.—It is by no means uncommon for *Herpes Circinatus* to be found co-existent with *Tinea*.

The disease may be determined from *pityriasis capitis*, which affects the whole head instead of appearing in circular patches, and the hairs are more adherent, and not brittle. From *favus*, in which the crusts are cup-shaped. From *alopecia areata*, in which the patches are smooth, and the hair follicles quite faint. From *impetigo*, in which the hairs are not diseased. In cases of doubt, an examination under the microscope will solve the difficulty; the hairs will be found thickened, the bulbs flattened, more or less

disorganized, or destroyed, with the presence of the fungus causing the disease. If, however, suppuration has occurred, the fungus being destroyed by the pus may not be found.

2. *Herpes Circinatus* or *Ringworm of the Body* is the second form of *Tinea Tonsurans*, and like it is due to the presence of the fungus, *Tricophyton*. It is met with in all classes, sexes, and ages, and is located in the hair and the epidermal lining of the hair follicles, and is usually met with on the neck, arms, and other parts of the body. It generally commences with circular, reddish, slightly elevated patches, varying in diameter from two lines to two inches, which soon become covered with extremely fine, furfuraceous, white, dust-like scales, and attended with more or less itching and tingling. The margins of these patches often consist of very minute vesicles or papules, that are extremely evanescent, and leave a simple furfuraceous desquamation. These circular patches have a tendency to increase in diameter, new erythematous rings forming around their circumference, and which may continue until they attain a diameter of five or six inches. While the disease is thus spreading circumferentially, the central portions of the patches gradually heal, and the skin recovers its healthy condition; or if, as is sometimes the case, the central parts do not heal, then the whole rounded patch is entirely covered with the characteristic minute scales. There may be but one circular patch developed; but more commonly several, and even a number of them, located on different parts of the body.

Sometimes, especially in advanced cases, the disease loses its circular form, and manifests itself under the form of segments of circles, probably from a healing of the other parts. The disease may last an indefinite length of time, and then disappear spontaneously for want of nourishment.

Herpes Circinatus is of easy *diagnosis*. The red, elevated circular patches covered with minute furfuraceous scales, the seat of the eruption, and its being frequently associated with *tinea tonsurans*, or *sycosis*, are its peculiar characters. It may be determined from other eruptions in cases of doubt, by these characters, and by the detection of the parasitic fungus under the microscope.

3. *Sycosis, Mentagra, Sycosis Menti, Sycosis Contagiosa*, or *Barber's Itch*, is the third form of *Tinea Tonsurans*, and is likewise owing to the presence of the fungus, *Tricophyton*. It is a disease met with

principally among male adults, and is conveyed from one to another chiefly by means of the razor in shaving; a sharp razor especially. Its principal seat is the chin, though it may attack the hairy parts of the cheeks, the lips, whiskers, eyebrows, etc. When in the axillæ or other parts, females may also labor under it, but such cases are very rare.

The disease commences with a sense of more or less tension, unpleasant itching, and even slight pain, which is succeeded by an eruption of several small red spots, which increase in size circumferentially, the same as in herpes circinatus, are also of circular form, and covered with furfuraceous scales in which the parasite may be found. The hairs become affected, and may be extracted without difficulty.

The attention of the patient is, however, rarely called to the disease, until the deeper-seated tissues become involved in the irritation as manifested by the presence of small, acuminate, distinct indurations, upon the tops of which are formed pustules containing a pale-yellowish pus, which exudes when they rupture or are punctured, and which form, by drying, dark-brownish crusts that fall off in a week or two, leaving persistent, indolent, and purplish tubercles. In many instances large, fleshy-looking indurations, with lobulated or mulberry-like surfaces are present in the advanced stages of the eruption, from the disease extending into the deep-seated cellular tissue. The hairs, in this disease, lose their color, become very brittle, break off, or fall out, and, from partial or entire destruction of the hair follicles, more or less permanent baldness frequently remains. Upon the decline of the disease, the eruption and pustular elevations cease to be developed, the tubercles or indurations gradually diminish in size, and the epidermis is thrown off by repeated desquamations. However, the disease usually lasts for years, rarely disappearing spontaneously, but is kept up by a succession of eruptions around the circular patches, and also by improper local applications. In the advanced stages of the disease, the fungus becomes altered in its character, or else is wholly destroyed by the suppuration.

The *diagnosis* of Sycosis is not difficult; the red patches and circles among the hair of the chin, and perhaps also upon the neck and face, or wrist, the conical elevations, the pale-yellow pus, the mulberry-looking tubercles, the change in the hair, and the patches of baldness, will determine its true character, in conjunction with the microscopic examination, which should always be had in cases of doubt. Sycosis may be determined from *impetigo*, in which there are no circular patches; its seat is more superficial, and the subcu-

taneous swelling and induration is of less extent; the hairs adhere more firmly, and present no alteration, and the disease is not contagious; besides, no parasitic fungus is present. From *acne sycosiformis* which is not contagious, presents no parasite, is often accompanied with acne of the non-hairy parts of the face, and is not associated with the circular patches of herpes circinatus on the neck or other parts. From *syphilitic eruptions*, by their appearance, the enfeebled or cachectic constitution, and the history of the case. But the *microscope*, by detecting the presence of the Tricophyton, will always enable us to positively ascertain the correct nature of the malady in any of these cases.

Tricophyton Tonsurans, under the microscope, presents the following characters, viz.,—a number of round or oval, transparent, colorless spores, with smooth surfaces, homogeneous interior, and varying in diameter from the one two-hundred and fiftieth to the one one-thousandth of a line. Some present a distinct spot in their interior, or a badly circumscribed nucleus, and others, that are elongated, have a constriction at their center. These spores appear in the interior of the root of the hair in the form of a round mass. They give rise to some articulated filaments consisting of spores in chains or moniliform filaments, which, in becoming developed, creep into the thickness of the substance of the hair in a longitudinal direction. They only appear upon the external surface of the hairs after these break or split. The chains or bead-like filaments formed by the spores have borders tending to form an undulated line, but in the interior of which the spores may be seen very slightly separated from each other. Very rarely will the spores be elongated enough to resemble cryptogamic filaments; they are generally isolated, or accumulated in large groups, sometimes they are suspended to a very finely-fibrous thallus. Caustic potassa, and acetic acid do not affect the spores, but they are completely dissolved by tincture of iodine. The affected hairs are opaque, swollen in some places to nearly double their natural size, split up and ragged at the ends, broken off with a fibrous fracture, and studded all over with the spores; the medullary portion of the hair is either disorganized or has disappeared. In the early stages the hair bulbs are flattened and more or less disorganized; in the advanced stage they are wholly destroyed.—This fungus is primarily seated in the root of the hair, extends upward into the hair substance, splitting the hair; it also extends outward, even on to the skin between the hairs.

The *prognosis* of these three forms of Tinea Tonsurans, as to a cure, is favorable under proper treatment; when not treated, their course and persistency has already been explained.

The *treatment* is about the same as advised for Favus. When there is great irritation or suppuration, soothing poultices should be applied over the parts. It has been advised to extract the hairs, but this is not always easy, nor indeed is it always necessary, though they should be cut as close to the surface as possible, in order that the local remedies may be properly applied. Instead of depilation, it has been advised to apply the Acetum Cantharidis prepared with glacial Acetic Acid, painting it upon the eruption with a small brush, until it produces considerable pain. The vesication is effectual in curing the disease, and should be repeated once in every week or two, if necessary, being careful to well shake the bottle that contains the fluid, each time before using it. However, the parasiticide agents heretofore named will generally answer the purpose without this vesication, which can only be safely used in sycosis, or in the other forms when there are but few circular patches. Painting the eruption with Tincture of Iodine, or with a Compound Tincture of Iodine and Iodide of Sulphur will occasionally prove useful, as well as the Iodized Oil of Juniper.

ALOPECIA AREATA.

Alopecia Areata or *Accidental Baldness*, also known by the names of *Tinea Decalvans*, *Porriigo Decalvans*, *Ophiasis*, *Vitiligo Capitis*, etc., is a parasitic affection, due to the presence of the fungus, *Microsporon Audouini*. It may attack any of the hairy parts of the body, but more commonly the scalp, and may persist and extend itself until there is not a hair left upon any part of the body. The disease gives rise to more or less circular or oval, smooth bald patches, sometimes but one, but more commonly, many; there is but little or no desquamation from the skin, which sometimes becomes slightly paler than the surrounding skin; and the patches may vary in diameter from a line or two to several inches, or may even cover the entire scalp, leaving a permanent and complete baldness. Like the preceding parasitical maladies, it is contagious, but apparently much less so.

The disease is seldom noticed until a bald spot makes its appearance, although there may have existed some slight itching previously. At an early period the hairs of the affected parts are found dull and lusterless, and are very readily extracted; the surface from which they are taken is somewhat reddened and presents an œdematous-like swelling, but which does not pit on pressure. A

whitish substance, the parasite, will also be found upon the affected skin and hair. The hair soon falls out leaving circular patches of baldness, and the skin becomes white, smooth, and often slightly depressed. Frequently, the lost hairs are replaced by light, fine, downy-like hairs, which ultimately disappear, leaving the baldness complete. There is neither inflammation of the dermis, hypertrophy of the epidermis, vesicles, nor pustules in this disease. Itching is usually present.

The *diagnosis* is not so easy in the early stages as in the period when the disease is fully formed. But the *microscope* will render it accurate by showing the atrophied condition of the hair bulbs, and the presence of the parasite around the hairs.

Microsporon Audouini, under the microscope, presents a number of very small spores, together with an abundance of filaments. The spores are round or oval, cover the filaments, and sometimes their branches, are transparent, without internal granules, have a diameter varying from one twenty-five hundredth to one three-hundred and fiftieth of a line, and swell up when placed in water. The filaments are short, undulated, and arranged in the direction of the length of the hairs, parallel with their striæ, and have a diameter of from one eleven-hundred and twelfth to one one-thousandth of a line; they have no granulations in the cavity of the elongated cellule that constitutes them; sometimes they bifurcate at an angle of 30° to 50° . The branches are also short, and of the same diameter, and together with the filaments form a felt-like sheath around the hair, of the thickness of about one one-hundred and forty-fifth of a line. The branches may be distinguished from the filaments by the spores which accompany them. When the fungus is met with in the interior of the hairs, they collect into small masses and give rise to considerable swellings of the hairs.—This fungus is seated on the outside of the hair, forming a kind of sheath around it, and extending upward as far as the one twenty-fifth to the one-eighth of an inch from the surface.

As far as a cure is concerned the *prognosis* is favorable; though it must be remembered that the disease may disappear spontaneously, and either leave a permanent baldness, or be subsequently followed by a return of the growth of the hair.

In the *treatment* the same measures are to be pursued as named in the preceding parasitici. Previous to applying the parasiticide, it has been advised, in order to prevent the disease from extending, to carefully extract all the healthy hairs within a couple of lines of the circumference of the bald patch. Or, the disease may be treated by blistering the diseased patches, as named under

the treatment of *Tinea Tonsurans*, page 1087, or, by means of Cantharidal Collodion. The head should be frequently cleansed with soap and water. The following forms a very excellent wash for the head in these cases: Take of pure Carbolic Acid ten parts, Cologne (or other essence) two parts, Tincture of Quillaya Saponaria fifty parts, Water one thousand parts; mix. To be used with considerable friction, once or twice a day.

PITYRIASIS VERSICOLOR.

This malady, also known by the names *Chloasma*, *Liver Spots*, *Teigne Pelade*, *Leberflecke*, etc., is parasitic, and is due to the presence of the fungus *Microsporon Furfur*. It may occur upon any part of the surface of the body, but is more commonly met with on the anterior part of the chest, the abdomen, and neck, rarely upon the face and extremities, its favorite sites being the parts of the body that are habitually covered with clothing. It is a common affection, is met with in all classes of society, and is more frequently observed in youth and adults, very seldom in children. It is of a contagious character, but less so than some of the other parasitici, as it must find a congenial soil in which to flourish. Lymphatic persons, and those disposed to struma appear to be more liable to it; yet uncleanness is undoubtedly a predisposing cause. It is frequently encountered among those who are in the habit of wearing the same shirts or flannel next the body for two or three weeks at a time, without changing, and especially among those who continue to wear them in this manner both during the day and night; also among those who do not wash the surface of the body sufficiently often. It also frequently exists with patients laboring under syphilitic affections. The disease has been called "liver spots," from an erroneous supposition that some unhealthy condition of the liver occasioned its presence. The discoloration of the face, morpè, that frequently accompanies pregnancy is an entirely different affection. If the disease be allowed to run on without treatment it may last for several weeks, months, or even years; and often, when nearly well, it is liable to relapse. The general health remains unaffected, the disease, being purely local in its nature.

The disease is characterized by the presence of one or more small circular spots of a pale or saffron-yellow color, sometimes brownish-yellow, and again almost black, (*Pityriasis Nigra*), which gradually increase in diameter, unite, and form large irregular

patches of various sizes and forms; in some instances their outline has been compared to that of a map, representing continents and islands.* These patches usually present at their edges little convex spots about the size of small pin heads. Sometimes, the color will be so light as hardly to be detected from the healthy skin, unless it be attentively observed. The patches may or may not be very slightly elevated above the surrounding surface, and, as they advance in size, their centers do not heal, as is the case with those of herpes circinatus. Itching may or may not be present; more commonly, when present, it is quite slight, but occasionally it is rather troublesome. These patches impart a roughish aspect to the skin, which in many cases is barely perceptible to the touch, and are covered with a more or less, very fine, furfuraceous or branny desquamation which readily falls off upon scratching or rubbing the parts, the scales having somewhat the color of the eruption, and consisting of epithelial debris and the spores and tubes of the parasite.

The *diagnosis* of pityriasis versicolor is by no means difficult; its more usual seat *upon the body*, its irregular form, its yellow or dark color, its scarcely perceptible elevation above the surrounding healthy surface, the slight itching or its entire absence, the fine, mealy desquamation which becomes renewed with great facility, the color of the minute scales that are shed, together with the presence of the parasite, when the scales are examined under the microscope, will enable us to readily recognize it. It may be determined from *nigrities*, which is due to an augmentation of pigment, without any elevation of surface, itching, or desquamation. From *ephelis* or *freckles* which are also owing to an increase of pigment, without elevation or desquamation, and are more commonly observed on parts of the body that are kept constantly uncovered. From *pityriasis vulgaris*, and *P. capitis*, in which the scales are more abundant, larger and thicker, are not yellow, and, any patches that are presented are red. From *syphilitic erythematous patches*, by the little eruptive spots about the size of a pin's head that are present in pityriasis, around its edges, but which are absent in the syphilides. But in all cases of doubt, the presence of the fungus, under the microscope will at once render the diagnosis accurate. A few of the scales may be scraped off, placed upon a glass slide, moistened with a few drops of Liquor Potassa diluted with two parts of water, covered with a thin glass cover, and then placed under the microscope for examination.

Microscopon Furfur, under the microscope, presents a net-work of short tubes or filaments with terminal spores. The spores are gen-

erally in groups or grape-like clusters, are round or oval, strongly refract light, present no granules in their interior, but often show a double outline or margin, and vary in diameter from one three-hundredth to one six-hundredth of a line. The fungus grows in the epidermic cells.

The *prognosis* of pityriasis versicolor is favorable.

In the *treatment*, the general health must be attended to, and some parasiticide be applied locally to the eruption two or three times daily. I more commonly give a Solution of Bromide of Potassium internally, and, as a local application, a mixture of Carbolic Acid one part, Vinegar or dilute Acetic Acid fifty or one hundred parts. In very unyielding cases, an exposure every other day to a fume bath of Sulphur and Iodine, and which should be kept up for two or three weeks, in conjunction with the preceding-named measures, will effect a permanent cure. The solution of Sulphite of Soda in water and glycerin, named under Favus, will frequently prove an effectual local application.

To prevent a return of the disease, the patient should frequently bathe the surface of the body with soap and water; should not wear the under-clothing used while the disease was present, but should procure new flannel, etc., and be careful to change it frequently, and especially to remove it every night, wearing, during sleep, a night-garment expressly prepared for such purpose.

ANIMAL PARASITES OR ECTOZOA.

SCABIES OR ITCH.

This is a very common contagious affection of the skin which is due to the presence of a minute insect called the *Acarus Scabiei*, or *Sarcoptes Hominis*, and which is transferred from one person to another by actual contact, as, in sleeping together, shaking hands, etc., or, through the medium of clothing that has been worn by an infected individual. Persons who neglect personal cleanliness are especially liable to it, hence, it is very frequent among the lower classes; and when the disease is met with in respectable families, it will generally be found that servants or hired persons have communicated it. Certain professions, as, weavers, tailors, dyers, mattress-makers, shoemakers, etc., appear to be more obnoxious to it than

others. The disease may appear upon all parts of the body, except the face, which is almost always exempt; but the spaces between the fingers, the wrists, elbows, axillæ, abdomen, thighs, and penis, are the parts more especially liable to be affected. Parts of the skin exposed to pressure are also liable to be severely attacked. When left to itself it may continue for years, or even during life.

In the young and healthy the disease will manifest itself in from two to six days after contact; if the system be enfeebled, it will require a longer time. In the adult from seven to ten days is required in the spring and summer, and from fifteen to twenty in winter; older persons require a still longer time before the characteristic papules will be developed. It is more frequently met with in summer than in winter.

When the itch insect comes in contact with the skin, it burrows in the epidermis, and the irritation produced thereby gives rise to itching, and the development of an eruption of distinct, pale, slightly acuminate, and conical papules or vesicles, with transparent summits, and which contain a viscid and serous, or opaque fluid, which is discharged when they are ruptured by scratching or otherwise. The itching is sometimes almost insupportable, and is augmented by warmth, heat of the bed, excessive exercise, and the use of alcoholic drinks, as well as of high-seasoned food. The irritation produced by the scratching gives rise to a number of small, red, inflamed spots or eruptions, and may even cause a degree of inflammation resulting in the formation and discharge of pus.

The *diagnosis* of itch may be frequently made out by the character and situation of the eruption. A papular, vesicular, or pustular rash on the back of the hands between the fingers, on the abdomen, inner part of the thighs, etc., attended with much itching, which is augmented greatly when in bed, are the common *symptoms*. If there is any doubt, the channels or cuniculi should be looked for, by means of a magnifying lens; they have generally a serpentine shape, look like streaks or lines, are from half a line to three lines in length, or even longer, and present a whitish dotted appearance, the dots being due to the eggs deposited in these cuniculi; and if it be desired to examine with the microscope, one or more of the cuniculi may be sliced off with a sharp knife or pair of scissors, and the whole be examined in mass; to remove the parent acarus we must cut rather deeply. The young acari may frequently be procured by cutting off the heads of some of the vesicles or papules. If the parent acarus can be seen, a small delicate pin may be passed along the cuniculus, and on reaching its farther extremity the insect will be brought out on the point of the pin; it may

always be known by being situated at the termination of the cuniculi, which has a slight elevation over it, and by the grayish or yellowish-white speck beneath, which is the insect itself. The parent insect is never found within a vesicle or pustule.

The female itch insect varies from one one-hundred and forty-seventh to one-seventy-seventh of an inch in length, and from one-three hundred and third to one-ninety-fourth of an inch in breadth; it is almost egg-shaped, being broader anteriorly than posteriorly, is whitish, and has no true head, but a projection beyond the body, having a rounded edge, a central, mouth-like fissure, and, anteriorly, proboscis-like mandibular organs furnished with four bristles. There are eight legs, four, anterior, are inserted into the thorax by the side of the proboscis or head-like projection, they are conical, tapering toward a point, each one consisting of several jointed segments, and the last joint terminating in an adherent disk or sucker, from the side of which arise several small hairs and bristles. The four posterior legs have no suckers, but terminate, each, in a very long curved bristle. The body presents numerous, wavy lines, and the back is convex and furnished with numerous little angular spines, as well as with small round tubercles, upon each of which is seated a small conical spine. The male is much smaller than the female, and its posterior legs are furnished with suckers like the anterior.

The animal burrows in the epidermis, and forms minute channels (*cuniculi*), at the end of which it may often be discovered, and from which it can not emerge, but may continue to eat its way through the skin, until it ceases to lay eggs, when it dies; it does not inhabit the vesicles or pustules which constitute the eruption and are simply excited by the irritative action of the animal. A fresh egg is laid every day, perhaps two, and after the deposition of each egg the insect penetrates further, so as to leave room for the next. The eggs are about one-twenty-fifth of a line broad and one-eleventh of a line long, though their size will be found to vary. The eggs inhabit the cuniculi, and the young acari, which, at first, present but two posterior legs, may often be found in the vesicles and pustules.

Itch is a purely local disease, and exerts no influence upon the general constitution, except when severe and occasioning intense itching, with constant scratching, causing extensive, varied, and loathsome eruptions. Its cure is very easy. The *treatment* consists in allaying any excessive irritation by emollients and anodynes, and, destroying the insect by the local application of a parasiticide. In all instances, previous to this application, the whole surface of the body should be thoroughly washed with soft soap and warm water.

The parasiticides that may be used are,—1. The preparation of Carbolic Acid, No. 2, under the treatment of Favus, page 1081.—2. Phenol Sodique.—3. Benzole or Benzin.—4. Liquid Sulphuret of Lime, made by boiling together Lime half an ounce, Sulphur one ounce, Water half a pint; it should be constantly stirred till a homogeneous mixture is produced, and then passed through a sieve.—5. Compound Ointment of Sulphur.—6. An ointment composed of Sulphur two drachms, Subcarbonate of Potassa one drachm, Lard twelve drachms; mix.

One of these parasiticides should be applied to the *whole surface of the body*, except the head, every night, and be continued thus for ten or twelve days, or until all the insects have been destroyed.

The clothing, as well as the bedding, should also be exposed to the action of one of the parasiticide fluids, to the vapor of sulphur, or to boiling water, in order to destroy any of the insects that may have become deposited upon them; and, in cases where the disease has proved uncommonly obstinate, it would be desirable to destroy the infected clothing.

The *Acarus Folliculorum*, is an insect often met with in the sebaceous glands of the nose and face, the outer extremity of which presents a black point; it is popularly termed a *grub* or *worm in the skin*, and is frequently pressed out between the fingers by many persons. It is also frequently met with in acne, and is more common among strumous and lymphatic persons. Its presence gives rise to no morbid condition, though quite annoying to some persons on account of its appearance. It may be removed by the use of Soap and Water, in conjunction with one or two applications every day of a mixture of Carbolic Acid one part, Ether fifty or one hundred parts. Apply to the parts on lint, and cover to prevent evaporation; then wash with soap and warm water.

The human body is liable to three kinds of lice which vary in their appearance and location; they are termed *pediculi capitis* or head lice; *pediculi corporis* or body lice; *pediculi pubis* or crab-lice. They may be removed by daily bathings with Cologne; with Tincture of Staphisagria; with a solution of Carbolic Acid one part, Acetic Acid four parts, Cologne, Water, each, seven and a half parts. There is no necessity for the use of filthy and dangerous mercurial ointments. In cases where the pediculi are in great abundance on the head or genitals, the hair should be cut as short

as possible before commencing the application, in order to facilitate the destruction of these parasites.

Having referred to the treatment of *Warts* or *Verruca* in several places, I will make a few brief remarks thereupon at this place. These growths are too well known to require a description; the *cause* of their appearance is not understood. They may be removed by touching them daily with Nitric Acid, Nitro-hydrochloric Acid, Concentrated Acetic Acid, or Carbolic Acid, removing the disorganized material as fast as it is produced. A saturated solution of Bichromate of Potassa, or of Chromic Acid, has been successful; being careful, in all cases where caustics are used, not to touch any of the surrounding healthy tissues. Manganic Acid also forms a very effectual remedy. The juice of Milkweed, of Celandine, or, of Marigold Flowers, are very popular remedies among the country people. Hydriodide of Ammonia, and also a solution of Copper dissolved in strong Aqua Ammonia, have both been found serviceable.

For the treatment of *Syphilitic Warts* or excrescences, see pages 465 and 957.

PART IV.

SPECIALTIES.

CHRONIC DISEASES OF THE PROSTATE GLAND.*

PREVIOUS to puberty the prostate gland is in an immature condition, and, therefore, not so liable to attacks of disease as when fully developed and in the exercise of all its functions; and its tendency to disease becomes more marked after puberty, as we advance in years.

The prostate gland may be detected through the anterior wall of the rectum, by placing the patient upon his back, with the legs separated and drawn up toward the abdomen; then, having oiled the index finger, carefully pass it into the rectum, (which must have been previously evacuated), keeping the hand in a supine position, that is, with its back downward and its palmar surface upward. As soon as the extremity of the finger has passed beyond the sphincter ani, it will, at first, come in contact with the posterior extremity of the urethral bulb situated directly above the sphincter, then with the membranous urethra, and as the finger advances, the apex of the prostate, and finally the rectal face of its body. This will be found hard, somewhat concave at its median line, from each side of which it widens outwardly to its base in a convex form. If the patient lie with his face downward during the examination, the hand of the surgeon must be held with its back looking upward, and its palmar surface downward. The average measurements of the gland are, from its apex to its base,

*In the selection and preparation of matter furnishing the preliminary remarks, causes, symptoms, etc., of prostatic diseases, I am principally indebted to Thompson, Velpeau, Beraud, Cruveilhier, Vidal, Horion, Mercier, Brodie, Rayer, Leroy, (d' Etiolles), etc.

from one and a quarter to one and a half inches; its greatest transverse diameter, from one and a half to one and three-quarter inches; its greatest thickness, from five-eighths to seven-eighths of an inch; and, the distance from the center of the urethra or median line of the prostate to its extreme border at its vesical extremity, is from six-eighths to seven-eighths of an inch.

It is only within the present century that the various affections of the prostate have been carefully studied. The tumefaction of this gland, its engorgements, and abscesses, the urethro-prostatic discharges so frequently met with, and for so long a time misunderstood and neglected, may all give rise to such results as to seriously endanger the life of the patients laboring under them.

Diseases of the prostate are serious, not only of themselves, independently of the obstacle they may present to the passage of urine, but they also frequently determine inflammation of the kidneys and ureters. More or less extensive abscesses have frequently been observed at the autopsy of individuals who have fallen in consequence of tumors and inflammations of the prostate; it is also known, from experience, that the greater part of organic diseases of the kidneys, and the various functional disturbances of these organs, with regard to the quantity and quality of the urine, generally depend upon diseases of the urethra and bladder, and upon disorders observed in the functions of this last-named organ.

Prostatic diseases also exert a great influence upon the genital organs. The intimate connections which exist between the gland, the seminal vessels, the spermatic ducts, and the testicles, perfectly account for this. The greater part of men affected with engorgement, or any other chronic disease of the prostate, experience a marked derangement in the reproductive functions; only it may not be so clearly and prominently manifested in all cases by symptoms fully appreciated by them. More frequently we will observe a considerable diminution of the sexual desires, or, of virile energy; the acts are repeated at longer intervals, and to the sensation of voluptuousness is added another, partaking of fatigue and labor. An indisposition, not previously observed, is experienced, a depression, which causes the person in many instances, to avoid the approach of a woman. The testicles are sometimes atrophied or growing smaller; sometimes soft and hanging low; occasionally, on the contrary, they become firmer and larger, but almost always more or less painful to pressure.

One of the most frequent causes of diseases of the prostate gland is the abuse of coition, and various analogous acts of the genital functions. It is undeniable that a licentious life, especially

among men of advanced years who desire still to keep up an excitation of the genital organs, is very frequently productive of prostatic enlargement. Indeed, most of the diseases of this gland are the result of venereal excesses.

Inflammations of the urethra, especially gonorrhea and the various runnings to which young men are so frequently subject during the first years of their manhood, also exert a great influence in the development of the various lesions of the prostate. Yet I have observed serious affections of this gland among persons who never had any gonorrhea, any runnings, nor any urethral stricture, and among very continent and very studious men.

Whatever may be the original cause of the prostatic disease, the patient's age will exert a great influence upon it. Among old men, the prostatic alterations are hypertrophy, abscess, excrescences, and productions which indicate a prolonged excess of nutrition. Among adults, diseases of the gland present special characters, they may coincide with affections of the seminal vesicles, they may be associated with excessive continence, or, they may depend upon the various acute diseases with which the genital organs may be attacked, particularly retentions of urine the consequence of obstacles in the urethral canal. Among old men, the mode of life and all the circumstances which concur more or less directly to determine the circulation to the inferior parts of the body, are to be regarded as powerful aids in bringing on prostatic diseases. Horseback riding, which sometimes determines hematuria and rupture of the veins of the neck of the bladder, may also contribute to the production of disease of this gland, especially when previous causes have occasioned a tendency thereto.

The little attention generally manifested toward establishing a correct diagnosis of the various and frequent diseases of the prostate, involves serious consequences, as, in the treatment of several other affections of the urinary apparatus; thus, we frequently see vesical catarrh, hematuria, incontinence of urine, and paralysis of the bladder, in which the resources of art prove powerless, and we may, as a general rule, safely attribute the persistency of the symptoms to a deep-seated and unknown lesion of the prostate gland. Fortunate indeed, will be the patient, if he has not been robbed of precious time, during which the affection has been placed beyond all known remedial measures, by hazardous and unskillful attempts at cure. The diseases, etc., of this organ are as follows:

Absent Prostate.—The prostate gland will necessarily be absent when the genital organs are not present; it may, however, be absent,

when the faulty conformation is less radical. Thus, in cases of exstrophy of the bladder it is by no means uncommon to find the prostate wanting; and its absence has likewise been verified among certain persons with whom the balance of the genito-urinary apparatus was present, and in a normal condition. These faulty conditions of the gland have been very rarely met with, and are beyond the resources of art;—the term “Congenital Atrophy,” which has been applied to them, is not strictly correct, as we can not well conceive of the atrophy of an organ that has never been developed.

Double Prostate.—When there is a failure of the symmetrical union of the prostate during the process of development of the genital organs, the urethra may open inferiorly and the gland be separated into two distinct lobes, forming what has been termed a “double prostate.” Art can effect nothing in such cases, which fortunately are by no means common.

Atrophy of the Prostate.—Atrophy of the prostate gland is of more frequent occurrence than the faulty conformations just referred to; it consists in a gradual wasting away of the gland, or of some of its elementary structures, so that the organ diminishes both in volume and weight. It may exhibit itself under several forms, as follows:

1. True or complete atrophy, involving all the constituent structures of the gland proper.
2. Atrophy involving only one of the elementary structures of the gland; or, a partial atrophy, in which the unaffected parts remain normal or stationary.
3. Atrophy of certain structures or portions of the gland, with hypertrophy of others.

The *causes* of atrophy of the prostate are various, and are principally comprised in the following list, viz.: Structural disease of the organ, as, tubercular deposits, malignant affections, ulceration or abscess, which, either by interfering with the nutrition of the gland, or by disintegrating more or less of its tissue, occasion a partial or complete wasting away; mechanical compression, as, bougies frequently introduced and retained for a long time; calculi in the bladder or deposited in the tissue of the gland; neighboring tumors or hypertrophy of the muscular fibers of the prostate, etc., either of which occasion considerable diminution both in bulk and weight, of the entire gland or of only certain portions of it, owing to the continued pressure which they exert upon it; certain diseases, which,

by their exhausting influence upon the general system produce atrophy of all the tissues of the body as well as of the organ under consideration ; and lastly, senile atrophy, or that which is occasionally met with among aged persons, and which occurs independently of the preceding causes.

As a general rule, there are no *symptoms* which may be considered peculiar to simple atrophy of the prostate, and its discovery is more apt to be the result of chance than of any sufferings on the part of the patient ; cases, have, however, been observed, where the patients were troubled with some derangement in micturition, or were partially or entirely impotent, and, in a few instances, very severe deep-seated pains were experienced. Ordinarily, the health remains but little affected, and the disease, when uncomplicated, presents no serious aspect.

If, in a case of atrophied prostate, a bougie be introduced into the bladder through the urethra, and a finger be also passed into the rectum, and pressure be then made with the finger upon the bougie, and parts around it, instead of finding the hard tissue of the gland, regularly widening outward on each side of the urethra, the parts will be found soft and yielding, and the bougie will be very readily distinguished. Should a catheter be introduced into the bladder instead of a bougie, it will be observed to enter the bladder rather suddenly, as it were, as soon as the instrument has passed the curvature of the urethra, and this, too, without requiring the operator to elevate its beak as must be done when the gland is hypertrophied. In many cases the urine will also be observed to flow as soon as the perforations in the catheter have passed the urethral curve, and which is due to the fact that in atrophy of this organ, the prostatic portion of the urethra is commonly very short and considerably dilated, while the membranous part may be reduced in length.

As to *treatment*, all that can be done will be to obviate the derangements that may occur in the function of micturition ; nothing can be done which will restore the atrophied organ to its normal condition. However, should the atrophy be due to stricture, ulceration, tumors, etc., a successful treatment of the cause may be followed by more or less benefit to the affected gland.

CONTUSIONS OF THE PROSTATE.

From the position of the prostate, and its protection from external mechanical influences by the neighboring bones and the perineal

aponeuroses, it is rarely that contusions of the gland are met with. However, they do sometimes occur, and may be occasioned by a very violent blow or fall from a height upon the perineum, or a fall in which a small blunt body comes forcibly in contact with the perineum. Severe and long-continued horseback riding may also give rise to contusion of this organ, as well as the introduction of too voluminous bougies or catheters; it may likewise originate from the operations of lithotomy and lithotripsy, especially when the calculus is very large, requiring the neck of the bladder to be dilated.

There is always an infiltration of blood, or a collection of it in a certain portion of the contused gland, the quantity of which depends upon the degree of the injury; and these sanguine effusions are supposed by some writers to be the commencing point of certain prostatic tumors, while others believe that the color of small blackish gravel sometimes observed in the prostate is due only to the coloring matter of the effused blood.

There are no positive symptoms for diagnosing a contusion of the prostate; but when the circumstances lead to a suspicion of this injury, we should administer *treatment*, which, from its promptness and efficacy, will lessen the chances for the future development of tumors, which are almost always difficult of cure. For this purpose, leeches may be applied to the perineum, or cupping may be substituted. Sitz baths as well as general baths will also prove useful. An infusion of St. John's Wort may be drunk freely, and a portion of it may likewise be carefully injected into the prostatic portion of the urethra, several times a day. The following may also be rubbed, two or three times daily, over the rectal portion of the prostate, by means of a speculum (especially made for the purpose), introduced into the rectum, through which a curved probang holding some of the mixture may be passed up to the desired point: Take of Aleoholic Extract of Aconite one drachm, Aleohol q. s. to dissolve the Extract,—when dissolved, rub it up with one ounce of Glycerin. In a similar manner solutions or ointment may be topically employed, of Hydrochlorate of Ammonia, Conium, Stramonium, Iodide of Ammonium, and other resolvents, either alone, or in various combinations.

WOUNDS OF THE PROSTATE.

Wounds of the prostate may be divided into two classes, viz.: incised, and lacerated. In the former, the tissues are smoothly divided by a sharp-cutting instrument; the latter may include deep

or superficial punctures, either narrow or wide, straight or crooked, occasioned by a blunt body, as well as cases where the tissues of the gland, having been forcibly torn apart, present a wound with ragged and irregular edges. These wounds may be confined to only a single part of the gland, or they may involve it in several directions, and throughout its whole extent, and even pieces of the organ may be detached from it.

Wounds of the prostate may occur either from without inward, or from within outward, and, as just stated, are caused by blunt, pointed, or cutting instruments; in most of the operations for the removal of stone, this gland is cut or wounded to a greater or less extent, and rents of the prostate made by instruments (*lithotriptors*) frequently become fatal in a short time. It may also be wounded by a fall upon a somewhat pointed body, as upon the end of a pole, the pointed part of a chairback, upon the point of a knife, or similar objects; blows upon the part with pointed or cutting bodies, may likewise result in severely wounding this organ. Hard substances in the rectum, as fruit-stones, pins, gravel, fragments of bone, and the like, by causing ulceration or dividing the tissues above the sphincter, may also wound the prostate. When shot by fire-arms, the ball may pass through the pelvis and wound this gland. In the operation for puncture of the bladder, the enlargement of the prostate may be so excessive as to materially alter the relations of the pelvic organs, so that, at the moment of puncturing, the trocar will penetrate into the prostatic tissue.

Wounds from within outward are much less frequent than the preceding; they may occur in the course of operations on the prostate, or in the extraction of a large calculus, during which the gland is very liable to be torn, etc.—Perforations or false passages will be considered separately under the next head.

Whatever may be the extent of the incision in the prostate, the lips of the wound generally remain in contact, and are seldom separated or slightly gaping; the principal causes of this are the various aponeuroses which surround the gland, together with most of its anatomical conditions. And if to these physical conditions we add the physiological ones of contraction and vascular congestion, we may readily comprehend why solutions of continuity, produced during life, should have so little tendency to separate or gap.

There are certain *symptoms* indicating the presence of wounds of the prostate, as the flowing of urine,—semen, or blood, and which fluids may escape through the external wound, the rectum, or the urethra; in the latter instance, it may occur under wholly different

conditions, and we will then have to observe the character of the symptoms in order to determine the diagnosis.

When the wound is through the perineum, the flow of urine will afford a sufficiently exact indication. If the urethra alone is involved, the urine will flow through the wound only when the patient expels it voluntarily. If the prostate be divided, the urine will escape through the wound from the commencement of the vesical contraction, and will continue to flow through it for some moments after it has ceased passing through the meatus. If the wound extends so as to involve the neck of the bladder, the urine will be constantly escaping in spite of all efforts on the part of the patient to the contrary.

The escape of semen will furnish less certain indications; beside, it passes from its reservoirs only at more or less distant intervals. If the seminal vesicles empty themselves, we may discover the spermatic fluid on the linen applied over the surface of the wound, and then we may diagnosticate with certainty that the ejaculatory canals are wounded. And in order that we may not confound this fluid with the prostatic liquid, it should be examined under a microscope having at least three hundred diameters.

If the wound be inflicted through the perineum, in addition to the escape of urine, semen, or blood from it, we may, in many instances, confirm the diagnosis, by feeling the wound in the gland by means of a finger.

If the wound be through the rectum, the same indications will be present. But when it has occurred through the hypogastrium, we can only point out the constant flow of blood through the meatus urinarius; and even this indication may be wanting, because the blood may pass into the bladder, or it may continue to flow through the urethra for so short a time as to lead us to mistake it for only a wound of the bladder.

Wounds of the prostate may be *complicated* with hemorrhage, which, although of frequent occurrence, generally ceases without the assistance of art. Phlebitis is also a very frequent accompaniment of these wounds, and which very likely is the cause of the death of most of the old men who have undergone the operation of lithotomy. Obliteration of the ejaculatory canals may be a consequence of these wounds, especially in the operation of lithotomy by the method of Mariano, or Apparatus Major; and which is a serious accident to a young man or an adult. Finally, wounds of the prostate may be accompanied with inflammation or suppuration of the organ.

Ordinarily these complications are not present; if the wound

be effected by a cutting instrument, the surfaces swell, and, coming in contact with each other, prevent the urine from any longer escaping through the divided parts. In lithotomy operations where the prostate is cut into, we frequently observe the wound to close toward the fifth day. So that in simple wounds it is very seldom that a fistulous opening remains.

But when the wound is a contused or lacerated one, in which the tissues are torn apart or present a loss of substance, the case is different. There may be such violent pains and so great a degree of prostration, as to endanger the life of the patient; and should he survive the injury there will probably be a lengthy period of suppuration, followed by a very troublesome urinary fistulous opening.

The *treatment* of these injuries will be given under the following head:

PERFORATIONS OR FALSE PASSAGES IN THE PROSTATE.

These are true contused wounds, and may be produced purposely, as in cases of forced catheterism, but they are more frequently the result of imprudence or unskillfulness, and are much more liable to occur when the prostate is hypertrophied or softened.

Perforations of the prostate have been divided into incomplete, complete, simple, multiple and complicated. They may occur in all directions, above, below, or at the sides; the most frequent are met with at the sides, the most infrequent above or in the upper portion of the gland.

Incomplete perforations consist either in a simple abrasion, or a furrow formed on the surface of the gland, or, in a hollow canal made in the thickness of its tissue. Complete perforations pass entirely through the tissue of the organ in any of its diameters, causing the urethra to communicate with the rectum, with the cellular tissue of the pelvis, or, with the interior of the bladder, by a second collateral canal, the length of which is susceptible of many variations. Multiple perforations or false passages are frequently presented, and are quite common among old men who are in the habit of introducing the catheter into their urethræ themselves. Complicated perforations are those in which the urethra is made to communicate with the rectum or with the bladder; but, in the last instance, by a different opening from that which naturally leads to the neck of the bladder. These various forms may occur separately, or two or more of them may be found existing at the same time in the same person. Sometimes small calculi or gravel engage

in the prostatic portion of the urethra, producing a distension of the mucous membrane at that part, and terminating by hollowing out an excavation into the substance of the gland, producing symptoms that may require prompt remedial treatment.

The *symptoms*, of false passages in the prostate are not well marked; indeed it is almost impossible to detect them except by an exploration of the prostatic portion of the urethra, and even then we may not always be successful. The hemorrhage, pain, and sense of laceration, which are more commonly present, are valueless as diagnostics. When a false passage exists in the prostate, and the perforation is not complete, either on the side of the rectum, or on that of the surrounding cellular tissue, if we pass a catheter or bougie, it will almost invariably engage in this artificial orifice, and will not reach the bladder; we feel an obstacle to its further advance. This is all we have upon which to base our diagnosis; because, the hemorrhage which accompanies the withdrawal of the bougie may be due to several other causes,—and even the obstacle that we have detected may itself be a bridle, a fold of membrane, a tumor, etc., instead of a false passage. However, if the engaged extremity of the instrument can not be turned from right to left, and if the resistance to its farther advance be great, we will be justified in diagnosing a false passage; and more especially if, immediately previous to meeting with the obstacle, the bougie suddenly slipped from its position, with an accompanying rough or grating sensation, and the stem of the instrument assumes a direction not coincident with that of the canal. Again, if the false route is found to be at a greater distance from the meatus urinarius than five and a half inches, and if a finger introduced into the rectum feels that the bougie is separated from the walls of this intestine by merely a slight thickness of tissue, these are still additional indications of a false passage.

Incomplete perforation is less serious, all things being equal, than complete, because the tissue of the prostate is less susceptible of inflammation, and is not readily infiltrated with urine. An incomplete false passage may be eventually obliterated; or it may remain as a diverticulum, which, if it be large, will necessarily receive some of the urine, and thus favor the development of prostatic calculi.—Among complete perforations, those which reach into the bladder have been considered the least serious; from which fact, forced catheterism or puncture of the bladder through the prostate, has, in certain difficulties, been recommended and successfully performed by several eminent surgeons.—As to the perforations which communicate with the bladder through the cellular tissue surrounding this organ, they are almost invariably followed by infiltration of

urine. The greater part of the wounds made in the prostate gland by incision, or by tearing it, no matter what instruments occasion them, are cured with much facility. We have the proof of this in the various operations of lithotomy performed by the perineal section, as well as in the results produced by catheters and bougies unskillfully introduced, and by the hazardous employment of some of the instruments used in lithotrity. These facts are so numerous and so conclusive that we can not doubt the power of the resources which nature displays in like cases. Nevertheless, there are some exceptions, and it is by no means rare to see wounds of the prostate degenerate into abscesses and ulcers, terminating in the total destruction of this gland, and even in death. We can readily comprehend the irritating and injurious effects arising from the flow of urine over these wounded parts.

No special medication is required when wounds and perforations do not open into the urethra. If they open into the rectum, the bowels must be kept free to prevent the accumulation of fecal matter. Prostatic fistula has not been observed as a consequence of these lesions.—When the wounds communicate with the urinary passages, catheterism must be frequently repeated, and means be adopted to protect the wound from the contact of urine; when the wound opens at the same time into the urethra and the bladder, the same course may be pursued.

If the wound be purely urethral or vesical, there will be no necessity for the employment of the catheter; it will be better to regulate the diet and regimen of the patient, and administer emollients and other agents to keep down inflammation.

CHRONIC INFLAMMATION OF THE PROSTATE.*

Chronic Prostatitis has been entirely ignored by many medical writers, and more, probably, from the fact that attention is not

* Although not included in the plan of the present work, it has been deemed advisable to make some reference to the *Acute form of Prostatitis*, the anatomical characters of which have not been sufficiently based on observation. Acute inflammation of the prostate is an affection of adult age, and is more commonly the result of gonorrhea. Thus, an inflammation of the mucous membrane of the urethra may extend along the whole canal, and affect not only the prostate, but even pass beyond to the bladder, ureters, and kidneys, according to the same law which admits, for instance, of the extension of an inflammation of the nasal mucous membrane to the throat, bronchi, and even to the lungs; the inflammation progressing from without inward, and not from within outward.

If a person having gonorrhea, is suddenly taken with frequent desire for urinating, accompanied with sensations of weight and pain about the perineum and

generally called to it, until it has resulted in some one of the forms of prostatic disease in advanced life, than from any other cause; and

anus, and perhaps succeeded by a retention of urine, these are undoubted indications that the urethral inflammation has reached the prostate; at this period there may also be inflammation of the testicle, due to an extension of the urethral inflammation to and beyond the prostatic region, and not to a metastasis.

Among the other causes that may give rise to acute prostatitis, are, unskillful attempts to pass a bougie or catheter into the bladder; the operation of lithotripsy to remove calculi from the neck of the bladder; the injection of irritating fluids; cauterization; inflammation of the bladder; sitting upon cold and damp places, especially when the body is heated; and any mechanical violence done to the parts.

Other causes have been named by writers, which, although they may occasionally induce the acute form, are, however, more apt to give rise to the chronic form of prostatitis, as, the improper use of cubebs, copaiba, oil of turpentine, cantharides, alcoholic drinks, excessive masturbation, excessive sexual intercourse, and urethral stricture. Riding on horseback, obstinate constipation, drastic purgatives, falls or blows upon the perineum, piles, irritation of the rectum, and sedentary habits, have likewise been named by writers as causes of prostatitis, but it is very doubtful whether any of these have ever occasioned it in the acute form, and very seldom even in the chronic form unless there were already existing a tendency to this affection.

Acute inflammation of the prostate may be limited to the mucous membrane of this gland; it may be seated in the prostatic ducts; or the whole organ may be affected.

The *symptoms* of acute inflammation of the prostate, when the mucous membrane only is attacked, are, frequent desire to urinate with some pain in micturition, and a sense of weight and fullness about the perineum, eventually followed by a muco-purulent discharge from the urethra.

When the body of the organ is affected, symptoms similar to the above are present at the commencement, but they soon become more intense, and an examination per rectum will detect a certain degree of sensibility in the gland. The sense of weight and fullness extends to the anus; the pain, at first dull, becomes more severe, lancinating, and throbbing, and is accompanied with a sensation of heat; fever establishes itself, and all the symptoms of a general reaction rapidly manifest themselves. Motion of the limbs or of the body, or a sitting posture, is more or less painful. An evacuation of the bowels is productive of so much suffering, that the patient will retain his stools as long as possible in order not to increase his distress. The voiding of urine is yet more painful; the desire to urinate increases rapidly and becomes more permanent, until a true vesical tenesmus is established. The urine passes in a small stream, then drop by drop, with much straining on the part of the patient, and as it is voided it causes so much heat, burning, and pain at the neck of the bladder as frequently to compel the sufferer to cry out aloud. It is not uncommon to observe a retention of urine complete the symptoms.

In connection with these symptoms, there will frequently be more or less pain in the back, loins, and thighs, also in the glans penis; a constant desire to stool; the body will be flexed forward, as is usual in acute attacks of any of the abdominal viscera; the urine will be high-colored, and, on standing, deposit a sediment in which pus, or a muco-purulent matter may be seen under the microscope.—

yet it is well known that a violent attack of gonorrhea, affecting this gland, may terminate in a gleet which will continue uncured

If an attempt be made to pass a finger into the rectum, it will cause the patient much pain; but when introduced, the prostate will be felt hot, swollen, and very painful upon pressure. If a catheter be passed into the urethra, it will give rise to severe pain when it reaches the prostatic portion, which it will traverse with more or less difficulty, or, perhaps, it will be completely arrested at this point.

Acute prostatitis is rapid in its progress, generally passing through all its stages in from eight to ten days. In its mildest form it may terminate by resolution or by a plastic exudation often passing without being observed by either the patient or physician.—When the inflammation has attacked the prostatic ducts it generally progresses less rapidly, and more commonly terminates by induration. It may pass into a chronic form of the disease. Engorgement or hypertrophy of the prostate is more ordinarily the result of this variety of prostatic inflammation.—When the prostatitis is phlegmonous, suppuration is almost inevitable; and it may even prove fatal.

Whatever may be the form and the degree of the inflammation, it may terminate either by resolution, by induration, by ulceration, gangrene, or suppuration, or, it may pass into a chronic state.—If there be a subsidence of the symptoms, the desire for urinating becoming less frequent, and the pain gradually disappearing, with a more natural flow and appearance of the urine, the attack is terminating by resolution.

If the symptoms obstinately continue, the gland remaining swollen and painful upon pressure, for an unusual length of time, it is terminating by induration.—The termination by ulceration is very rare, and the symptoms indicating it will be explained under the head of Ulceration of the Prostate.—The termination by gangrene is occasionally observed, and is apt to be the result of constriction or a kind of strangulation produced by the presence of calculi in the tissue of the prostate itself, or by tumors.

When the case is complicated with symptoms of peritonitis, with tympanitic abdomen, nausea, vomiting, frequent ejaculations, with purulent, or bloody semen, or both, very small and quick pulse, very violent pains, and shrunk countenance, it is very probable that the disease has terminated by abscess which will prove fatal.

In forming our *diagnosis* of this disease, we must bear in mind that it may be confounded with acute inflammation of the bladder, and with stone in the bladder. If the inflammation affects the *neck of the bladder*, there will be frequent desire to urinate, with pain in passing the urine, but never to that degree common to prostatitis. Besides, an examination per rectum will fail to detect a swollen and painful condition of the prostate, when the bladder only is inflamed.

In *stone in the bladder*, we may have dysuria, the same as in prostatitis; but, by changing the position of the patient, resting him upon his knees and elbows, so as to place the calculus against the anterior face of the bladder, and thus free the vesical orifice of the urethra, he will pass urine very readily; in the prostatic inflammation, change of posture does not overcome the difficulty of urinating. In fact, a position such as the above, would be very apt, in prostatitis, to check the urinary flow completely, on account of the compression of the prostate and the neck of the bladder occasioned by the contraction of the diaphragm and abdominal muscles.

The *morbidity* of simple uncomplicated acute prostatitis in its first stages

until the chronic inflammation succeeding the acute prostatitis, and which keeps up the gleet, has been overcome.

has rarely, if ever, been observed. Post-mortem examinations are rarely had until at a greater or less period from the subsidence of the active symptoms. The gland is usually found firm and considerably swoln; the mucous membrane is of a deeper tint than in the normal state, as well as the tissue underneath it. The mucous membrane will sometimes not only be redder than usual, but thicker and soft like velvet; or it may be found ulcerated, or attacked with gangrene, but these conditions are present only when the inflammation has been violent, obstinate, and of considerable duration. The blood-vessels running along the external part of the organ contain dark-colored blood. Upon pressure, after having made an incision, the gland discharges a muddy, reddish mixture of blood, serum, effused lymph, prostatic fluid, and a small amount of pus. If the inflammation has reached a more advanced stage, the pus, which is of a sticky, viscid character, will be present in greater quantity; and, at a still later period of the disease, small abscesses will be discovered in various parts of the prostate, with more or less grumous blood. Softened or even gangrenous portions of the organ may also be present; conditions, which will be referred to hereafter.

In the *treatment* of acute prostatitis, if the attack be very violent, resisting the baths, narcotic cataplasms, Gelseminum, etc., it may become necessary to apply leeches around the perineum and anus, varying in number from twelve to twenty according to the constitution, the age of the patient, and the intensity of the inflammation. These may be succeeded by a hot hip bath, which should be used in all cases whether leeches be applied or not, and which may be repeated as often as required during the treatment of the disease; the bath being at a temperature of from 98° to 105° F., and the patient remaining in it for a period not to exceed six minutes at a time, the design being to relax the cutaneous vessels, without determining a flow of blood to the parts and subsequent persistent congestion. In many cases, the Spirit Vapor Bath, will have a very beneficial influence, in consequence of the general diaphoresis it occasions, and the more equal circulation established in the blood-vessels.

After the bath, warm fomentations or cataplasms should be applied upon the perineum, and kept there during the intervals between the bathings, frequently renewing them; these may be composed of Stramonium, Belladonna, Hyoscyamus, Lobelia, Hops, etc. The fresh leaves of Stramonium pounded to a pulpy consistence, and then moistened with hot water, should be preferred whenever they can be procured.—(Hypodermic injections of Muriate of Morphia, in solution, into the tissues around the perincum, will sometimes prove valuable.)

The bowels should be evacuated at as early a stage as possible by emollient injections, repeating them occasionally whenever required, if the sufferings of the patient be not so great as to prohibit the repetition. Small injections, however, of anodyne solutions, not to exceed an ounce in quantity will be found very serviceable in arresting the more violent symptoms; a mixture of from two to four grains of Alcoholic Extract of Belladonna in half a fluidounce, each, of Water and Glycerin, forms a very efficacious injection, and which may be repeated according to indications every six or eight hours. In order to be more effective these anodyne injections should be retained within the rectum as long as possible; they will also aid in relieving the painful rectal tenesmus, when this is present. Anodyne suppositories will also effect a similar beneficial result.

As to internal medication mucilaginous drinks, to which some tincture of

The structure of the prostate is such, that if it be attacked by inflammation, this will not manifest a very prompt tendency to

Opium, of Belladonna, of Aconite, or, of Veratrum, etc., is added, have been recommended, and also employed with advantageous results. I have obtained most decided and prompt benefit from the internal use of the Tincture of Gelseminum, given in doses of from twenty to sixty drops, repeated every hour or two, until the specific effects of the medicine were produced, and then maintaining this condition for several hours. Indeed, as the prostate is more of a muscular than a glandular organ, this effect of the Gelseminum might have been anticipated, as it appears to exert its power upon the muscular system more especially. In very violent cases, a few drops of the Tincture of Aconite may be added to each dose of the Gelseminum. The diet must be of a mild, mucilaginous character, avoiding all food and drinks of a stimulating character, or which will produce an irritating urine.

After the severe symptoms have abated, it will still be necessary to continue treatment, in order to guard against induration, enlargement, or chronic inflammation; and this treatment may be required for a period of six or eight weeks. The patient should continue the use of mucilaginous drinks, the occasional employment of rectal anodyne injections, and the use of the Spirit Vapor Bath, weekly; the bowels and bladder should not be allowed to remain distended with their contents, though it will frequently be found as difficult to pass a catheter into the bladder, for a shorter or longer time immediately after the active symptoms have abated, as while during their presence,—too much care and circumspection can not be taken in the introduction of this instrument, which may give rise to serious results in the hands of a rash or unskillful practitioner; the diet should be light and nourishing; active exercise, as well as sexual intercourse, should be positively prohibited; and every means be used to strengthen the general system, and to reduce the prostate to its normal volume, as it is exceedingly apt to continue enlarged for some time after having been attacked by inflammation.

In phlegmonous prostatitis, where pus is formed in the prostatic tissue, it may be recognized by the finger when introduced into the rectum; the fluctuation is so manifest that it can not be mistaken. I have witnessed cases where, from the favorable pointing of the abscess, an operation with the knife, through the rectum, had been decided upon; but, the physicians having been persuaded to postpone the operation, and make use of very thick emollient injections into the rectum, the abscess speedily ruptured spontaneously, the pus was discharged through the anus, the previous difficulty of urinating ceased at once, and the patients were soon cured.

Several cases of similar collections that opened spontaneously into the urethra or into the rectum, have been related by authors; but these abscesses have no relation with those that are developed at the perineum, or in the parts which are near the canal of the urethra and the anus. These last require to be promptly opened, without waiting for the fluctuation, and the incision brings away only a sanious and bloody matter. Experience has shown that these collections, at first circumscribed, manifest themselves under the form of a renitent tumor and without severe pains, and that, if we do not open them at an early period, the inflammation may suddenly become greatly extended, progress very rapidly, giving rise to serious symptoms, among others a communication of the abscess with the urethra, bladder, or rectum, and the evil is then beyond the resources of art.

resolution, but will continue for an indefinite period. And it is often the case that the treatment of the acute disease is too soon abandoned, and the hyperemia not having been sufficiently combated, there remains in the gland a constant cause which keeps up a low grade of inflammatory action. Again, an acute inflammation just on the point of disappearing, may be considerably augmented with a tendency to a morbid persistence, by the patient fatiguing himself, performing coitus, or committing some excess at the table.

This termination of acute prostatitis occurs more readily with lymphatic persons, and those who are subjects of rheumatism and scrofula. Sometimes, especially among feeble persons, suppuration will advance rapidly, notwithstanding the active employment of antiphlogistic measures; the inflammatory congestion is soon dissipated, but the little purulent collections provoke and keep up around them, for a long time, an inflammatory or irritant action that will remain until the pus has disappeared by absorption, or by evacuation.—Chronic prostatitis may be primary as well as consecutive, and in either case will present similar symptoms and pathological characters, requiring similar treatment.

One of the most common *causes* of chronic prostatitis is gonorrhea; but it may also be occasioned by exposure of the adjacent parts to cold and damp; by excessive venery; excessive masturbation; stone in the bladder or prostate; long-standing urethral strictures; inflammation of the neck of the bladder; and by the imprudent or unskillful introduction of instruments through the prostatic passage.

Although certain tumefactions may owe their development to a previous inflammation of the prostate, the same as may be recognized for the origin of certain forms of atrophy, yet neither this hypertrophy, nor this atrophy, constitute chronic prostatitis. The hypertrophy and the atrophy are due to an increase or decrease of the healthy constituents of the prostate, the enlargement, rarely if ever, attracting attention previous to the fiftieth or sixtieth year; while the enlargement from inflammatory action is owing to the presence of lymph, pus, and other morbid products which have been effused into the structure of the gland, and which condition is more commonly met with between the ages of twenty and forty-five.

The first noticeable *symptom* of chronic prostatitis, whether this be primary or consecutive, is, a more frequent desire to urinate, and with less ability to resist the calls than previously; the urine, at first, will pass naturally as to color, stream, and character, but will

be expelled with less force; as the disease advances there will be a slight burning or pain at the commencement, or at the end of urination, more generally the latter, but this symptom is not always present. A sense of weight will be experienced in the perineum and at the anus, and sometimes transient or persistent dull pains; an itching or tickling sensation in some part of the urethral canal, generally in the glans penis, is frequently complained of. Not unfrequently there will be heat in the parts, sudden twitching pains, dull pains in the loins and thighs, and a sense of fatigue after coition. There may also be an almost imperceptible oozing of a transparent, viscous substance from the urethra, which imparts slight stains to the linen in contact with it; a drop of this fluid is generally more apparent in the morning; or, it may merely glue together, as it were, the lips of the external orifice of the meatus urinarius. This, however, may be produced by other causes.

If the prostatic ducts are involved in the chronic inflammation, there will, from time to time, be discharges of the prostatic liquor either spontaneously, or while straining at stool, or after urinating; these discharges have frequently been mistaken for spermatorrhea, but may be determined by an examination under the microscope. Spermatorrhea, or an abnormal discharge of semen, may be known by the numerous spermatozoons or moving filaments observed in it; while the fluid of prostatorrhea or prostatic catarrh, presents a homogeneous liquid of mucous consistence, with numerous granules of a fatty aspect, having brilliant, yellowish centers, with dark outlines, to which it partly owes its whitish color. Beside, more or less numerous grayish molecular granules will be observed; prismatic or pyramidal epithelial cellules, more or less regular, but not very numerous, and some of which will contain vibratile cilia. These cellules sometimes inclose fatty granules around their nucleus; and, with some patients, reddish granules presenting all the characters of hæmatin. In the latter instance, some of these reddish-like granules will be seen floating in the liquid.

If the ejaculatory ducts are involved, there may be nocturnal emissions, loss of sexual desire, or of sexual power, and too premature a discharge of semen on attempting coitus, with more or less impairment of the general health; these symptoms are more common to masturbators and persons who have committed sexual excesses; but, it must be recollected, that they may also be due to disease of the cerebellum and spinal marrow, especially when these exist as complications with the prostatic disease.

More commonly chronic prostatitis remains stationary, or at all events, the patient experiences no very acute sufferings. The urinary and genital functions continue to be performed sufficiently well, so that sometimes, much to his detriment, he forgets or overlooks his disease. Patients laboring under this malady should always be notified that they are constantly liable to serious symptoms, especially when they commit any imprudence or excess that may arouse the apparently torpid inflammation into a more or less acute affection of the organ, with prostatic irritation, retention of urine, suppuration, abscess, and, sometimes, death.

The *morbil anatomy* of chronic prostatitis, has not received the same degree of attention as that of other parts. Prostates which have been for a long time the seat of chronic irritation, are usually augmented in size, occasionally diminished, and often form adhesions with some of the surrounding tissues by means of a denser substance than is customary. The mucous membrane is pale, ash-colored, or, somewhat livid, thickened, and spongy; sometimes, it will be observed much thinner than natural and more vascular; again, it may present a rough, opaque appearance at certain points, from deposits of lymph more or less organized.

The prostatic ducts will be found thicker, more voluminous, and of a firmer tissue than in the normal state, generally having their orifices dilated, and their cavities filled with an opaline, lactescent fluid, thick, but not mucus, rather purulent, and which may be traced within the bladder, where it has emptied itself by a retrograde movement; sometimes pus will be found in the sinus peculiaris. The cellular tissue of the diseased gland will vary, sometimes being of greater density and cohesiveness than natural; at others, being found less firm, and having more of a spongy consistence, and, when cut into, the incised surfaces present a dark appearance, and, when the parts are strongly squeezed, yield considerable quantity of a dark fluid. One or more abscesses may also be present either in the diseased gland, or in some of the adjacent tissues.

As to the *treatment*, much will depend upon the degree of the inflammation, and the peculiar tendencies of the system. In recent cases, and especially when consecutive upon the acute form, the continuation of local and general measures to allay the inflammation, followed by emollients, a proper attention to diet, and an avoidance of all excesses, will be sufficient. And, in all instances, should there be great difficulty in urinating, the catheter should be employed as often as may be required. If, after a sufficient use of these means, the prostate still continues enlarged, it will be

proper to administer agents that will promote absorption of the effused matters, as Iodide of Potassium, Iodide of Ammonium, Bromide of Potassium, etc., together with the means named below.

When the disease is primary, it will very rarely be presented to our notice, until it has been in existence for several years; in such cases, our treatment must be more active, and every means must be employed to reduce the enlargement, and restore the gland to its natural size. For this purpose, in addition to the internal use of the iodides and bromides above named, they must also be employed locally, bringing them in contact with the gland both by the urethra and by the prostatic portion of the rectal walls, either in the form of fluid injections, suppositories, or ointments. Thus, as a fluid preparation, the following may be used: Take of Iodide of Potassium two grains, Extract of Belladonna five grains, Glycerin half a fluidounce; triturate thoroughly and strain. As an ointment, the same quantities may be used, substituting Simple Cerate for the Glycerin. These preparations are to be applied by means of instruments especially prepared for the purpose. We must not confine ourselves simply to these formulæ, but, if necessary, avail ourselves of the action of Bromide of Potassium, Iodide of Ammonium, Hydrochlorate of Ammonia, Chloride of Zinc, Stramonium, Conium, etc.; and, in many cases, the addition of Strychnia, or of Sulphate of Quinia to the mixture, will be followed by the most favorable results.

Suppositories composed of from two to five grains of the Iodide, or Bromide of Potassium to eight or twelve grains of Simple Cerate, and introduced into the rectum every night, have been highly recommended. Other suppositories have also been found useful, as Butter of Cacao six parts, Spermaceti one part, Powdered Opium one part; mix. Or, instead of the Opium, one part of Extract of Belladonna may be added; or, Sulphate of Morphia one-half to two-thirds of a part, with six parts of Extract of Conium; or, Opium two parts, with Extract of Conium six parts, etc. Each suppository must weigh about eight or nine grains. From the formulæ given, the practitioner can form an idea of the character of the remedies to be used, as well as of their general method of preparation; they will often require to be changed, as there is no specific remedy for this malady.

Cool or tepid sitz baths taken at least once a day, for ten or fifteen minutes each time, are also useful as a local measure. Anodyne plasters to the perineum frequently answer an admirable purpose, especially in recent or mild cases; while again, other cases, which are very obstinate or of long standing, will require counter-

irritation, as the constant or intermittent use of the Croton Oil Liniment, or of the Compound Tar Plaster, upon the perineum. The bowels should be kept regular but without active purgation; retention of urine should be overcome as soon as possible by the catheter; the whole surface of the body should be frequently bathed, and once in every week or two a Spirit Vapor Bath should be administered. The digestive powers should be sustained by tonics; the diet should be light, unirritating, and nutritious; coition and exercise should be avoided, as well as horseback riding, or too long sitting at a time. The character of the urine as to alkalinity, excessive acidity, etc., must be watched, and means be taken to keep it in as normal a condition as possible.

If the patient be scrofulous, suitable remedies may be conjoined with the others; if rheumatic, preparations of Cimicifuga, Caulophyllum, Senecio, Alettris, Iris, Chloride of Propylamin, etc., will be indicated, in conjunction with the other means; if feeble and anemic, preparations of Iron, as the Tincture of the Sesquichloride, Hypophosphites, etc. It may be proper to remark here, that in obstinate and long-standing cases, I have advantageously employed currents of electro-magnetism, and of galvanism, passing them through the gland by means of instruments expressly made for the purpose, one of which is to be introduced within the urethra, the other into the rectum. These currents should never be strong, but always of moderate power.

Cauterization has been recommended by Lallemand and other writers, and may have proven beneficial; I used it in my earlier practice, but with little or no success, frequently increasing the difficulty; of late years I have dispensed with it altogether in this disease.

When the chronic prostatitis is due to strictures of the urethra, calculus in the bladder or prostate, or to other diseases of proximate organs, the cure of these maladies will most commonly be followed by a disappearance of the prostatic inflammation. (*See Gleet, Stricture, Spermatorrhea, and Retention of Urine.*)

TUBERCLE OF THE PROSTATE.

Tubercle of the Prostate may occur under three conditions, viz.: 1st, in connection with general tubercular disease, as manifested by tubercles in the lungs, mesentery, etc.; 2d, in connection with tubercle of some of the urinary or reproductive organs, as the kidneys, ureters, or testicles, etc., and of which it may be either the starting point or the termination; and 3dly, it may exist

when all the other organs of the system do not show the least vestige of the disease. Some writers have divided these tubercles into *simple* or *benign*, and *malignant*.

As in tubercle of the lungs, that of the prostate may be met with in the state of erudity, softening, and of liquefaction, following, consequently, the same evolution as when in the other organs. The glandular tissue of the prostate is the first invaded by tubercle, and it is not until at a later period that the fibrous, museular, and other tissues become involved in the degeneration.

At the commencement of the disease the tubereular formations appear to be more frequently met with on the urethral surface of the prostate; and instances are on record where this surface had undergone material alteration from softened tuberele, while the rectal surface presented no alterations at all appreciable to the touch. Yet, notwithstanding, it is by no means uncommon for the tubercle to commence in the center of the gland. Again, the two lobes of the gland are almost always attacked simultaneously, or, if one lobe is first invaded, the other very soon afterward becomes so likewise.

The *symptoms* which are common to tubercle of the prostate, as, frequent desire to urinate with pain in micturition, dysuria, sometimes retention of urine, blood in the urine, pus in the urine, pains in the back, loins, and pelvic region generally, debility, emaciation, etc., are of themselves of but little value in the diagnosis, as they may be due to calculus, or other genito-urinary malady; yet, if in connection with them, tubercles are suspected or discovered in the lungs, then they may prove of some assistance in determining the condition of the prostate. And if hemorrhage manifests itself during the intervals between urination, or is mixed with the semen in greater or less quantity, we will have strong grounds for believing that the flow of blood is due to prostatic tuberculosis.

The most important symptoms for *diagnosis* are the anatomical; catheterism may detect a slight swelling at the neck of the bladder, but this sign is not of much value, as a prostate affected with tubercles is not increased in size, or, at least, if there is any increase, it is inconsiderable. The examination per rectum affords the greatest aid in forming a diagnosis, for by it we can palpate the prostate and recognize its volume and consistence. When the finger is carried within the rectum, no very manifest augmentation of the size of the gland will be discovered; but if pressure be made with the extremity of the finger upon the rectal surface of the prostate, we will feel either a hard nucleus in the center of the gland, or softened points by the sides of others which are harder

and deeper, forming so many purulent centers. To be more certain, the examination should not be limited to the inferior part of the gland; the hand should be strongly pressed upon the perineum so that the end of the finger may be enabled to reach the base of the organ, at which point tubercle often begins. An incomplete examination might lead us to diagnose an inflammation of the neck of the bladder, or a neuralgia. It will also be proper to observe whether one or both testicles is swollen, indurated, with little knots or protuberances disseminated along the deferent canal or the epididymis, and if, with these, the patient complains of pain of the bladder, tenesmus, etc., we have certain indications of an invasion of the prostate.

Everybody knows the almost invariable fatal termination of tubercle of the lungs; that of the prostate progresses in a similar manner. Once seated in the prostate, tubercle undergoes its transformations, destroys the organ and ends by sooner or later effecting disastrous results. If tubercles co-exist in the lungs, those in the prostate may not run through all their phases. If the fatal termination is prolonged, the tuberculous centers soften, furnish a supuration which discharges itself outwardly, and develops a new series of phenomena which will be studied hereafter; in this case, the prognosis is doubly serious, because of the constitution which is constantly forming or feeding the tubercle, as well as because of the local condition of the organ, which may of itself cause death by some great derangement in micturition.

If the tubercle becomes cretaceous, as it may, when the lungs are healthy, the progress of the disease will be less rapid and not so serious in its character.

Post-mortem examinations have found tubercle in the prostate, in the seminal vesicles, and in the testicles. The vas deferens and seminal vesicles, are often thick, hard, and crackle under the scalpel, and present ulcerations and tuberculous cavities upon their walls, while their canal is obstructed by tuberculous matter. Sometimes the walls of the bladder will be hypertrophied, especially in the prostatic region, the mucous membrane more particularly. Parts of the prostate and adjacent organs may likewise be completely destroyed from tuberculous ulceration, forming cavities of various sizes. Sometimes, the urethra will also be found involved in the disease.

The prostate will be found studded with more or less numerous tubercles in a miliary state or in more voluminous masses, the smaller ones resembling small, yellowish points, the others being rounded and of a cheesy consistence; at a more advanced stage,

these tubercles soften in the center, and ultimately pus is discharged from them, with more or less destruction of the tissues immediately surrounding them.

If a minute examination be instituted, it will be found that the fibres of the cellular tissue, and the muscular fibres of organic life which accompany them, can not be so readily separated as in the normal state; they break much more easily. There appears to be an amorphous matter interposed between these elements, which obstructs the examination and renders their outlines less distinct. But the presence of numerous fine granulations, will be very manifest; some of which will be grayish and soluble in acetic acid; the others, yellowish, insoluble, and distributed throughout the substance of the gland.

The tuberculous matter escaping from the prostate is of a yellowish white color, rather whiter and less yellow than softened tubercle, and, unlike this, is viscid. Placed in water, some of it will mix with the fluid, the other portion will remain intact. Under the microscope, that portion taken up by the water is found to consist of an amorphous, very granulous matter, the granules being very fine and of uniform size. The other consists of large corpuscles, from .0024 to .0042 of a line in diameter, somewhat polyhedric, with irregular outline, and very fine granules distributed throughout, but no nucleolus. These corpuscles become paler and clearer by acetic acid, without being dissolved, and more distinctly present a nucleus or nucleolus.

The *treatment* of tubercle of the prostate, like that of tubercular consumption, can only be palliative. The various means recommended for tubercles in other parts may be employed in this affection, as preparations of Iodine, Iron, strengthening tonic regimen, Iodine baths, sea-bathing, nutritious but properly selected diet, exercise, residing in the country, etc.; certain preparations may also be made to act upon the gland through the rectal walls, as Iodide of Ammonium, Iodide of Potassium, etc., with a view of at least postponing the fatal period, for, a cure may be considered as almost, if not entirely, impossible. Every means should be used that will strengthen and invigorate the system; avoiding coition, and the introduction of instruments, of whatever character, into the urethra. Pains should be combated with anodynes and sedatives; nervous irritability by nervines and antispasmodics; weakness by tonics and nourishment; and so on, as the various symptoms develop themselves combating them by the appropriate remedies. Very fortunately, tubercle of the prostate is an extremely rare disorder.

ULCERATIONS OF THE PROSTATE.*

Ulceration of the prostate may occur upon the rectal or perineal surface of the gland, or, upon its urethral surface. In the first instance, the ulceration is generally the result of some disease in the surrounding tissues, which has extended to the prostate, the ulceration of which gland is an epiphenomenon of some other disease. Indeed the prostate does not appear to be susceptible of primitive ulceration.

Ulcerations of the urethral surface of the organ, may be of greater or less depth, and may be situated either upon the right or left side, near the membranous portion of the urethra, or near the bladder; sometimes, even upon the apex of the trigone; but more frequently, in the small anfractuositities bordering upon the verumontanum, and on the verumontanum itself. These ulcerations may be of a simple character, or they may be sinuous, aphthous, varicose, tuberculous, or cancerous.

Prostatic ulcerations may be the result of a surgical operation upon the gland; for though in the majority of cases, these wounds may be cured, it sometimes happens that no such happy result follows, and then ulceration establishes itself. This has been verified by autopsy. Some authorities believe that these ulcers terminate by destroying the gland, and reducing it to a fibrous shell. To this *cause* may be added another, no less real and much more frequent, that is, excoriations produced by catheterism. Perhaps, it would be proper to state, that these causes are much more likely to give rise to ulceration when there is a predisposition to it, as in tuberculous subjects.

Ulceration of the prostate has also been occasioned by irregularly and angularly formed calculi, or fragments of calculi, becoming lodged in the prostatic part of the urethra, distending the lining membrane, and cutting their way through it into the body of the gland. It may also result from an urethral stricture of long standing; from retention of urine; from bougies or catheters being too long retained in the urethra; and is rarely met with among feeble subjects somewhat advanced in years, who have suffered for a long time from disease in the bladder, paralysis, etc.

* Simple, uncomplicated ulceration of the prostate, is a disease very rarely observed; and, as the ulceration is almost invariably consecutive, many authors do not consider it at all, except as part of the primary disease. However, it has been deemed best to refer to it in this place under a separate head, in order that a few remarks may be made, which are not so fully applicable to the original affections more generally causing it.

This affection is very difficult to recognize, the *symptoms* not being very positive, but such as are common to other diseases of the neck of the bladder and prostate. We may suspect ulceration, when, upon introducing a catheter or bougie into the urethra, it gives rise to a sharp, acute pain upon coming in contact with the ulcerated part, and the point of it contains a few drops of blood when withdrawn; when there is a sensation of heat and throbbings felt upon a very limited point at the root of the urethra; but the same symptoms may be present with other disease of the parts where there is no ulceration present.

If, however, to the above symptoms, be added, a more frequent desire to urinate than natural, with a painful acute burning sensation in the prostatic region upon the accumulation of urine, or at the moment when the first drops commence flowing from the bladder, which sensation slightly diminishes as the flow continues, only to become more acute immediately after, we may hardly hesitate to diagnose ulceration, especially if there is nothing to indicate a tumor or stricture at the neck of the bladder, a fungus or other abnormal production. Indeed, even then, the conclusion would only be half erroneous, for the appearance of the blood, the pain from contact with the sound, and the burning during micturition, also indicate that some point of a tumor, etc., is denuded and in a state of ulceration. Another somewhat reliable symptom of prostatic ulceration, is a more or less profuse discharge of a muco-purulent character, and which must not be confounded with seminal losses.

The progress, duration and termination of prostatic ulceration, and, consequently, its *prognosis*, will necessarily depend upon the nature of the ulcer, its seat, depth and extent. As with ulcerations of other organs, simple superficial excoriations very seldom present a serious aspect, and are readily healed; anfractuous ulcers, which proceed from behind forward, hollowing out the parenchyma of the prostate, are usually of long duration, and render the prognosis more serious. Ulcers which occupy the surface of the gland only are more dangerous, because they continually irritate the orifices of the ejaculatory ducts, giving rise, not only to pains, but to seminal pollutions, which terminate by exhausting the patient.

In the *treatment* of ulceration of the prostate, we must endeavor to ascertain its true character, for, if it should be tuberculous or cancerous, we must then direct our means not specially to the ulcer, but almost entirely to the principal affection.

In simple superficial ulcerations, which alone require any special treatment, it will be necessary to bestow attention upon the general health, fortifying the system by tonics and nutritious diet, if the pa-

tient be feeble, or, by a spare diet, if he be robust and of full habit; the bowels and surface of the body should be kept in a normal condition; exercise of all kinds should be avoided; coition must not be indulged in at all; and all stimulating food or drink be dispensed with. Injections of warm water, or of warm mucilaginous infusions, as of Marsh Mallows, Buckhorn Brake, Comfrey, Barley, etc., to which some narcotic should be added in case there are severe pains, must be used at first. Anodyne injections into the rectum, or suppositories, may also be required to aid in relieving the more severe pains.

Then, a weak solution of Sulphate of Zinc, of Sulphate of Copper, of Chloride of Zinc, of Tannic Acid, or a decoction of *Geranium Maculatum*, Alum Root, Rhatany Root, etc., may be employed in injection.—In some cases of ulceration of the prostate, as well as of other portions of the urethral canal, I have derived marked advantage by administering injections of a solution of Chloride of Gold and Soda, five or ten grains to two fluidounces of Water. In administering the above articles by injection, a metallic or elastic catheter should be introduced into the urethra, at least as far as the bulbous portion, in order that the fluid may reach the ulcerated parts. If the catheter has an opening upon its extreme end, it will be preferable to those in ordinary use.

Powdered Alum brought in contact with the diseased surface will sometimes be beneficial; and, in some cases, a solution of Nitrate of Silver, ten grains to the fluidounce of Water may be injected with advantage; it has also been advised that the ulcerated part be slightly cauterized with the Nitrate; but great care and discretion is necessary in the use of this agent as a caustic; it frequently fails, and, sometimes, even augments the difficulty.

ABSCESS OF THE PROSTATE.

Abscess of the Prostate may be the result of a previous acute inflammation which has passed into the stage of suppuration; or, it may be present where little or no inflammation existed antecedently, being the result of contusions caused by lithotomy instruments; or, it may be due to pyemia; badly-treated, or long-standing urethral strictures. As a general rule, acute prostatitis is more apt to terminate in abscess among feeble, scrofulous, or cacoehymous subjects. Abscess may also take place from long-standing diseases of adjacent organs, as, of the kidneys, ureters, or bladder, likewise from calculus, more especially if it be lodged in the prostatic portion of the bladder.

Whenever an acute prostatitis continues for six or seven days, without any amendment of the symptoms; and whenever throbbing pains are felt in the perineum in front of the anus, the formation of a prostatic abscess is to be feared. Our fears will be increased if the patient experiences a sense of weight, vesical tenesmus, frequent desire to urinate, followed with a burning sensation, and a severe pain with the last contractions of the bladder, together with rectal tenesmus, and frequent calls to stool, as if a fecal mass occupied the rectum. Sometimes the pain will be very violent, with increased difficulty in urinating, or a complete retention, difficult defecation, more or less severe rigors, and, perhaps delirium. All these physiological *symptoms* belong, however, to most of the diseases of the bladder, urethra, and rectum, and are only secondary aids in the diagnosis.

A rectal examination will furnish more satisfactory diagnostic indications.—As the introduction of the finger into the rectum generally causes severe pain, it should be passed slowly and with great gentleness; if suppuration has occurred, and a purulent cavity is formed in the substance of the prostate, the finger will find the gland swollen, and presenting to the touch a soft and elastic sensation: if the pus, instead of forming at one center, or cavity, is infiltrated, this sensation will not be so distinct. Should the abscess be directed toward the urethra or neck of the bladder, instead of toward the rectum, the diagnosis will be more difficult. However, if, at a period when the cessation of the inflammatory symptoms ought to be followed by a more ready flow of urine, we find it retained, or passing with difficulty, we may suspect a prostatic abscess forming upon the urethral portion of the gland. Should this be the case, a catheter introduced into the urethra, instead of meeting with a sensation of resistance at its prostatic part, will transmit a feeling as if it were in contact with a flabby and somewhat yielding body. The careful efforts made by the operator to pass the catheter into the bladder to empty this organ of its contents, will sometimes rupture the purulent abscess, and the flow of pus will remove all uncertainty.

However, when the diagnosis is not very readily made out, it will be better to simultaneously combine the rectal with the urethral examination. Having passed the catheter into the urethra, and the finger into the rectum, the instrument must be gently pressed upon the prostate, which will drive the pus toward the finger, which may then feel the peculiar sensation above named, and which would have escaped notice without this method of exploration.—When a prostatic abscess is about to open in the rectum, the retention of urine or difficulty in passing it, the pains at the neck of the bladder, and the burning sensation during the flow of urine will be by no

means so severe as the rectal tenesmus, the heat, throbbing and tension at the anus. Defecation will be attended with much pain, and any attempts at relief by injections will be accompanied with great suffering; all of which symptoms become suddenly relieved upon the rupture of the abscess.

An abscess in the forming stage, situated between the rectum and bladder, may be mistaken for a prostatic abscess; but the rectal examination will remove all uncertainty by determining the precise seat of the swelling. A prostatic calculus may also be mistaken for an abscess; the differential signs will be referred to when treating upon *Calculi of the Prostate*.

The progress of prostatic abscess may vary very much; in some cases, the pus may be carried back into the system, or be insensibly eliminated, as observed in submucous abscess of the urethral or rectal surfaces, and both patient and physician may be ignorant both of the formation and disappearance of the abscess. In other cases, the pus will be surrounded with a kind of cyst; then the pus will be concrete, taking the form of tubercle, and it becomes a difficult matter to distinguish between a tuberculous prostate, and a prostate with small purulent foci or cavities distributed throughout it. But more commonly the pus forms an external issue for itself either into the bladder, the urethra, the cellular tissue of the perineum and pelvis, or the groin.

The opening of the abscess on the urethral portion of the gland is of more common occurrence, the tissues in that location being more fragile, presenting less resistance, and consequently being more apt to become broken, torn, or ulcerated than at other points. As soon as the pain ceases, the pus is discharged from the urethra, either alone or mixed with the urine; the general symptoms improve, and the patient commonly experiences a prompt relief. But a spontaneous rupture does not always happen; the efforts during urination or defecation, or catheterism for a retention of urine, may also cause an opening of the abscess. Abscesses which form around the verumontanum, may have only a single opening, or, there may be many apertures, like the orifices in a watering pot, and which to a certain extent prevents the penetration of the urine into the purulent cavity.

The least serious cases are those in which the pus is discharged through the excretory ducts of the gland itself, which mostly open in an oblique manner upon the surface of the urethral mucous membrane, and form a kind of little valve at their mouths, which is directed from behind forward, a very favorable disposition to prevent the admission of urine. But, when the opening of the

abscess into the urethra is very large, the patient is constantly exposed to the accidents arising from the urine penetrating and remaining in a purulent center, such as, large cavities and fistulous canals.

The opening of the abscess into the bladder, generally occurs when the purulent center is seated upon the sides, at the upper and posterior part of the prostate.—The matter may be discharged by the rectum, when the case is, at least as favorable, if not more so, than when evacuated by the urethra or elsewhere, because the walls of the abscesses are not exposed to the contact of urine, and an adhesive inflammation will promptly effect cicatrization. In this case, the matter accumulates in the rectum, and may be observed mixed with the feces after stooling. The size and consistence of the feces are such as to prevent them from entering the cavity of the abscess.

Should the abscess open into the cellular tissue and between the aponeuroses of the perineum and pelvis, the case will be a serious one; the pus, instead of escaping from the external surface, constantly infiltrates and burrows in these tissues; developing a new active inflammation around the prostate, and an augmentation of the symptoms, instead of an immediate relief. The suppuration may extend in various directions, forming communications with the scrotum, the ischio-rectal fossæ, and the central portion of the perineum. When the course of the abscess follows that of the vas deferens, it may open in the groin, as has been observed in some rare instances. Should the same abscess form a communication with both the rectum and the urethra, a troublesome urethro-rectal fistula will be the result.

Prostatic abscesses may close up in several ways. In simple cases, the suppuration, at first creamy and laudable, diminishes in quantity, gradually assumes more plastic characters, and becomes exhausted, while the cavity continues to close up and heal. In other cases, the lips of the orifice of the abscess cicatrise, while its walls continue to produce pus; the cavity becoming filled, the recent cicatrix is distended, soon ruptures, and a new evacuation of pus occurs. These phenomena may be reproduced at greater or less intervals, and for a longer or shorter period; each time, however, the quantity of pus is diminished; and the cure eventually takes place. This reparatory process, as feeble as it may be, is sometimes wholly absent, and then the constitution may become debilitated by the continual flow of purulent matter, as is apt to be the case among persons of a tuberculous diathesis. It must not be forgotten that as long as a person is affected with abscess,

he is exposed to serious accidents, as, for instance, from purulent infection.

Pathologists have pointed out the relations which exist between affections of the urinary passages and those of the encephalic centers; thus, a patient is taken with symptoms characteristic of an inflammation of the prostate; at the end of several days, supuration is manifested, and from this moment, delirium supervenes, which is soon succeeded by coma, and the patient dies in a deep state of adynamia.

The *prognosis* of prostatic abscess will vary according to the cause, the seat, and the extent of the purulent collection; it is difficult to form a general law, but we may arrange these abscesses into three classes, viz.: 1. Those which heal very quickly, or which are not accompanied with any very marked disturbance of the functions. 2. Those which present a greater degree of gravity, by reason of the phenomena preceding them, or accompanying them, as those which are complicated with stricture of the urethra, calculi in the bladder or prostate, or with tubercles. Of course, a cure of the abscess can not be expected until after the removal of the complication. 3. Those of inflammatory or tuberculous origin, which transform the prostate into a genuine excavation, terminating seriously.

Upon a *post-mortem* examination, prostatic abscesses will be found to vary in their seat, number, and size. Some, small and numerous, may be found disseminated beneath the mucous membrane of the urethra, scarcely affecting the prostate; these are generally produced during a gonorrheal attack, and may be situated in any portion of the urethra, into which they gradually open, and their contents are expelled with the urine. These abscesses are common, and frequently remain unperceived during life.

Others, may be situated more deeply, and are generally of greater size, but they are also less common. This kind of abscess may be developed in the prostate in a manner analogous to those which form in the uterine tissue; they may occupy the whole prostate, converting it into a purulent reservoir. There then exists a genuine pouch or cavity, which will be referred to hereafter.

Again, some abscesses may be met with occupying but one lobe, or only part of a lobe of the prostate. In this variety, the pus may remain for a long time, even in the tissue of the gland, without giving rise to any phenomena that may cause the physician to suspect its presence during life. And, finally, abscesses may be

discovered all around and in the vicinity of the gland, in the perineum, or in the pelvic cavity.

In the *treatment* of prostatic abscess we should endeavor to procure a discharge of the matter as soon as possible, not permitting the abscess to rupture indeterminately, or in a wrong direction. If the tumor can be felt through the perineum, giving the impression of a hard, fleshy mass, or if it be diagnosed as pointing toward the perineum, it is better not to wait for fluctuation, but to at once enter deeply into the perineum, with an elongated, narrow-pointed bistoury, being careful, however, to cut in the mesial line, and not to injure the bladder or rectum. The index finger of the left hand should be kept within the rectum during the incision, as a sort of guide to the direction of the knife, which should be entered into the raphe of the perineum at about the distance of nine lines from the anus, having its cutting edge looking upward; it should be boldly carried in the direction of the prostate, a little *below* its situation in a healthy condition, that is, if the rectal surface of the gland has been found swollen or increased in bulk. The instrument should be made to penetrate in this direction to the depth of not less than one and a half or two inches, and the incision should be made of sufficient width. Should no matter be discharged, the application of poultices will hasten the suppurative process, and thus the abscess will be prevented from communicating with the rectum or urethra.

Of course, such an operation is not to be attempted unless the physician is thoroughly satisfied that he has correctly diagnosed the case; otherwise, it were better to confine his treatment to the relief of urgent symptoms, until some positive indications are manifested. The advantage of thus opening the perineum is, that the pus escapes directly without involving other important organs, and the healing process may progress more rapidly.

If it be satisfactorily ascertained that the abscess is pointing toward the rectum, or, that the rectum presents the most convenient place for the artificial opening, it may be effected by means of a long, curved trocar. An internal blind fistula of the rectum may be the result, but usually it heals very promptly. The bowels should be kept as quiet as possible for several days after the operation.

If the abscess becomes somewhat prominent on that side of the gland toward the urinary passage, it is an indication that the rupture will occur on the urethral surface; we should endeavor, therefore, to make the artificial opening at this place. A metallic sound with a small curve, and a conical extremity may be employed, or an ordinary silver catheter. The instrument must be carefully intro-

duced within the urethra, until it meets with an obstruction behind the pubis, (the prominent abscess) when moderate efforts should be made to pass it onward to the bladder; frequently, by this means, the instrument will pierce the purulent pouch, and the matter will make its exit through the urethra. If, however, the swelling is not readily pierced, we may, by introducing a finger into the rectum, and pushing or pressing the prostate against the extremity of the catheter, to which we also communicate a slight impulsion, readily effect its rupture. Again, if the suppuration is not complete, and the symptoms present, as, retention of urine, etc., demand immediate interference, the operation may be performed with a lancetted stylet. In all these operations the physician can not exert too much care and prudence.

If the abscess tends to open into the bladder, the catheter may be passed into this organ with but little or no difficulty; it must then be moved about so that its beak will press upon the sides of the trigone or vesical triangle, or upon the root of the urethra; in this way the purulent swelling may be ruptured and the pus be discharged.

When there is an uncertainty in the diagnosis, and when, from a microscopical examination of the urine or feces more or less pus is discovered, leading to a mere suspicion of an abscess already formed and discharging, it is much better to treat the case by attending to the general health of the patient, prescribing such means as are calculated to strengthen and improve it, and omitting all instrumental interference. Indeed, even where we are fully aware of the presence of an abscess of long standing, it will be a much better course to discard the use of instruments, and devote all our appliances to the improvement of the system generally.

Where a calculus is present, it must be removed before we attempt to treat the abscess; and if this be due to the stone, its removal will be followed by a healing of the consecutive abscess.

CAVITIES, AND FISTULAS OF THE PROSTATE.

Cavities and Fistulas of the Prostate may be *caused* by wounds, inflammations, tubercles, and abscesses, and when they exist they develop new symptoms, and require new therapeutical treatment. The following hypothesis has been given, as to how these cavities may be produced: "The aponeurotic planes form a kind of cage or box in which the prostatic tissue is contained. Let us suppose the contents of this box removed, and then what will occur?

Instead of approximating toward each other, as would have taken place if a subcutaneous tumor had been removed, the walls will remain separated, not sinking in upon themselves to fill up the empty space; and from this time we will have the same result as in the ischio-rectal fossa, where the osteo-fibrous walls circumscribe a space filled with cellulo-adipose tissue. An empty space will exist in the aponeurotic cage, which can not be removed; and into which all the fluids and matters passing through the neighboring canals will have a tendency to lodge, constantly giving rise to morbid phenomena by their remaining there."

As to the *symptoms*, fistulas may be seen in the rectum or at the perineum by ocular inspection. The rectal touch will recognize an indurated cavity in the vicinity of the prostate, and upon pressure the finger will feel a purulent fluid passing through the fistulous orifices.

If the cavity opens into the rectum, an indurated point will be felt around its orifice, through which orifice a probe may be passed, and it will enter a cavity in which we may readily turn the instrument in every direction. When the cavities are tuberculous, the fistula may follow the anterior face of the rectum to pass through the fibres of the anal sphincter muscle; and then, on the first examination, we may suppose we have on hand merely a simple fistula in ano, when in reality the case is a much more serious one, having its origin in the prostate. Indeed, Ricord has made the inquiry whether the greater part of anal fistulas met with among consumptives were not due to tuberculosis of the prostate? This view of the matter may be an explanation for the opinion of several surgeons, viz.; that fistulas in ano among tuberculous subjects should not be disturbed by any operations.

Through the fistulous orifices issues a fluid which may present a great many varieties as to its physical and chemical properties, as well as in regard to its quantity. Sometimes it will be tinged with blood, at others it will be very fluid, and again it may be of a cheesy consistence, according as the cavity contains pus, urine, blood, serum, or tubercles.

As to the urine there will be many modifications; if the cavity communicates only with the urethra and this is not wholly destroyed, the urine will readily pass outwardly; but, if this canal have a stricture in its membranous portion, the urine may pass through this obstruction with some difficulty, and will then distend that portion of the urethra behind the stricture; in consequence of which some of the urine will be forced into the cavity, perhaps filling and distending it, and the bladder will be evacuated partly

into the cavity, and partly through the urethra, externally. If the cavity becomes accustomed to the presence of the urine, it will be held therein, from which it will escape drop by drop; the patient will then have a continual flowing of urine, or, as it were, a new kind of incontinence of urine.

If, with the prostatic cavity, there is at the same time, a complete solution of the urethra, and some perineal fistulas, the urine will not pass through its natural channel, but will escape through the fistulous orifices after having distended the cavity, which, in its turn, will allow this fluid to flow out, whenever the patient assumes any position favorable to its escape.—If the cavity communicates with both the rectum and the urethra, a portion of the urine will pass into the rectum, from whence it will be expelled during defecation.

If we are aware that the patient has had a previous violent attack of acute prostatitis resulting in an abscess, and that he is, at the period of examination, evacuating both pus and urine from the rectum, we may be almost certain of the existence of a prostatic cavity; if there is any doubt upon the subject, catheterism will readily solve it. The catheter, being introduced into the urethra, which it enters without any trouble or causing much pain, having arrived at a point beneath the symphysis pubis, will, notwithstanding the efforts of the physician, pass into a kind of cavity too small for the bladder, and too large for the urethra, in which cavity it may be inclined in various directions, and from which it extracts a certain quantity of pus, mixed with a more or less clear urine. If, while the instrument is yet in this cavity, we desire to form a more perfect *diagnosis*, we may introduce a finger into the rectum, when the beak of the catheter will be at once felt through a partition of more or less thickness. Great care must be observed not to confound this cavity with that of the bladder, especially in cases where the catheter is introduced for the relief of a retention of urine.

If the cavity communicates with the bladder alone, the diagnosis will be almost impossible. The physician will then have to base his views upon the antecedent condition of the patient, the rectal examination, and the discovery of pus in the urine, when this is observed under the microscope.

The *prognosis* of a prostatic cavity is always serious; these caverns do not undergo a spontaneous cure, even when recent; beside, they are causes of constant inflammation, or, of an unhealthy suppuration. When the urethra, and even the bladder has undergone considerable disorganization, the prognosis is still more unfavorable, because the patient is inevitably exposed, at a more or less distant

day, to all the consequences of a urinary infiltration, either between the peritoneum and the pelvic fascia, the superior and middle aponeurosis of the perineum, or, even underneath the inferior aponeurosis; and from thence, very formidable infiltrations of the anus and scrotum, which of themselves may cause death. In some instances, where these symptoms do not occur, the cavities develop very obstinate urinary fistulas, which are often beyond the resources of art. If the cavity has a tuberculous, and not an inflammatory origin, the prognosis will be still more unfavorable.

The mode in which these caverns are formed is very simple. An inflammation attacks the prostatic tissue, and terminates by suppuration or gangrene, and from thence to the production of the cavity is but a step. When there is gangrene, the disorganized tissue may be eliminated, either by pieces, or under the form of more or less considerable detritus from the urethra, or from the rectum. But more frequently, the cavity is the result of suppuration. The pus being lodged in the interspaces of the prostatic tissue, gradually compresses or destroys it, and when the pus is evacuated there remains only a pouch between the rectum and the urethra.

Tubercle also produces cavities, perhaps as frequently as inflammation; the tubercle accumulates in the body of the gland, then softens, liquefies, discharges, and leaves in its place only a cavity more or less anfractuons, containing some detritus of the gland and of the less softened parts of the tubercle.

Ordinarily, the prostatic cavity has the form and size of a turkey egg; it may either be simple, or with several compartments, which may be distinct, or communicate with each other. The cavity may occupy the whole gland, or even establish itself between the fibrous walls and the remains of the organ. If it be due to tubercle, it will co-exist with tuberculous disease in other organs, and not only the prostate, but all the surrounding organs may become disorganized by the tuberculous action, the degree and rapidity of which disorganization will depend upon the degree of the tuberculous diathesis of the system. The urethra may simply be perforated with one or more orifices, or, it may present a complete solution of continuity. Or, the cavity may open into the rectum, the perineum, or the bladder, forming prostatic fistulas. To undertake to treat these last independent of the cause producing them, would be to adopt an inefficacious therapeutics.

When a cavity communicates with the external surface, notwithstanding it receives fluids and irritating solids, it not only may not occasion still greater disturbances, but it neither becomes aggravated nor disposed to heal, except under the treatment of the

physician. It is not disposed to heal, because the walls which limit the prostatic area are formed by fibrous layers which can not approach each other, and also because, in forming itself, the abscess has created in this cavity a pyogenic membrane, a kind of mucous membrane, the surfaces of which in no wise favor a reparatory adhesion. Inflammatory disturbances are not developed, notwithstanding the presence of irritating matters, because this kind of protective membrane gives out a fluid which dilutes these matters and thus neutralizes a portion of their irritating properties.

In the *treatment*, the first thing to be done is to remove or discharge the abnormal fluid from the prostatic cavity, and to keep up this discharge. If the opening be at the perineum, and should it be too small, it must be enlarged. If it is tortuous, we must regulate it so that the abnormal fluids may find a ready issue as fast as they are produced. For this purpose, we must carry the knife into the sac, the finger serving as a conductor in dividing all bridges or anfractuositities which impede the free flow of these matters.—If there be a rectal fistula, it must be changed into a complete one, or rather, all the inferior wall should be divided, as would be done for an abscess the inside of which it was desired to stimulate.

When the prostatic cavity simulates a blind urethral fistula, it has been advised to make it a complete one by the establishment of a counter-opening in the perineum; but, this course will not in the least advance the cure, as the artificial fistulous opening will be as difficult to heal as the one formed originally by the cavity. It has also been advised to introduce a catheter, and allow it to remain. This may answer in the early stages, but the chances for being successful by this plan are, after all, doubtful. In fact, it only prevents a few drops of urine from entering the cavity,—it favors the accumulation of pus in this accidental pouch,—it also interferes with its cicatrization, and finally it acts as a foreign irritating body which may give rise to troublesome symptoms. On the other hand, if we catheterize the patient every time the bladder requires to be emptied, we run the risk of passing the instrument into the cavity, and thus may destroy, each time, the slightest reparatory process that may have been established. The better plan is, to introduce a catheter made for the purpose, into the bladder, removing it only occasionally, continuing its use as long as it gives rise to no symptoms contraindicating its further employment. This catheter should be made as follows: A small tube should be fastened within a larger one, in such a manner as to leave a sufficient space between the two for fluids to pass; the smaller tube, is designed for the urine to flow through, and communicates with this fluid in the bladder by means

of an orifice at the extremity or beak of the instrument; at about half an inch or an inch from the beak, the outer tube is perforated with numerous small apertures through which the pus and other liquids contained in the cavity may flow and be discharged externally. The two canals of the tube should not communicate with each other.

While employing these means, they should be associated with narcotic or emollient injections into the cavity, as may be indicated; and endeavors may also be made to bring about a healthy excitement of the walls of the cavity by detersive or stimulating injections. Great attention should also be bestowed upon the general health of the patient, employing tonics, nervines, anodynes, etc., as may, from time to time, be required.

While the resources of art are very limited for the cure of cavities of inflammatory origin, they may be said to be powerless when these are due to tubercle.

PROSTATIC CALCULI.

Under this head will be considered those concretions which have become imbedded in the substance of the prostate gland, and which may be divided into three distinct classes, viz.: 1. Those which have their origin and development in the gland itself. 2. Those which enter the gland after the operation for removing stone from the bladder. And, 3. Those which, having their origin in the bladder, escape, while yet small, from this organ, and become lodged in the prostate in a cavity formed by themselves, where they remain.

The *first class* of these calculi, more properly termed "prostatic concretions," are rarely observed by the naked eye previous to middle age, though they may be detected after the age of puberty, by means of the microscope; and there are very few adult persons, if indeed any, who are entirely free from them. So common are they in healthy prostates, that they have been considered as a normal product. They have, sometimes, presented more or less impediment to the seminal ejaculation, and, perhaps, have also been a cause of sterility, by interfering with the emission of this fluid. The "concretions" under consideration, vary as to number; there may be one, two, three, and so on, until they become too numerous to count; generally, they are in considerable numbers. They also vary in size, from that only visible under the microscope to that of a hen's egg. More commonly, when their number is considerable, they are very small, seldom exceeding the size of a pin's head. This last named size is rarely seen, except among individuals who have

attained or passed their fiftieth year, or who have hypertrophy of the prostate, or, phosphatic calculi.

When very small, they are more often colorless, sometimes amber-yellow, either pale, or darker when visible to the eye. They have also been seen whitish, chesnut-brown, and bistre color. In some instances they present to the naked eye a blackish aspect, having a resemblance to grains of snuff, but, when viewed under the microscope, they appear of a reddish color, similar to that of hematin. Their form is very variable, whatever may be their size, being sometimes rounded, ovoid, or triangular; when they have attained a diameter of from one-twenty-fifth to one two hundred and fiftieth of an inch, they are more apt to be quadrilateral or polyhedral, with rounded angles. Their great irregularity of form is, probably, due to the compression they exert on each other. When in the prostatic ducts, they present a somewhat arborescent form, occasioned by their formation along the ramification of these ducts. They usually present a smooth, shining surface, and, when their number is considerable, with facets. Their structure is very remarkable; they have an elegant appearance not observed in any other concretion. Some, generally whitish, and of very great consistence, are amorphous; but the others, which are more common, present concentric layers, having a focus or nucleus of small granulations. Around this nucleus, the mass of these concretions is composed of more or less regularly disposed concentric layers, the greater ones being proportionably nearer to the circumference and around smaller ones which are proportionably nearer to the center; and from the thickness and the regularity of these concentric layers may result an almost endless variety of appearances under the microscope. The larger the "concretion," the thicker are the concentric layers, and the wider are the intervals between the lines which separate them; in these cases, the substance of these concentric layers is finely granulous, instead of being wholly homogeneous as in the "concretions" invisible to the naked eye.

The nucleus of these concretions is more commonly granulous, and better formed than the rest of the substance. When the concretions are blackish or reddish, the nucleus, whether granulous or not, presents, as has already been remarked, the color of hematin, and seems to be formed by the hæmatin proceeding from some slight effusions of blood. We also find in the midst of this nucleus, and especially near its surface, epithelial cells, or some nuclei of the prostatic epithelium. Upon compressing these calculi between two plates of glass, they break, cleaving in some manner from the surface to the nucleus, which sometimes resists,

and, at others, yields to the pressure. The smaller and more recent ones divide, upon compression, similar to the division of soft bodies, while the larger and older ones are more brittle. It is common to see the concentric layers separate from each other, and exfoliate, as it were, under the pressure.

Their chemical characters are likewise variable. Whatever may be the size, when a transparent or translucent concretion is submitted to the action of hydrochloric or acetic acid, it becomes slightly paler but without any disengagement of gas. It is only when the concretion is opaque that the employment of these acids produces an evolution of gas, the same as if they were acting on concretions of carbonate of lime. Gas is also set free quite rapidly by the action of sulphuric acid. The tincture of iodine develops a yellowish-brown or reddish color in these calculi, similar to that which it determines with nitrogenous substances generally; and these actions have led to a belief in the minds of some that the concretions thus acted upon were of a nitrogenous character. When these bodies are soft they remain unaltered in the presence of nitric, sulphuric, hydrochloric or acetic acids, cold, sulphuric ether, and the alkalies; when large and hard, nitric and hydrochloric acids, also sulphuric acid, and the caustic alkalies exert an influence upon them in a greater or less degree. Heat eliminates a strong ammoniacal odor, and the soft ones leave no residue under the blow-pipe.

At first, these "concretions" are soft, but become darker, firmer, and more solid by age, and may eventually attain a size and hardness as to be "calculi," in the true sense of the word. They have their location in the glandular parenchyma, in which case they are small and numerous, and may readily be seen upon making an incision to lay open the gland. Sometimes they will be detected immediately beneath the urethral mucous membrane, the portion covering them being so thin, that it will rupture upon the least friction, and expose one of the surfaces of the calculi to the urethral canal. Their most frequent seat, however, is in the prostatic ducts and around the veru montanum; they are less frequent in the ejaculatory canals. They are found in normal prostates, as well as in those which are enlarged; indeed, it is seldom that a hypertrophied prostate exists, without an abundance of them being present, and which may be either invisible or barely perceptible to the naked eye. These formations must not be confounded with *phlebotites* or stony concretions sometimes discovered in the vesicoprostatic veins, nor with the cretaceous form of tubercle.

The origin of these concretions is not satisfactorily ascertained.

By some, a portion of the semen has been supposed to form in some way a lodgment in the gland, inspissate, and become a nucleus for other seminal matter to be deposited around it. By others, this action has been attributed to the prostatic liquor; and again, both the semen and the prostatic liquids have been referred to as the cause. The most satisfactory explanation that I have seen is, that there exists in the prostatic liquid, as well as throughout the substance of the prostate, numerous minute yellowish bodies, sometimes granular, sometimes homogeneous, resembling oil globules; these coalesce in the follicles of the secreting portion of the organ, fuse into a mass, and give rise to the early or purely organic form of the "concretions." Having thus formed in a follicle, and increased in size by fresh layers of secretion, their presence sooner or later creates an irritation, which results in the secretion of a fluid containing earthy matter, in the same manner as is known to be the case with secreting membranes generally when irritated; the deposition of this earthy matter, gives hardness, opacity, and dark color to the concretions; and with this earthy substance, are also intermixed in various proportions, mucus, gland cells, etc. When the concretion has reached a certain size, the walls of the follicle containing it become absorbed, from its pressure upon them, it then comes in contact with other concretions which have gone through similar phases, being now contained with them in a common sac, and they all acquire their various forms and facets by attrition or juxtaposition.

The *second class* of prostatic calculi, results from the lateral or bilateral operation for stone in the bladder, in which the prostate is necessarily involved in a greater or less degree, as it is through its tissue that the calculi are extracted. A small, hard calculus may be removed entire, without leaving the least fragment of it in the bladder, or in the incised portion of the prostate. But it sometimes happens that there may be other calculi by the sides of the principal one, the existence of which was not even suspected; it may also happen that by the pressure of the forceps, some layers of the calculus seized upon, are broken and remain outside of the instrument, in the form of scales, gravel, etc. These fragments may remain in the bladder or they may be dropped along the tract of the wound in the perineum. If they find their way into this last named place, they may be arrested there, be completely isolated from the urinary passages, and gradually become developed until they acquire a considerable size. Then, one or more years may pass before their existence will be recognized. There may be only one calculus, or several may be present; and

their chemical composition will be the same as when they were in the bladder.

These calculi present several varieties; thus, sometimes the wound made in the prostate heals on its urethral side and closes on the perineal side. After some months, or a year or more, the cutaneous wound re-opens, to close again. We then recognize a calculus in the prostate; it may be small, angular, and irregular; having preserved nearly the form it had at the time when the operation was performed, the period at which it became lodged in the prostate. This must be so, since, having from that period had no communication with the urine, this fluid has no longer furnished it with the materials necessary for a rapid growth.

At other times, the perineal wound closes completely and solidly; while the urethral wound closes imperfectly, ready to re-open on the least occasion. A calculus at the bottom of this wound, is, certainly, in a good situation for an increase of its size, because of the urine, which, coming in contact with it from time to time, is constantly depositing new layers upon it, so that it enlarges upon its vesical as well as upon its perineal surfaces.

Again, both extremities of the wound made in the prostate may firmly cicatrize, and then the calculus is enclosed as in a cyst, where it may remain for an indefinite period without growth, and without discovering its presence; or, if it be in contact with any fluid whatever, it may more or less rapidly be increasing in size.

The *third class* of prostatic calculi are those which form in the prostate independent of any operation. These may form in the same manner as named in the first class, and may be due to a rapid augmentation and hardness of the "concretions," from increased activity in the earthy depositions. They may vary in size from that of a grain of rice to that of a large pea; may be single or multiple, one mass being frequently composed of several accurately fitting fragments, and occupying a cavity in the prostate in which they are imbedded. They are white, fawn, or pale-brown, the surface being darker than the internal parts; have a rounded, or irregular form; are of very close texture, like porcelain, and quite hard, and are composed of a large proportion of phosphate of lime, with animal matters and a minute quantity of carbonate of lime. In their early stages the animal matters preponderate, but as they advance in age, this predominance is lost and the mineral constituents manifest themselves more and more abundantly. As they increase in size the cavity or cavities containing them enlarge by distension, and have occasionally reached a length of from three to five inches, having within them masses of coalescing calculi.

But, *another character* of prostatic calculi may be met with; thus, a small stone or gravel formed in the bladder escapes into the prostatic portion of the urethra, where its further progress onward is checked, and it becomes arrested in the lateral furrows of the verumontanum. If no symptoms manifest its presence, and if it is not expelled with the urine, it gradually depresses the urethral mucous membrane, excoriates and ulcerates the tissues beneath it, and is soon imbedded in their midst, from which place it continues to increase in size. If this calculus becomes so buried in the tissues as eventually to have no communication with the urethra, we may have the same phenomena as is common to calculus thus situated of the second class. If, however, its surface remains exposed to the urine, it may rapidly augment in size from the continual addition of deposits from this fluid. Velpeau states that such calculi are almost always multiple, have an excoriated looking surface, and, being developed in a kind of purulent sac, they seldom become very large.

If a calculus formed in the bladder near its neck, becomes of large size, it may press against the prostate, and even become engaged in its tissue, and it may then continue to increase in size both on the part of the bladder and on that of the prostate. This has been called a "vesico-prostatic calculus." Its most striking character is that of having two lobes of unequal size, the vesical lobe being the largest. A "prostatic-vesical calculus," is exactly the inverse of the preceding, its prostatic lobe being the largest.

When prostatic calculi are of large size, we find the prostatic portion of the urethra become so dilated as to almost acquire the capacity of the bladder, which organ, on the contrary, gradually diminishes, so that there is, as it were, an exchange of capacity between the bladder and the urethra. Moreover, while the bladder is retracting so as to directly cover or envelop the calculus, its walls undergo a kind of hypertrophy, which renders their section difficult when we practise the High operation.—But, by way of contrast, the walls of the prostatic portion of the urethra, which form a kind of supplementary bladder, become atrophied and exceedingly thin.

However, it is not always by dilatation that this prostatic cavity increases its size; more frequently, the calculus advances by ulceration even to the center of the gland, and when the ulcerative process passes beyond the limits of this organ, the calculus may form a protuberance in the rectum, or even escape into it.—In a case of chronic abscess terminating in a large cavity communi-

contact with the urethra, the decomposition of the urine retained in this cavity may produce another kind of prostatic calculi.

The *symptoms* of prostatic calculi are not very marked when of small size; indeed, instances have been cited where quite large ones existed (in one instance the size of a hen's egg), without presenting any symptoms to attract the physician's attention.

Small calculi, generally multiple, manifest themselves by pain and a sense of weight at the perineum, and a frequent desire to urinate. A catheter introduced into the urethra, as it passes through the prostatic portion conveys a sensation of grating. A wax bougie, properly prepared so as not to break within the urethra, when left in for some minutes and then withdrawn, will present the characteristic impressions made upon it by its pressure upon the calculi.

With the large calculi, there will be added to the above symptoms, a more or less complete dysuria, a difficulty in the emission of semen, and, perhaps, a continual partial erection of the penis. These calculi, imbedded in the midst of the soft parts of the perineum, terminate by presenting an obstacle similar to that of a tumor. They may be recognized by introducing a finger into the rectum, passing it inward as far as possible, or until we meet the prostate, when, if this organ contains a calculus, we will feel it under the form of a small protuberance, which may be distinguished from any tumor by its hardness, its inequalities, and by the pain, sensation of pricking or of tearing, which it gives rise to when we press upon it as if to rub it against the pubis. In the case of multiple calculi, they will feel somewhat like a bag of small marbles, and the pressure just referred to will determine an evident crepitation.

Catheterism will also give further information to aid in the diagnosis. The existence of fistulas in the perineum, the catheterism of this fistula, the antecedents of a previous lithotomy operation, the cicatrices of which have re-opened, are all so many reasons for a belief in the existence of a calculus, especially if attention has already been called to the case by other symptoms. If a catheter be passed into the urethra, and the stone presents one of its free surfaces in this canal, the metallic instrument will, upon coming in contact with it, produce a characteristic sound or click; and the distance to which the catheter has to be carried before it touches the calculus, will determine whether this be in the bladder or in the urethra. The clicking sound will be more distinct, if the stone be brought in more direct contact with the catheter or sound, by a finger in the rectum pressing the gland up toward it.

These manœuvres are often interfered with or entirely prevented by the presence of an urethral stricture, in which case, they should be dispensed with until the canal has been sufficiently dilated.

Left to themselves, prostatic calculi may escape spontaneously, either through the urethra, previously ulcerated, or through the rectum or perineum, an abscess having been first formed. Sometimes, these calculi may escape into the bladder, where they increase in size, and constitute, at a later period, calculi of mixed composition.

In the *treatment* we must be governed by the symptoms present, and the number and size of the calculi. If a fistula is present, we must extract the stone through it, enlarging the passage by dilatation or incision, so that the calculus may be seized by forceps.—If there be no external wound, and the calculus is not very large, we may extract it by means of one of the modified or improved instruments of Hales, Hunter, etc. Weiss' forceps will frequently be found to answer. Or, if the stone can not be thus extracted, it may be detached from its situation, pushed into the bladder, and be removed from thence by such means as would be pursued in case of a similar original vesical calculus.—If the calculus is too voluminous to be extracted in this manner, it must be broken by means of a lithotrite, and the several fragments of it extracted successively.

But if these means are insufficient, the calculus being found too large to extract by the urethra, and too hard to be broken by the lithotrite, or when it is completely enveloped in the prostatic tissue, the only course to pursue, is, to introduce a grooved staff into the urethra, and cut down upon the prostate in the mesial line, through the raphe of the perineum, until the calculus is brought within reach, when it may be removed by the forceps or scoop. Great care must be taken not to allow any fragments to remain behind, as they will form nuclei for future calculi. This is a much safer operation than that of ordinary lithotomy, as the bladder remains untouched, provided there be no calculi of this organ, which should, in all cases, be positively ascertained previous to the operation. If the case be complicated with calculi of the bladder, lithotomy may have to be performed, either by the lateral or median operation.

After the extraction of the calculi, internal and other means should be used, to improve the patient's health, to overcome any untoward symptoms that may manifest themselves, to lessen irritability of the neck of the bladder, and to lessen the tendency to phosphatic deposits.

In cases of large prostatic cavities containing multiple calculi,

these have sometimes been extracted through an incision of the prostate by the rectum; the operation, however, is an unsafe one.

CANCER OF THE PROSTATE.

Cancer of the prostate is an exceedingly rare affection, and when it does occur it may be either in a primary or secondary manner, though more commonly the former. The encephaloid, scirrhus, colloid, melanotic, and fibro-plastic forms of this malignant disease are stated to have been observed upon the gland, of which the encephaloid is the most frequent. Children seem to be as liable to this disease as adults.

It is very difficult to diagnose cancer of the prostate; the local *symptoms* indicate nothing of the nature of the disease, or, at least, not until it has considerably advanced. If the finger be passed into the rectum in the early stage, the gland will be found hard and enlarged; in connection with this, the patient will frequently complain of severe pains in the part, which are sometimes very severe, and may occur either during, or in the absence of, urination; more or less profuse hemorrhage is likewise apt to be present; and the patient becomes weak and reduced in flesh. With these symptoms, there will also be either a partial or complete retention of urine, with a desire to pass water much more frequently than before, and other symptoms common to the various kinds of prostatic obstruction. At a more advanced stage, the rectal touch will find the gland softer; the pains continue, and will be felt shooting to some distance in various directions from the diseased organ; the hemorrhage will be more abundant than before; frequently enlargements of the neighboring lymphatic glands will be discovered; the urine may be bloody, and may likewise contain considerable debris, from the malignant growth; if present, cancer cells may be detected in the deposit from the urine, but it is not a common thing to find them; and with these symptoms the strength and embonpoint of the sufferer rapidly diminishes, so much so, in some instances, that he succumbs, even, before softening of the growth has taken place.

A *post-mortem* examination will reveal fungus projections from various points of the gland, more commonly on its urethral and vesical surfaces, which vary in size, hardness, and color; some being hard, others soft, sprouting; and presenting colors varying from an almost white to yellowish, brown, or dark-red; again, others will be pulpy, gangrenous, and presenting grayish tints. A sanious fluid may exude from the diseased surfaces; or a cream-like liquid; some-

times flakes of disintegrated structure will be found in the fluid; and small collections of pus may also be observed at various points. The disease appears to attack the glandular tissue of the organ at first, but ultimately invades the fibrous structures, so that as the disease progresses the prostatic tissues disappear to give way to the cancerous product. In other instances, no fungus or projections will be seen, but the prostate will be enlarged, the malignant affection confining itself to the limits of the enlarged organ, with ulceration and disintegration. Cancerous matter may be found to exist in the neighboring glands and veins, in all cases.

As to the *treatment*, we can not hope to effect a cure; palliation is all that we can do, relieving pain by sedatives and anodynes administered by mouth, and by injection per urethra and rectum; checking undue hemorrhages by the internal administration of astringents, also injecting mild solutions of them into the prostatic part of the urethra; as, Gallic Acid, Geraniin, diluted Sulphuric Acid, Oil of Turpentine, Warren's Styptic Balsam, etc.; supporting the strength by nourishing diet; overcoming prostration by stimulants; and, in case the catheter becomes absolutely required to relieve retention of urine, introducing it with the greatest care and gentleness.

Anodyne suppositories in the rectum will often be found useful in lessening severe pain; and the Peroxide of Iron will be found valuable as a chalybeate tonic. The anodynes which have been the most useful, are, Belladonna, Conium, and preparations of Opium.

CYSTS AND TUMORS OF THE PROSTATE.

Cysts are rarely, if at all met with in the prostate, and, consequently, any knowledge concerning them is extremely meagre and negative. Among old persons the follicles of the gland are apt to dilate, and its excretory ducts to enlarge and close, and it is possible that these conditions may have been mistaken for cysts.

Tumors of the prostate are by no means uncommon; they are met with both when the organ is of natural size, and when it is hypertrophied. Sometimes they may project inward so as to be imbedded in the prostatic tissue, but remaining unconnected with it, or else slightly united to it by means of a few fibres; at other times, they grow from the surface of the gland, and may be apparently continuous in structure with that portion of the gland upon which they are seated, or, may be only partially connected with the gland structure.

As to the *causes* of these tumors nothing positive is known;

as *local* causes, irritations, excesses, inflammations repeated more or less frequently, gonorrhea, diseases of the rectum, stone in the bladder, etc., have been named; as *general* causes, tubercle, cancer, and syphilis.

The *symptoms* of prostatic tumors vary, according to their size and location. Some patients may be affected with a prostatic tumor, without any troublesome symptoms that might lead to a suspicion of its presence. But when the increased size of the prostate effects a change in its position, as well as in the dimensions and the direction of the corresponding region of the urethra, we will then have, as a prominent symptom, more or less difficulty in micturition. The stream of urine may cease flowing for a few moments, and then come on again, as usual; or, beside this interruption in the flow, sudden checks to it may also occur, as if the neck of the bladder were closed by a valve. In certain instances, the urine is only voided drop by drop, and the greater the efforts made by the patient to empty his bladder, the less will be the amount of fluid expelled. Again, there may be a complete retention of urine. These several forms of dysuria may be transient or continuous, and sometimes they will follow each other in succession.—Incontinence or involuntary flow of urine, is sometimes present instead of the dysuria above referred to.

Other symptoms will also manifest themselves, as a sense of weight at the fundament, or a burning sensation, or, acute lancinating pains. Constipation is generally present, and the inferior portion of the rectum may be congested or subject to piles. Indeed, the symptoms very much resemble those named under “Hypertrophy of the Prostate,” to which the reader is referred.

The prostate being accessible by the rectum, this mode of exploration should not be neglected to verify prostatic diseases; but, it does not always give positive indications. In fact, the finger introduced into the rectum will give, at the most, the sensation of any development of the gland, of the inequality of its lobes, its projections, its depressions, etc.; but, as all tumors generally develop themselves toward the urethra, the rectal exploration will be of little service. And when the tumor carries the prostate high up in the pelvis, it is but slightly, if at all, appreciable to the finger. In such cases, if the finger can be made to come in contact with the gland, the other hand may be placed upon the abdomen immediately above the pubic bone, and by a kind of palpation, the enlarged organ may be seized between the finger in the rectum, and the hand at the pubis, and its volume be thus verified.

Catheterism has been named as one of the best methods for determining prostatic tumors; but we can not rely upon it to form a positive *diagnosis*, as it may be extremely difficult, if not impossible, to determine between a hypertrophy of, and an outgrowth from, the gland. The operation requires much skill and experience; sometimes the instrument passes in very easily, at other times it passes with great difficulty, or, perhaps, can not be introduced at all. If there is no urethral stricture, the large catheters with rounded beaks pass the most readily. The necessity for considerably depressing the external extremity of the catheter, or of inclining it to the right or to the left, in order to enter it into the bladder, are so many evidences of a tumefaction of the prostate, indicating the deviation of the prostatic part of the urethra.

When the catheter is in the urethra, we may sometimes feel it through the prostato-rectal walls; if it appears to be separated from the finger by only a thin layer of tissue, we may conclude that the lateral lobes are enlarged, as well as displaced.—If the urine passes through the catheter with a normal projection, or, even slightly augmented in power, it indicates that the contractile force of the bladder still remains. If there is a slight hemorrhage at the commencement, or at the termination of the micturition, it will have the more value as a symptom, if the surgeon has practised the operation so carefully as to give rise to no suspicion of an accidental tearing of the tissues.

In our endeavors to form a correct diagnosis, we must be very careful not to confound a prostatic tumor with a stone in the bladder, much less with a fissure of the anus. The preceding descriptions will be sufficient for the differential diagnosis.

The surgical diagnosis, or a determination of the form, size, and position of prostatic tumors, as well as of the condition of the bladder, whether there be a calculus or other obstruction present, can not be established by means of ordinary catheters, but by those especially made for this purpose. There are three forms of the instruments which have been successfully used; one by Leroy D'Etiolles, the other by Aug. Mercier, and the third by Henry Thompson; they are straight instruments with a very short curve or beak at their extremity.

The sound or catheter of Mercier, is simply a stem, straight throughout nearly its whole length, or to within one-half, or three-quarters of an inch from its vesical extremity, where it is curved nearly at a right angle, 100° to 110° at the most. The external extremity is furnished with a polygonal plate perpendicular to the plane of the curved portion; a mark is placed upon that face of it

which corresponds with the beak. The stem ought to be graduated on the side of the beak as well as on the opposite side, and the end of the beak should be well rounded. The diameter of this instrument should be that of a rather large catheter.

The sound of D'Etiolles has its curved part somewhat less in length than that of ordinary catheters, having an expansion and a plate or disk at its external end, and the curve at its vesical extremity somewhat less than that of Mercier's.

The sound employed by Thompson is made of steel, somewhat like the one ordinarily used in sounding the bladder, with a short beak, not over an inch in length, slightly bulbous and solid, and curved at an angle less than the preceding ones, but much greater than that of an ordinary catheter. As it is useful to have these sounds hollow, so that the amount of fluid in the bladder may be diminished or augmented, without removing the instrument, this steel one is made hollow, having its eye or vesical orifice on the convex side of the beak about half an inch from its extremity.

In diagnosing prostatic tumors, either of these instruments may be used; perhaps, in certain cases one form may be found more useful than the others, but this can only be determined by actual experience. Great care and gentleness is required in the manipulation with these sounds; and we must not expect in all cases to be able to succeed either in entering the bladder, or in determining the form, etc., of the tumor. The following are the modes recommended to diagnose tumors and hypertrophy of the prostate, by means of these catheters or sounds:

1. *Means of recognizing tumors which protrude into the bladder.* The instrument having been introduced into the bladder, the stem must be held nearly parallel to the axis of the body; we then draw the beak against the anterior margin of the vesical neck, and from thence slowly rotate it on its axis to the right and to the left, causing it to gradually pass all around the circumference of the orifice of the neck, constantly making slight traction upon the *external* expanded extremity so as to keep the beak close to the vesical neck. If the prostate is healthy, the beak will pass over the whole tract without undergoing any elevation, and the stem will remain in its original position; but if there is a tumor at the neck of the bladder, the beak will be arrested in its movement, and in order to pass the obstacle, we will have to elevate the beak proportionately to the height of the eminence, after which it will descend again as we continue the rotation and a moderate degree of traction. The plate at the external extremity indicates the side upon which the beak is arrested; the arc of the circle passed through from the moment the

sound commenced to ascend until it returned to its first level, will give, approximatively, the breadth of the tumor, and its depth or height is determined by observing the number of the degrees graduated on the stem, that are carried into the urethra with the elevation of the instrument. We may determine if the tumor is pediculated or has a large base, by the more or less abrupt manner in which the beak ascends and descends.

2. *Means of recognizing valvules, bridles, or bars at the neck of the bladder.* Prostatic bridles or bars have sometimes, a common character with tumors, requiring the beak to ascend in order to pass beyond them; but, in the former case this ascension occurs gradually, insensibly, while with a tumor it takes place very abruptly. In both cases, at the moment when the angle of the sound passes the neck of the bladder, it will be felt to approach the symphysis with a jerk; but this is more marked with a bar, than with a tumor. If the beak be turned downward to the bas fond, we may readily withdraw the instrument through the urethra, if the prostate be free from any tumefaction; if there be a bar, considerable force will be required to withdraw the instrument; if there be a tumor, the beak will hook against it, and will not leave the bladder until its position has been changed so as to free it entirely from the tumor.

If, in passing the beak through the prostatic portion of the urethra, we observe it to rise gradually, the external stem being at the same time depressed considerably below its original position, there is, probably, a spheroidal enlargement of the median portion.

3. *Means of recognizing prostatic tumors projecting into the urethra.* After having explored the bladder, gently draw the instrument back into the prostatic region of the urethra, pressing lightly upon it at the root of the penis, (its upper aspect), just under the symphysis pubis, so as to press the angle of the sound, or the salient part of its curve, against the posterior wall of the prostatic-urethral region; then draw the instrument forward without elevating its stem toward the body as in ordinary catheterism, and without removing it too much from the axis of the patient's body (15° to 25°). When there is a simple enlargement of the prostate in the antero-posterior diameter, the beak traverses it easily, without inclining to the right or left. If, on the contrary, there is a projection of one of the lateral lobes, the beak, in passing this spot, inclines to the opposite side; the exterior plate or handle indicates this movement, and the direction in which it is made. This operation does not always give positive information; we can not always succeed

at the first trial, even when the tumor projects considerably, for a very simple reason.

If, the angle of the sound remains pressing against the wall or rather against the posterior groove, the beak not deviating, or, deviating but very little from the anterior, a change of direction will not be possible, because neither of these walls abandon the median line. To be successful with the exploration, we must, keeping the salient part of the curve against the posterior wall, pass the beak pretty near the tumor or close upon it, because it will not fail to incline toward the opposite side. Consequently, if a first attempt does not succeed, we must make a second and even several others, varying the degree of inclination of the sound each time. (*See Diagnosis of Urethral Strictures*, page 967.)

Whatever may be the nature of prostatic tumors, they may all cause mechanical disturbances in the functions of the surrounding organs, the mode of effecting which has been ascertained by *post-mortem examinations*. This influence may be exerted in several different ways, as follows:

1. *Displacement of the tumefied prostate.* When the prostate is tumefied, it can not advance toward the perineum, because it is checked by the aponeuroses; consequently, it ascends in the pelvic cavity and recedes from the anus, at the same time advancing toward the front. These prostatic displacements are important in the diagnosis. When we explore the parts per rectum, the finger will, in these cases, have to penetrate more deeply than in the normal state in order to reach the superior limit of the gland, and, it would be a great mistake to conclude there was no tumor, because, the finger, having been carried only one, two, or three inches within the rectum, has not conveyed a very clear idea of its presence.

The displacement above and in front, is sometimes very manifest; this is when the prostate ascends behind the pubic symphysis, dragging along with it the neck of the bladder, elongating the urethra which undergoes a considerable increase of curvature, and which does not occur when the tumefaction or tumor occupies only the sides. This displacement presents an important practical application. If, on the contrary, the tumefied prostate can be distinguished only with difficulty by the rectal touch, hypogastric palpation will furnish valuable information.

2. *Influence of prostatic tumors on the urethra.* This influence is manifested upon the length, form, and capacity of this canal.

a. Lengthening. Prostatic tumors when advanced to a certain degree, inevitably augment some of the diameters of this gland,

and, in some cases, even lengthening all of them simultaneously. From this, a considerable lengthening of the prostatic portion of the urethra frequently follows, and this elongation is carried toward the pelvis. The middle aponeurosis of the perineum embraces the membranous portion of the canal too solidly to permit this to move upward; while, on the contrary, the prostatic portion experiencing only a feeble resistance from the pelvic fascia, gradually encroaches upon the cavity of the lesser pelvis. This explains why the prostate advances upward and backward.

This elongation may extend from one-third of an inch to an inch more than in the normal state, and which it is important to bear in mind, lest the physician from an ignorance of the fact, may seriously deceive himself during catheterism.

In the normal state, the catheter having passed under the pubis, enters the bladder almost immediately, because there is only about an inch for it to pass, between the membranous portion and the entrance into the bladder. But, in the case of tumors or tumefaction, the urethra elongates more or less, and then the catheter must be introduced to a much greater depth in order to reach the cavity of the bladder. If not apprised of this fact, the physician may believe that the instrument is in the bladder when it is only at the prostatic part of the urethra. Cases are met with in practice, where this elongation is so great that ordinary catheters are hardly long enough for their beak to be carried even as far as the apex of the trigone, and, consequently, longer ones are required.

The extension of the antero-posterior diameter presents many varieties. If the tumefaction bears equally upon all the diameters of the gland, the conformation of the urethra will not be much modified. More frequently this tumefaction is irregular; sometimes occupying a single lobe, sometimes occupying both lobes simultaneously, but in an unequal manner,—from which it necessarily follows that the form of the canal becomes very irregular. It then presents bars or small protuberances and depressions, which are situated on each side of and behind the verumontanum. If, in such case, the superior and inferior urethral walls have their normal length, and if catheterism be practised and we do not abandon these walls, we will believe there is no tumor.

The superior part of the prostate does not modify the length of the urethra to any great degree, because of its fixity to the pelvis by the vesical and pubo-prostatic ligaments. It is different with the inferior part of the prostate, where tumors are more frequently located. The extension of the prostate, occasioned by these tumors, rarely, if ever, advances downward, where the middle

aponeurosis of the perineum hinders the further progress of the tumefaction in that direction. The abnormal development of the parts is especially established between the apex of the trigone of the bladder and the anterior extremity of the verumontanum.

The tumefaction being thus prevented from advancing upon the perineal side by the aponeuroses, it projects backward, and into the rectum, which it may constrict or flatten, and obstruct, to a greater or less extent, the evacuation of this intestine. If the swelling occupies only the median portion of the gland it will depress the rectum in the median line, as if to divide it into two equal parts.

In those cases where the sides of the prostate only are attacked, we may find a gutter, a kind of concavity in the rectum, in the shape of a half-moon which will tend rather to constrict the intestine transversally, than to flatten it from before backward.

b. Deformation of the urethra by tumors. At the first glance, we would be led to believe that a tumor in proximity with a depressible canal like the urethra, would compress it and diminish its capacity; but it is not the case,—the most superficial observation shows that the urethra is very much amplified in prostatic tumors. In subjects affected with an enormous prostatic tumor, the urethra has been found so enlarged as to easily permit the introduction of a finger. Strictures proper, never exist in the prostatic portion of the urethra, and if there be found an obstacle to the advance of the catheter in that region, it must be due to tumefaction or a tumor.

When the two lateral lobes of the prostate are tumefied, the urethra is flattened on the sides. If the tumefaction is regular, the two opposed faces will be in more or less close contact. If the tumors are rounded, globular, they will come in contact by their culminating points, from which there will result a kind of double channel in that part of the urethra; a canal with a superior and inferior branch at the point of contact of the two tumors. To reach the bladder, we may pass the catheter either into one or the other of these branches, according as we elevate or depress the beak of the instrument after it has passed the concave border of the subpubic ligament. A straight catheter, or one improperly curved, will not pass by the superior branch, but will, on the contrary, enter the inferior channel without much trouble.

The lateral walls of the urethra present many modifications. If a tumor be located on one side of the prostate only, there may result three different dispositions. If the tumor projects forward, it will force the prostatic portion of the urethra on the opposite

side, to the left if the tumor is on the right side, and vice versa. This will give rise to a canal very obliquely directed from before backward in the pubis, and zigzag immediately behind; when the catheter is passed into a canal of this kind, its progress will be checked as soon as the beak reaches as far as the exterior part of the prostate. Under such circumstance we will be apt to make a false passage, if we do not incline the beak of the instrument toward the side of the first deviation, and immediately after incline it in an opposite direction.

If the tumor is situated at a part of the lateral wall of the urethra, it projects toward the interior of this canal, depresses the wall of the opposite side and forms a kind of hood or cap of it. In this case, the prostatic portion of the urethral canal forms a half-moon curve, concave on its healthy side, convex on its diseased, and which gives rise to the same difficulties in catheterism as the preceding, if this is the only deviation—being a little less abrupt on the perineal side, and rendering the passage of the beak a little less difficult.

If the tumor is situated behind the lateral wall of the urethra, in the neighborhood of the neck of the bladder, in projecting by its free side, it will place itself in contact with the other side of the vesical neck, in such a manner as to more or less completely, and often even completely, close the deep-seated orifice of the urethra. In such cases, this orifice is closed as if by a valve; and if catheterism be attempted, the instrument will be arrested only near the termination of its passage, and will not enter the bladder until after having undergone a deviation in the direction in which the opening into the bladder may be found.

If both sides of the prostate are the seat of tumors unequal in size and number, and if the single tumor is in the center, and corresponds to the double tumor of the opposite side, so that they reciprocally fit each other, they will give a half-moon curvature to the urethra, the same as stated in the preceding instance; but if, as frequently happens, each side of the prostate contains several tumors, we must expect to find them in some way toothed or dove-tailed, as it were, with each other, so that this part of the urethra becomes only a zigzag canal. If, instead of regularly occupying the sides of the gland, the several tumors are located here and there without order or symmetry, some in front, others behind, and others above or below, the difficulty in passing the catheter under these circumstances, may readily be comprehended. The urethra becomes, in this case, a kind of anfractuons canal, through which a sound or catheter may pass by chance instead of skill.

The vesical opening of the urethra also presents important modifications as a consequence of the proximity of these tumors. When both sides of the prostate are equally tumefied, the urethral orifice will resemble a funnel, or rather a gap directed from the pubis to the trigone. From this disposition of the parts, but little impediment to the flow of urine will be presented, and the tendency will be to an incontinence, instead of a retention of urine.

The posterior wall of the urethra undergoes several very variable modifications according to the size, situation, and form of the tumor. As all tumors of the urethral region generally have their origin behind the verumontanum, this part of the urethra becomes gradually enlarged, and eventually presents a concavity which may acquire a depth of from one-seventh to one-third of an inch on each side; if the tumor is broad, thick, and non-pedicated, it extends the walls of the gland so as to make the excavation of the inferior urethral wall as broad as it is deep. Tumors, with broad base, which project in the form of small embossments into the urinary passage, give a triangular form to the urethral opening, the base of which is represented by the vesical trigone, instead of a transverse button-hole form. (*Velpéau.*)

c. Valves, bridles, bars, or urethro-vesical crests. Tumors of the prostate very frequently develop projections into the urethra, which have been differently named by authors. These projections, bars, excrescences, etc., are seated above the verumontanum, at the apex of the vesical trigone, that is, at the entrance into the bladder. They form a transverse ridge or elevation, which may be more or less prominent. In the normal state, the trigone of the bladder in the adult, is placed upon the same plane as the prostatic portion of the urethra; but when these crests are developed, the urethra becomes gradually placed upon an inferior plane, so that the beak of the catheter having reached the inferior wall of the canal, is arrested in its progress by the projection. The height of this bar or excrescence, is sometimes very great, reaching, upon the urethral side, an elevation of nearly two inches, and upon the vesical side, an inch to an inch and a half, or more. Seen by its urethral surface, the projection represents a pyramid with its base at the neck of the bladder, and its free extremity or apex in the urethro-vesical cavity.

Under other circumstances the tumor of the middle lobe does not have this regularity; instead of being transverse, it has a globular form, slightly pediculated at its base, susceptible of being moved to the right or left, like a polypus, and, consequently, acting as a valve.

All these dispositions are important for the operator to be acquainted with; for if the beak of the catheter, having reached the neck of the bladder, comes in contact with one of these obstructions, and be forced onward to pass it, a false passage may be made through the obstacle. Indeed, these tumors or bars render catheterism very difficult, if not impossible.

One important point to elucidate is, the structure of these bridges or urethro-vesical obstructions. If we raise the mucous membrane, we will observe beneath it transverse fibres, the color, disposition, and relations of which, are of a muscular nature, and we will adopt this idea the more readily as the fibres are more considerably hypertrophied. In this case, the projection is transverse, regularly rounded, of slight thickness, and takes the form of a true bar. But, in another instance, this fibrillary disposition common to muscular tissue will not be present, there will be a dense, yellowish, irregularly-arranged tissue, having all the fibrous characters. This is the increased development of the middle lobe; the tumor formed by the projection of which has a more or less decided ovoid form. From which we may comprehend that retention of urine in prostatic tumors may not only be due to mechanical causes, but also to a more or less active power of the muscular contraction of the parts.

The bladder is often affected by the proximity of prostatic tumors. Its capacity may be diminished by the projection of these tumors into its interior; but, as there is frequently a retention of urine, the bladder may be considerably dilated thereby, and then the excess of the dilatation may counterbalance, to a greater or less extent, the diminution effected by the presence of the tumor. It is not, however, always so; sometimes the bladder does not enlarge, on the contrary, continually urged to contract itself, its capacity becomes more and more reduced, so that we have two causes present effecting one result, to wit, the presence of the tumor, and the contraction,—and the bladder may become almost as small as the prostate.

Sometimes, when prostatic tumors are present, they may give rise to, or be attended with, severe inflammation of the bladder. And it not unfrequently happens that the ureters and the kidneys become sooner or later attacked with inflammation, or some physical alteration.

Diseases of the prostate necessarily exert an influence upon the seminal vesicles. In simple hypertrophy they may be affected as well as the prostate, but in muscular or fibrous hypertrophy, they are more frequently atrophied. The ejaculatory canals are often compressed, or may have disappeared, and no pressure upon the vesicles will cause semen to make its appearance at the surface

of the urethra. In tuberculous tumors, the seminal vesicles are very often equally affected with the prostate. Changes may also occur in the vas deferens, and in the testicles, by prostatic diseases and tumors; having already glanced at them, under other heads, they will not be dwelt upon here. It may be proper to state that in some rare instances *polypus growths* have been found springing from the veru montanum, which are unlike any of the varieties of tumor heretofore named.

Varices of the prostate have also been met with; they more generally occupy the urethral part of the prostate, especially the superior segment of this gland; sometimes they exist in conjunction with varices of the bladder. Prostatic varices is more apt to accompany glandular than fibrous hypertrophy. Certain cases of urinary retention, which disappeared after a more or less abundant hemorrhage, have been attributed to the presence of these varices.

Other morbid changes have been occasionally met with in the prostate, as, osseous, and fibro-cartilaginous concretions; fatty matter in the interior of the gland; yellowish, glistening tracks, staining paper like oil, etc.

Prostatic tumors may exist alone, or they may be associated with hypertrophy of the gland; and as their *treatment* is in some measure similar to that adopted for hypertrophy, the reader is referred to the following article not only for this, but also for some remarks relative to symptoms, etc., which are equally applicable to either tumors or hypertrophy of this organ.

HYPERTROPHY OF THE PROSTATE.

By Hypertrophy of the Prostate is meant that condition of the gland which is characterized by increased growth of one or all of its parts, accompanied with an augmentation of its weight, volume, and sometimes of its consistence, but without any morbid change of its intimate structure. The disease is one peculiar to persons of advanced age; though some rare exceptions have been met with in adults, and even in childhood. Brodie says, "when the hair becomes gray and scanty, when specks of earthy matter begin to be deposited in the tunics of the arteries, and when a white zone is formed at the margin of the cornea, at this same period the prostate gland usually, I might perhaps say invariably, becomes increased in size."

The *causes* of chronic enlargement of the prostate are involved

in much obscurity, as will be observed by the following brief sketch of the views of the most experienced authors, relative thereto. My own opinion is, that anything which will create and keep up a continued low grade of irritation in the gland, may be considered a cause of this affection; and I am led to this belief from the fact that in the very numerous cases I have attended, there existed, without a single exception, at some prior time, long-continued irritations of the prostate, resulting from various causes, which were followed by the symptoms common to commencing hypertrophy of this gland, and which gradually increased in degree.

Sir Astley Cooper, considered the enlarged prostate as due to age, and not as the result of disease. And the remarks of Sir B. Brodie, quoted above, imply that he also coincides with this view. Yet how many old men are there who never experience any of the symptoms common to hypertrophy of this organ? Erichsen also considers it a malady of old age, seldom occurring before the age of fifty, and being commonly met with after this. He does not consider it as being a disease proper, unless the enlargement advances to such a degree as to interfere with the free escape of urine. He adds, "though age must be looked upon as the primary cause of this particular hypertrophy of the prostate, there can be little doubt that it may be predisposed to by any continued source of irritation of the urinary organs, such as gonorrhea, strictures, or hard living. Enlargement of the prostate is principally due to fatty degeneration of, with phosphatic deposits in, that organ, the texture of which is usually indurated, though sometimes it has been found to be looser and softer than natural."

Sir E. Home, Wilson, S. Cooper, and others, attribute the enlargement to stasis of the blood in the pelvic cavity; thus, Home names horse-riding as a proximate cause; Wilson states that he has met with cases justifying the observation that the hypertrophy occurs more frequently among those who, having been strictly continent, have not called the genital organs into that degree and kind of exercise naturally designed for them, as well as among those who have been excessive in their sexual acts. But, he also states that many persons who have lived a moderate and quiet life, without approaching either of the above-named extremes, have suffered from enlargement of the prostate. S. Cooper, after stating the cause of the complaint to be unknown, adds that he has known several very sedentary persons to be afflicted with it. Mercier, regards sedentary habits as predisposing causes, and names shoemakers, house-porters, weavers, and tailors, as forming a large part of his hospital cases; he also enquires whether a prolonged vertical

position of the body, may not develop the same results as a sitting one?

Vidal believes enlargement of the prostate to be promoted by irritations, by persistent urethral diseases, or which existed in early life. Sir Chas. Bell believed irritation of the bladder to be a frequent exciting cause where a tendency to prostatic hypertrophy was present. Desault speaks of the malady as being common among elderly persons who have suffered from repeated gonorrheal attacks. Amussat names, syphilis, foreign bodies in the bladder, urethral strictures, the long use of sounds or bougies introduced by the patients themselves, thereby causing a chronic inflammation of the gland, as among the most common causes. Organic stricture of the urethra has long been considered a cause of prostatic enlargement by nearly all authors, though denied by some. Calculus in the bladder has likewise been named as an exciting cause, though doubted by Mercier and some others.

Dr. Gross, in his excellent work on surgery, says: "Hypertrophy is always produced under the influence of causes which act in a slow and permanent manner. Whatever, therefore, has a tendency to keep up habitual engorgement in the organ may be considered as being capable of producing the affection. Augmented action necessarily occasions an augmented afflux of blood, and a corresponding increase of nutrition. Diminished action has a reversed effect. Among the more frequently enumerated causes of this disease, are excessive venery, stricture of the urethra, disease of the bladder, horseback exercise, gonorrhoea, and the employment of stimulating diuretics; but, in general, the influence of these causes is rather apparent than real. They are, no doubt, all capable of inducing the disease; but, on the other hand, it is equally certain that they are often accused when they are entirely innocent. Some of the very worst cases of hypertrophy of the prostate occur in old men who have led the chastest lives, who have not rode on horseback for forty or fifty years, and who have never had the slightest disease of any kind of the urethra.

"Hypertrophy of the prostate is emphatically a disease of old age. The *senile* form of the lesion rarely takes place, at least not in any considerable degree, before the fiftieth year; slight manifestations of it are occasionally met with at forty-five, and, indeed, even at forty, but this is exceedingly rare, and constitutes an exception to an important general law. Hypertrophy, not the result of old age, may occur at any period of life, under the influence of inflammatory excitement and vascular engorgement." It must be borne in mind, however, that the hypertrophy referred to in

the last sentence quoted, is unlike that met with in advanced years; the former is due to a morbid deposit, an interstitial plastic effusion occasioned by the inflammation, while the latter is independent of such inflammatory action, and involves the prostatic tissue itself, being, in fact, an undue development of this tissue.

Exposures to cold, use of vinous, malt, or alcoholic drinks, gout, rheumatism, serofula, lymphatic temperament, recession of cutaneous diseases, external violence, improper use of catheters or bougies, astringent injections for the cure of gonorrhea, habitual straining at stool, masturbation, seminal losses, the long-continued habit of holding the urine in the bladder for hours after experiencing the call to evacuate it, have all been named as exciting or predisposing causes of this affection; of the last three named causes I do not entertain a doubt.

The prostate has been termed the male homologue of the uterus, as there exists between the two organs a great similarity in the character of their constituent tissues, and in the manner in which these tissues are consolidated. H. Thompson, who has given considerable attention to hypertrophy of the prostate, considers it, as well as hypertrophy of the uterus, to be due to some force inherent in the structure of the organs, or associated intimately with some function peculiar to them, and that when the tendency to hypertrophy exists, all circumstances which induce active determination of blood to the locality may aid in its development.

My own view is, that the inherent force referred to by Dr. Thompson is a long-continued or oft-repeated irritation, of a certain degree, in the parts, not sufficient to excite morbid depositions, or decomposition of tissue, but capable of effecting a more or less active determination of blood, disposing the tissues to hypertrophy at that period of life when their vitality has become diminished in its plans or resisting power. And hence the reason why the remark of Dr. Gross is correct, viz.: "Hypertrophy of the prostate is emphatically a disease of old age." For, generally, the vital resisting power of the system begins to diminish at the fiftieth year, and gradually becomes more and more feeble.

Hypertrophy of the prostate is usually observed between the ages of fifty-five and seventy, rarely at fifty, and if not present prior to the age of seventy, it is seldom observed after this age. Although it is a disease peculiar to advanced age, yet all old persons are not subject to it; perhaps one out of every three or four may have a slight tendency to it, but any well-marked symptoms of considerable enlargement will be met with in only one out of

every eight or ten persons, on an average. It is seldom that prostatic enlargement is painful, at least not much so until at an advanced period of the disease. As the symptoms of this affection are nearly identical with some of those accompanying chronic affections of the kidneys, bladder, or urethra, great care must be taken not to confound it with any of them, and especially with those of stricture of the urethra.

As a general rule, the *symptoms* of prostatic hypertrophy, in its early stage, are so slight as hardly to be noticed; indeed, the disease may continue for months or even years before the patient's attention is called to it. In many instances, a sudden and complete retention of urine, following an exposure to some exciting cause, will be the first symptom noticed by the patient, indicative of the enlargement. These irregularities in the symptoms appear to be due to several causes, such as the partial or complete hypertrophy of the gland, the nature of the enlargement, the character of the constitution, habits of the patient, etc. The symptoms of prostatic tumors and prostatic hypertrophy, are so closely allied as to render it difficult to distinguish between them.

One of the earliest symptoms generally observed, is a loss of power in urinating, and the urine flows with less promptness than in former years; these symptoms gradually increase, until considerable effort or straining will be required to project the urine to an ordinary distance from the body. Sometimes, however, these efforts instead of causing a more ready expulsion of the water, tend rather to interfere with its flow. The calls to urinate gradually increase in frequency, the urine flows more slowly than natural, and when the stream ceases the patient does not experience the same satisfactory degree of relief as in former years; there remains a sense of slight irritation at the neck of the bladder, as if a portion of urine were still within this reservoir, and which is, indeed, generally the case. In some instances, the desire to pass water will occur every half hour or hour, and so strongly that the patient will have to make considerable efforts to retain it until he can reach a suitable place for its evacuation, and then, he will be surprised at the small amount of urine voided, or rather, at the disproportion between the degree of the desire to urinate and the quantity of urine ejected.

After a time, the first morning evacuation of the bladder will be followed in a few minutes by a renewed desire to urinate, which will result in the passage of a few drops or a small quantity of urine being discharged, but, generally, without the satisfactory sensation of a complete emptying of this reservoir experienced by persons in

health. Sometimes this desire will be repeated every few minutes for several times in succession. Finally, the patient will not only be frequently called upon during the day to discharge urine, but will also be disturbed through the night, one, two, or more times, by these calls. The sensation of uneasiness experienced at these times, from the irritation at the neck of the bladder, varies in degree from a sense of weight, fullness, or indescribable sensation, even to an actual pain, and extends from the perineum toward the sacrum in the direction of the urethra, and also to the inner and superior part of the thighs, to the pubis, and to the hypogastrium. This pain is especially apt to be felt after having remained for a long time in a sitting posture, in a car, or coach, with the whole weight of the body resting for several hours upon the perineum.

The character of the urinary difficulty will frequently be found to vary, and will not always be in relation with the development of the prostatic disease. Thus, many patients will preserve the faculty of freely urinating, even to the last, while others in whom the hypertrophy is much less advanced, will experience the most marked derangements. Again, in a great number of cases there will be experienced, particularly when the patient finishes urinating, or just after the last drops of urine have been expelled, at the moment when the walls of the bladder apply themselves upon the tumor formed by the enlarged prostate,—a more or less painful sensation, somewhat resembling that experienced by persons having stone in the bladder. More often the patient urinates frequently; awakes during the night to evacuate urine, and the fluid is not projected, but falls between the legs; the stream being flat and deviating as it passes out. In these cases the bladder is never entirely empty, its contents not being expelled below a certain level; this organ is constantly inflamed and irritated by the presence and the forced retention of the urine; a vesical catarrh soon comes on, which the physician as well as the patient may regard as the principal affection, but which, on the contrary, is only a consequence of the abnormal development of the prostate gland.

Among all patients who can not completely evacuate their bladders from prostatic hypertrophy, even the most timorous, those who dread the most the use of the catheter, a sudden and satisfactory feeling of relief and well-being is experienced immediately after their bladders have been emptied by this instrument. If we cease the use of the catheter too soon, or do not recur to it at the accustomed hours, more or less serious symptoms may set in.

As the hypertrophy advances, the uneasy sensations experienced about the pubes, perineum, etc., increase in severity; smarting sen-

sations, aching pains or shooting pains are felt in the urethra, frequently extending to the glans penis. The patient suffers from pains in the testicles, which are sometimes found swollen and tender to the touch. When there is considerable enlargement, attended with a constant feeling of weight and bearing down, or when frequent and great efforts are made to expel the urine, more or less rectal irritation or tenesmus is experienced; and the attempts made to evacuate the bowels, in these cases, eventually produce prolapsus of the anus or hemorrhoids. Evacuations of prostatic fluid, and occasional nocturnal emissions of semen, are by no means uncommon among patients afflicted with the malady under consideration.

The progressive development of the hypertrophy does not successively involve difficulty of urinating, incontinence, retention; this order is often inverted; sometimes the derangement commences with incontinence, sometimes with a complete retention. This incontinence is rather an overflow, or a condition in which the bladder is constantly filled with urine, the excess passing either by a partial urination, or leaking away by drops. This dribbling is more apt to occur at night, when the patient is in bed, though it eventually happens in the day-time also.

At almost any period of the hypertrophy a complete retention of urine may take place upon exposure to some of the exciting causes, as, irregularity in diet, irritating drinks, sexual excitement, cold or damp, retaining the urine for some time after the desire to pass it has been felt, etc., and if the retention be not relieved it will terminate fatally after a longer or shorter time. If the retention does not occur from the exposure just referred to, it will ultimately take place as a consequence of the enlarged gland obstructing the urinary canal. The symptoms, heretofore referred to, slowly increase in severity; it becomes very difficult for the patient to urinate, and it is rarely effected except by persistent straining, which straining augments the rectal difficulties, and not unfrequently gives rise to hernia. The patient makes use of various means to favor the flow of urine, he extends his legs to enable him to make more powerful efforts; he leans forward; pulls at the penis, etc.

As the symptoms become more aggravated, the constitution suffers more and more; there is a gradual loss of strength and appetite, the skin becomes sallow, or, perhaps, pale; the indications of age become much more strongly marked and manifest themselves with more rapidity; febrile attacks often present themselves; the mind becomes peevish or irritable, or the patient becomes careless and inattentive to the most important matters;

the powers of the system gradually fail, and a complete retention, a sloughing of some portion of the gland, excessive nervous exhaustion, hemorrhages, or uræmic poisoning, terminate the suffering patient's existence.

The changes which occur in the urine should, especially, be observed. This fluid at first clear and apparently healthy, gradually loses its transparency, becomes slightly cloudy, with a few small threads or flocculi floating in it; and upon standing deposits more or less mucons with phosphatic matter and crystals of triple phosphates. Not unfrequently a whitish opaque layer will cover the surface of the urine, which may or may not be iridescent. As the disease advances there is an increased deposit of mucons, which becomes thick, ropy, slimy, and very adhesive, does not mix with the urine, contains an increased quantity of triple phosphates, and adheres strongly to the sides of the vessel holding it: and the urine itself when passed, is turbid, opaque, of a pungent, ammoniacal odor, or more or less fetid, and alkaline. If blood be present in the urine, this fluid will be colored reddish-brown, or will present a dark, dirty hne. These characters of the urine are due to its decomposition in the bladder, for however much urine may be voided by the patient, the bladder is never completely emptied; from half an ounce to a pint or more, according to the degree and character of the obstruction at the neck of the bladder, is constantly present in this organ undergoing decomposition as well as abnormally influencing the walls of this reservoir.

If the urine be examined under the microscope, epithelium, blood and pus-corpuscles, large granular globules, uric acid, oxalate of lime, amorphous phosphate of lime, triple phosphates, and uriniferous tubes will be observed, the particular kinds of which and their quantity being dependent upon the peculiarities of the disease and its accompanying secondary affections, in each individual case. But, whatever, other appearances the urine may present, amorphous phosphates and more or less numerous crystals of the triple phosphate of ammonia and magnesia will always be present as essential characteristics of the disease.

It is frequently the case that blood will be observed in the urine, which may be owing to the passing a catheter over an ulcerated or tender surface; to the attempts made to introduce an instrument, when this it found to be difficult; or to an enlarged and congested condition of the capillary veins of the lining membrane of the bladder.

A correct *diagnosis* of prostatic hypertrophy can not, however, be formed from the symptoms alone, because these may be due to

some other cause; it will be necessary to institute a manual examination, which will give positive indications, and which is accomplished by means of the catheter, and the finger in the rectum.

The patient, having previously had the rectum well cleansed, is placed upon his back, on a bed or other convenient article, with his knees drawn upward and somewhat extended apart from each other. The catheter may now be gently introduced into the bladder, if required. But whether this be done or not, the physician, having the nail of the index finger of the left hand cut quite short, and having thoroughly oiled it, gently, slowly, and carefully passes it through the sphincter into the rectum, entering it as far as possible. The method of determining the healthy prostate has already been given on page 1096.

Having introduced the finger, he must, before withdrawing it, ascertain the following points, viz., whether the prostate is enlarged; the direction of the enlargement; whether one or both lobes are affected by it; the extent of the enlargement; whether the gland is uniformly enlarged in its breadth, or forms a globular projection into the rectum; or whether the enlargement is irregular, knobbed, or mammillated? Not unfrequently the enlarged gland will be felt as soon as the finger enters the rectum, and we will have to depress the tip of the finger very much in order to pass it beyond the presenting surface of the swollen prostate. When the finger has been carried up as far as possible along the median line, and meets with a fullness and hardness instead of the yielding coats of the bladder at this part, this will be due to tumor or enlargement of what has been termed the "middle lobe," or, rather, the "median portion" of Cruveilhier.

He must also ascertain the character of the enlargement as to its consistence; whether it is soft or hard; regularly so, or unequally so at various points; or, whether it contains fluid? Can fluctuation be distinctly appreciated beyond the enlargement? "In the latter case, the right hand should be applied to the hypogastric region, and firm pressure made there, with the view of ascertaining if a large body of fluid, such as a distended bladder, can be pressed down upon the apex of the finger, in the rectum below; then gentle but sudden taps should be made on the same region, for the purpose of imparting the wave-like impulse which, under such circumstances, will be communicated. This proceeding constitutes an important mode of verifying the condition of the bladder, and the proper position for the trocar, when the operation of puncture by the rectum is about to be performed, or its applicability to the case in question has to be determined. At

the same time, the situation of arterial branches is ascertained, one or two of considerable size may generally be felt lying a little to the right or left of the middle line, and sometimes crossing it, branches of the hemorrhoidal arteries. The presence of prostatic calculi may generally be thus ascertained, being usually felt with ease, when rather large or numerous, lying in one or more cavities of the prostate, with very little tissue intervening between them and the walls of the rectum." (*Thompson.*)

Any tenderness upon pressure must be ascertained, by pressing upon the gland with considerable firmness, at its center, as well as at its extreme right and left margins; the locality of the tenderness must be noted, also its degree, and the sensation caused by the pressure, as described by the patient at the time. Heat, tension, and severe pain are indications of inflammation.

If the catheter has been passed into the bladder, he may determine the thickness of the tissue which intervenes between it and the finger in the rectum, as well as the situation and direction of the prostatic part of the urethra. And should any calculi be in the prostate, by gently pressing the instrument downward upon the finger in the rectum, a grating sensation will be experienced by the examining finger.

If an ordinary full-sized catheter can not be passed into the bladder, or, if, having entered eight or nine inches within the urethra, no urine is found to flow; and especially, if, in entering it thus far, the handle had to be depressed considerably more than is usual, there will be no doubt of the presence of a hypertrophied prostate. In such cases, in order to reach the bladder, it will become necessary to employ one of the catheters named on page 1143, Mercier's, d'Etiolles', or Thompson's; and the rules there given for their employment in prostatic tumors will be equally applicable in enlargement.

A medical writer, in reference to these examinations into the nature of the disease, its degree of development, extent, and complications, remarks:—"The patient being in the most favorable conditions, and the irritability of the urethra being diminished, the management of exploring instruments becomes more easy and more practicable. We must especially direct our explorations to the interior of the bladder; we must distend its walls by means of an injection in order to determine the condition of its internal surface, and to appreciate the morbid changes produced there. We must carry the exploring instruments over all its surface, without being rough, causing pain, or unpleasant symptoms; we must maneuver in the water, the walls of the bladder being distended as much as their elasticity will allow, without provoking painful sensations and

urgent desires to urinate. By this method, we can determine whether the tumor met with at the entrance of the bladder, and which is due to prostatic enlargement, is complicated or not with fungosities, induration, or thickening of the vesical walls. If the prostatic tumor be considerable, it will limit the exploration, so that it will be difficult, or even be impossible, for us to learn the true condition of the internal surface of the organ; we may not even be able to recognize the presence of one or several calculi contained in the bas fond of the bladder. We see then how important it is to act with skill and coolness, and to renew these explorations if the first do not sufficiently enlighten us, for we can not adopt any mode of treatment whatever, if we are not sufficiently decided as to the correct nature of the affection we are called upon to treat."

Prostatic enlargement may be *determined* from *stricture of the urethra*, by the introduction of a full-sized catheter or bougie; in stricture, an obstruction is almost always encountered before the instrument has passed six inches within the urethra; while in enlargement, the obstruction is not presented until eight or nine inches have been reached; or, if the instrument can be passed into the bladder, its handle will require to be more or less depressed than usual. Stricture is common previous to the fiftieth year; enlargement, after this age. Yet a person may possibly be affected with both at the same time.

In *calculus of the bladder*, the stream of urine may suddenly cease to flow, and at the termination of micturition there is apt to be more or less severe pain. Other symptoms are also present, which it is hardly worth while to name, as, after all, the catheter alone gives the most satisfactory indications of the presence of a calculus. A calculus may exist in connexion with an enlarged prostate; being frequently developed during the progress of the enlargement, by the deposits from the decomposed urine retained in the bladder.

Tumor of the bladder is very difficult of determination; the pain is more severe than in enlargement, and the passing of instruments is almost insupportable. The urine contains sanious matter, flocculi of the structure of villous growth, and blood.—In *chronic cystitis*, *atony of the bladder*, and *paralysis of the bladder*, a rectal examination will ascertain whether they are complicated with prostatic hypertrophy.

Post-mortem examinations have shown us that hypertrophy may involve all the prostatic tissues, either separately or collectively, and that it necessarily effects important modifications in the form, weight, volume, and structure of the gland. The volume of the prostate may be increased even to that of a turkey egg, although

it is more commonly met with about twice its original size; but, much depends upon the age of the hypertrophy, as, an enlarged gland of a few years' standing will be of less volume than one of fourteen or eighteen years'. A few rare cases have been met with in which the gland was as large as an orange, and in one case it was of the size of an average cocoa-nut. The healthy prostate varies in weight from four to nearly six drachms, or, four drachms and fifty grains on an average. The hypertrophied gland varies in weight from six and a half drachms to seventy-five drachms; the most common weight being from seven to twelve drachms, in proportion to the duration of the disease. In the extreme cases, there can be little or no difficulty in pronouncing upon the hypertrophy; but, especially when the gland is a little more or less larger than a horse-chestnut, the most experienced anatomist will be embarrassed in deciding whether there exists a real hypertrophy.

General hypertrophy is when the whole of the prostatic mass has its volume augmented, the gland preserving its natural conformation; its two lobes advancing behind the vesical neck forming a regularly-rounded relief around that region.—*Partial hypertrophy* is when only a part of the gland is affected, as, the right lobe, the left lobe, or the median lobe. As far as the structure of the prostate is concerned, sometimes it is only the gland proper which is hypertrophied, sometimes the muscular tissue, at others, the fibrous tissue, and, again, the vascular structure; or, all these tissues may be equally affected at the same time.

Hypertrophy of the glandular tissue of the prostate. This tissue is more especially hypertrophied when the median portion is affected. The tissue of the gland does not lose its consistence or softness; it is of a deeper-grayish color than in the normal state; and upon cutting into the tissue we can distinctly see the direction and the volume of the prostatic and ejaculatory canals. These canals, as well as the prostatic utricle, are more or less enlarged, and the prostatic canals usually contain an excess of fluid, less opaque, however, than in the normal state.

Hypertrophy of the muscular tissue of the prostate. The muscular fibres which pass from the neck of the bladder into the lateral parts of the prostate, being lost either in the body of the gland or at its surface, are very frequently hypertrophied. In some instances, these fibres are carried downward into the muscular portion of the urethra, and upward in the walls of the bladder itself, which walls are in their turn considerably hypertrophied. There is even a mutual association between hypertrophy of the bladder and that of

the prostate, due to this kind of muscular fibres; accordingly, whenever we discover a hypertrophy of the bladder, we may positively affirm that there is hypertrophy in the antero-lateral region of the prostate. It is in these cases, especially, that the lateral lobes of this organ, not sharing in the enlargement, being even atrophied by the compression, are carried outward and forward; and if we make a rectal examination while the catheter is in the urethra, we will feel this instrument through a thin membrane, so that at first we will believe that the urethra is carried backward. We may thus diagnose hypertrophy of the bladder, by induction.

But while the anterior fibres of the bladder are especially directed in the horizontal direction, the posterior muscular fibres have a transverse course, and may in their turn be hypertrophied; which is more frequently the case. This hypertrophy gives rise to a projection into the urethra, at the level of the vesical neck, and it is one of the most efficient causes of urethro-prostatic obstruction. We must not forget that the development of this portion of the muscular fibres of the prostatic mass is wholly independent of that of the antero-lateral muscular fibres; so that we may observe the lateral fibres very much enlarged, while the transverse are small, and vice versa.

Hypertrophy of the fibrous tissue of the prostate. The prostatic mass is traversed by fibrous septa which represent partitions, filaments, or bridles for each lobe of the gland; beside which, each prostatic duct is surrounded with cellular tissue. Morbid influence upon this part, will, therefore, rather result in fibrous tumors, than in hypertrophy.

The history of these tumors is of some interest, especially as regards their mode of formation. Velpeau has compared the prostate to the womb, and has pointed out an analogy between tumors which are developed in these two organs. Among aged women, especially, tumors are very often observed in the uterus, which are either fibrous tumors or fibrous cords. In this respect, there is a perfect analogy between the prostate and the uterus. These fibrous bodies may exist throughout the substance of the gland; in the lateral lobes, as in the "median portion."

They vary in number from one to twenty or more; generally, they are small when numerous, but, when few in number attain a considerable size. They have been known to become as large, each one, as a normal prostate. They are whitish, and slightly grayish in color, and are of very firm consistence, sometimes being quite hard. Usually, they are imbedded in the glandular paren-

chyina; occasionally they project beneath the mucous membrane of the prostate.

The relations existing between themselves and with the other tissues of the gland are very remarkable. The cellular tissue which surrounds these hard and condensed bodies decomposes very soon, so that by the employment of maceration and putrefaction we may readily detach them. We will then observe that they are round, ovoid, and sometimes irregular. If, on the contrary, a fresh piece be examined, and if we cut through the common fibrous envelop, they will pass out through the orifice as by enucleation; and if we attempt to separate them from the surrounding parts, we may readily do so, but there will always remain a kind of pedicle which is a part of the common mass. When the prostatic mass is filled with such productions, the proper glandular tissue is always atrophied. We seek in vain for traces of the gland; there are no more canals, no more fluids either in the interior of the prostate, nor at its surface. Compress it in all directions, and not a drop of fluid will be expressed; and more frequently the ejaculatory canals will have disappeared from the midst of these fibrous masses.

In stating that these bodies are produced from the fibrous tissues of the region, we must not forget the view of Velpeau, who gives another explanation for some cases. He says, "I have no doubt that these productions *sometimes* have their origin in some matter effused in the substance of the organ; a drop of blood, of plastic lymph, or of pus, may, it seems to me, frequently be the commencing nucleus. In all parenchymatous organs with compact tissue and obscure functions, as the breasts, the uterus, the prostate, there is produced, as a result of congestions, obstructions to the circulation, sanguine, lymphatic, or other exudations, which readily account for the fact in question. The knowledge of the various changes which the blood, or other effused animal fluids may undergo, when retained within living tissues, authorize, it seems to me, the hypothesis I have just advanced."

Some authors have believed that these fibrous bodies were only the natural vesicles or lobules of the prostate, enormously hypertrophied; Velpeau thinks that two things are confounded, in this view. He has also witnessed hypertrophy of vesicles or lobules of the prostate; but it never exceeded the size of a large hazel-nut, was not disseminated throughout the organ in an isolated manner, and almost always presented a pedicle or root with each enlarged lobule, a vestige of their old excretory duct. Upon cutting them, there may be readily expressed from them, a white, viscid matter,

analogous to the prostatic fluid. Fibrous tumors, on the contrary, are homogeneous, larger, more elastic, and formed rather of convoluted fibres than of vesicles; yet, when vesicles are present, they are small, like miliary pimples, instead of constituting the whole tumor. The matter expressed from these tumors differs but little from that of fibrous tumors in general.

In almost every case of hypertrophy of the prostate gland, the neighboring organs become more or less affected, and frequently to a very tormenting degree. The muscular coat of the bladder will be found thickened to a greater or less extent, from the extraordinary efforts made by this organ to expel the urine; while the mucous lining membrane, suffering constantly from chronic inflammation, will present a dark red or black appearance, be thickened and pulpy to the touch, and will have its blood-vessels in a turgid condition; sometimes, this membrane will be seen protruding through the triangular intervals between the muscular fibres, forming cysts or pouches, or it may be ulcerated.—The prostatic portion of the urethra will be found elongated, curved to one side, or, as in the case of enlargement of the “median portion,” it will be drawn upward and immediately posterior to the pubic arch. The seminal vesicles rarely escape being in some manner implicated in this affection.—The ureters are generally more or less dilated, having their walls thicker or even much thinner than in the normal state; and, sometimes, this dilatation will even extend to the pelvis of the kidneys and infundibula.—Even the kidneys themselves will present evidences of inflammation, and of alterations in structure, form, and volume.—The rectum seldom escapes being involved, as indicated by the presence of hemorrhoids, prolapsus, etc. (*See Diagnosis of Urethral Stricture*, page 967.)

The *treatment* of enlarged prostate may be divided as follows:

1. Treatment of prostatic engorgements.
2. Treatment of hypertrophy of the prostate, when detected at an early period.

3. Means of obviating urinary and other difficulties attendant upon enlarged prostate.

4. Operations which have been recommended for prostatic tumors.

1. Prostatic engorgement may occur as a consequence of neglected or badly treated gonorrhea, gleet, stricture of the urethra, irritations caused by the unskillful introduction of bougies or catheters into the bladder, masturbation, excessive venery, etc. (*See Chronic Prostatitis*, page 1106.) In these cases, the prostate may become enlarged to five or six times its natural size, giving rise to various symptoms, among which the most common are, frequent

desire to urinate, more or less difficulty in passing urine, scalding of urine, too rapid emission of semen during coition, and, often, considerable diminution of the sexual desires. Sometimes, there will be no difficulty in voiding urine, but there will be experienced a difficulty or obstruction in the rectum, during the evacuation of the bowels. In the young adult the lateral lobes of the prostate are more commonly found tumefied; hence, although there may be a frequent desire to urinate, there will not be that difficulty in voiding the urine to which old men laboring under hypertrophy of the gland are subject, in whom the "middle or median" lobe is so greatly hypertrophied.

These are not cases of true hypertrophy, and are met with more commonly in early adult life, frequently terminating in abscesses. When the gleet, urethral stricture, or other cause is cured, the enlargement gradually subsides spontaneously. If, however, the tumefaction continues notwithstanding the removal of the cause, therapeutical means must be adopted. The means of treatment are,—*hygienical*, or those directed to improving the health of the body; and, *therapeutical*, or those intended to more directly exert an influence upon the diseased parts. With regard to the *hygienical* measures, they may be briefly summed up as follows:

The bowels must be kept free, never allowing fecal matters to accumulate in the rectum; the skin must be regularly attended to by bathings and vapor baths; hunting, horseback riding, violent exercise, coition, and other causes of prostatic irritation must be prohibited; if there are pains in the spermatic cord or testicles, swelling of the testicles, and desire to urinate frequently, a suspensory bandage should be worn; the diet should be nutritious but moderate, avoiding all kinds of food that will occasion a sense of distress, weight, or heaviness at the pit of the stomach, that will give rise to acid stomach, flatulency, constipation, or that will render the urine of an irritating quality. All high-seasoned food, spices, every kind of liquor, much saccharine matter, and all acids must be positively prohibited. The body should be kept clad comfortably warm, and all sudden changes of temperature, cold, and dampness be avoided or guarded against as much as possible. Exercise may be taken, but not to fatigue; walking or short rides in carriages on a smooth road may be practised; but riding on horseback, or long rides whether in cars or coaches, must be positively prohibited. The patient should associate frequently with pleasing, agreeable companions, to give tone to his mind and overcome any tendency to melancholy or depression.

The *therapeutical* means are for the purpose of reducing the en-

larged prostate to its natural size, and may be considered under two heads, viz., internal and external.

Among the agents used internally, are, Hydrochlorate of Ammonia, Iodide of Potassium, Iodide of Ammonium, Bromide of Potassium, Bromide of Ammonium, and Alcoholic Extract of Conium Maculatum. In many instances, and especially when the engorgement is the result of gonorrhea, the Iodide of Potassium, or of Ammonium, may be administered with marked advantage; a persistent and long-continued use of them will, however, often be necessary,—a rapid diminution of the enlarged prostate must not be looked for under the most successful course, only a gradual approach to the normal condition will be observed. The great difficulty in the way of curing even true prostatic hypertrophy, is the erroneous view of physicians that medicines must, in chronic functional or organic disorders, effect beneficial results in a short time; if they do not, they are discarded and pronounced inefficacious. Chronic or slow, long-standing diseases require chronic, slow, or long-standing treatment, and probably no one of them yields to the influence of remedies more slowly than the enlarged prostate.

I have used the Hydrochlorate of Ammonia in only a few cases, and generally in combination with the Alcoholic Extract of Nux Vomica, and the Alcoholic Extract of Cimicifuga, thus: Take of powdered Hydrochlorate of Ammonia forty-eight grains, Alcoholic Extract of Black Cohosh forty-eight grains, Alcoholic Extract of Nux Vomica six grains, Sulphate of Quinia twelve grains; mix, and divide into forty-eight pills. The dose is one pill, to be repeated every three or four hours through the day. Some little benefit has been observed from the employment of this combination.

But the agents which have appeared, in my experience, to be of the most value, are, the Bromide of Potassium, and the Bromide of Ammonium, more especially the latter. These may be administered in pill form, or in solution, and may be combined with various agents to suit each individual case under treatment; thus, the Alcoholic Extract of Nux Vomica, or, Sulphate of Quinia, (a Bromide of Quinia would answer better) may be associated with the agent used where a tonic is indicated; Reduced Iron, Phosphate of Iron, or Bromide of Iron, etc., where Chalybeates are required; Lupulin, Extract of Belladonna, Extract of Conium, Extract of Cannabis Indica, Atropia, Morphia, Extract of Hyoscyamus, etc., where an anodyne or sedative is needed; etc. The dose of Bromide of Potassium is from three to ten grains, to be re-

peated three times a day; that of Bromide of Ammonium, in solution, two to five grains.

The external or local therapeutical means consist of direct applications to the prostate, or upon some of the neighboring parts, with a view to the reduction of the enlarged gland to its natural size. Direct applications are made either by injecting, through a tube passed into the urethra as far as the prostate, a solution of Iodide of Potassium, Iodide of Ammonium, Bromide of Potassium, or Bromide of Ammonium; or, by bringing the gland in contact with an ointment of the same salts, through the medium of an instrument devised for the purpose. The strength of the solution or ointment employed must be such as not to cause pain, give rise to unpleasant symptoms, or prevent the patient from taking a moderate degree of exercise. The following will give an idea of the proportions: Take of Chloride of Zinc from five to ten grains, Iodide of Potassium from ten to twenty grains or more, Extract of Belladonna from ten to twenty grains, Lard or Simple Cerate, one ounce; mix thoroughly together. Another: Take of Bromide of Potassium from ten to twenty grains, Lard or Simple Cerate one ounce; mix thoroughly together.

These applications are to be made according to the effect they produce; in some cases, two or three times a day, in others once a day, and again, only once every other day. It can not be expected that they will remain in contact with the gland for any great length of time; yet they will remain sufficiently long each time to exert an influence; in addition to which, after they have passed into the bladder and been taken up by the urine, they continue to act efficaciously; it being well known that the quality or character of the urine exerts its influence, for good or evil, upon the neck of the bladder and the prostate.

In addition to this, the same ointment which is applied to the urethral surfaces of the prostate, should likewise be applied over its posterior surface, or rather upon that portion of the rectal wall which covers this surface, and which should be repeated at least as often as every other night; this will greatly aid in facilitating the reduction of the tumefied gland. This operation may be effected by means of a slightly-curved tube, (about an inch in diameter, having an oval opening of the proper size, at its extremity, upon its concave side), being passed within the rectum up to the desired point; through this tube a bent piece of whalebone carrying a sponge holding the ointment is introduced, and the latter brought into contact with the part to which it is to be applied, through the oval opening on the concave side of the tube.

Or, suppositories of these agents may be employed. Of course these urethral and rectal applications are to be made only when the bladder and rectum are empty.

Galvanism, or electro-magnetism, may likewise be employed to stimulate the gland, in severe or obstinate cases, and thus favor its susceptibility to the influence of the medicines used. Although I have but very little faith in these agents as a means of lessening the enlargement, when used alone, I am thoroughly convinced from experience that they render abnormal organs, through which their currents are passed, more sensitive to the action of remedies, thereby causing such organs to return with greater facility to their normal states. One of the conductors being applied to the lower part of the spinal column, the other should be placed upon the perineum, to the groins, and even to the prostate itself. For the latter purpose, I cut off the closed end of a gum catheter or bougie, pass a copper wire through it, and firmly attach to one end of this wire a cylindrical button of silver, about an inch in length, and having the same diameter as that of the bougie; to the other extremity of the wire a ring is screwed on, so as to bring the cut end of the bougie and the upper part of the silver button in close and smooth contact. The urethral conductor or silver button, thus prepared, is passed down into the prostatic portion of the urethra, one of the conducting wires from the battery is then attached to the ring at the upper end of the instrument, and the current applied. It is important, in all cases, that only a moderate current be employed—if too powerful it may prove injurious. This should be applied daily, and for fifteen or twenty minutes each time; if it should cause too much irritation at first, the power of the current must be reduced, or it may be applied every other day.

These means, carefully and perseveringly employed, will seldom fail of proving successful, more especially when the auxiliary measures for overcoming any urinary difficulties which may be present are used in conjunction, as referred to below in section 3. The means above recommended may, probably, be found advantageous in tubercle of the prostate, and even in prostatic hypertrophy.

2. It is very doubtful whether any treatment will be successful in diminishing the hypertrophied prostate of old persons; the tendency of all the tissues of the system, even in a state of health, is, to gradually become more dense and firm as age advances, while, at the same time, the resisting power to disease gradually loses its energy and influence, and the vital stamina advances toward its

minimum. Hence, old persons are less susceptible to the influence of remedies, and less apt to have thorough and permanent cures made of chronic disease, than young ones. And, as Sir B. Brodie has correctly stated,—“The prostate of a man advanced in life can not be rendered like that of a young man, any more than his gray hairs can be converted into black; but the train of evils which the enlarged prostate produces by its influence on the urinary organs may be, in some instances, altogether prevented, and in others very much diminished, so as to remove the patient from a state of extreme, and even immediate danger, to one of comparative security.”

Notwithstanding this, it is certainly the duty of the physician to attempt the reduction of an enlarged prostate, by the means recommended, especially when the patient is in the prime of life, healthy, the enlargement of the gland is regular and uniform, and there are no contra-indications to the treatment. When it is taken into consideration that the remedial agents advised have exerted beneficial influences in bronchocele, uterine enlargements, and other instances of hypertrophy, it must certainly be deemed, at least, justifiable on the part of the physician, to employ the same agents with a view to the diminution of prostatic hypertrophy, when such agents may be used without exhausting the system or disturbing the functions of digestion, and without increasing the severity of the symptoms or the irritation of the parts around the neck of the bladder. And, although we can not hope for much benefit therefrom, in the case of prostatic tumors and outgrowths, we may certainly anticipate some beneficial results in the treatment of hypertrophy of this gland, especially when we have been enabled to detect its existence at an early period. The agents and means advised for this purpose are the same as recommended for prostatic engorgement, in the preceding section, and their employment should be perseveringly persisted in for several months in order to allow them full opportunity for exerting a beneficial influence.

3. However doubtful may be the result of a treatment instituted for the cure of hypertrophy of the prostate, much may be done toward relieving the various accompanying symptoms, diminishing some, and preventing others, thereby not only affording a greater degree of enjoyment to the patient, but also prolonging his existence. And the earlier these measures are adopted, and the more perseveringly and skillfully they are pursued, the less liable will the patient be to any serious results from the disease under consideration.

One of the ordinary symptoms of prostatic hypertrophy, and which occurs even at an early period, is, the habitual *partial retention* of a part of the urine, this fluid not being completely removed

from the bladder, whatever may be the efforts of this organ to expel it. The retained urine may vary in quantity from a few fluidrachms to several fluidounces; usually, in these cases, shortly after having urinated, the patient experiences nearly, if not quite as urgent a desire to pass urine as before; and the irritation of the parts, the pain, and the constant desire to void urine, is a source of the greatest annoyance and suffering, and especially, when in addition, a few drops leak from the urethra, after a urination, and moisten the patient's linen.

When this symptom is present, and the physician has determined by the introduction of the catheter, as well as by a rectal examination, that the prostate is enlarged, it will be his duty to make use of means to ensure a complete evacuation of the urine from the bladder, which will not only lessen the tendency to irritable and other conditions of this viscus, but will also diminish the progress of the hypertrophy. To accomplish this purpose, there are two important measures to be pursued; first, regularity of the bowels, and second, the use of the catheter.

Constipation, or an accumulation of fecal matter in the rectum is very commonly met with among persons having enlargement of the prostate, and is often a source of annoyance to both patients and physicians. It may be due to want of tone in the lower bowels, or, more commonly, to an encroachment of the enlarged prostate upon the calibre of the rectum, thereby obstructing the free passage of the feces; and when constipation is obviated, the introduction of the catheter will be thereby facilitated. In instances of complete retention of urine, where I have met with no success in my endeavors to pass the catheter into the bladder, an injection, or a laxative medicine by mouth, has, by causing the evacuation of the bowels, enabled me to introduce the catheter with facility, and thus give relief to the patient; and, in a few instances, I have known the urine to flow without the aid of the catheter, as soon as the alvine discharges were procured. I recollect one case in which it was absolutely impossible to introduce the catheter into the bladder, and in which the patient was in great agony from complete retention of urine; he had been greatly constipated previously, and purgative medicines by mouth exerted no influence, while the impacted, hardened feces prevented the injection, attempted, from entering the rectum. In this case, a portion of the fecal matter was scooped from out of the rectum, so that an injection could be administered; and as soon as an evacuation of the bowels was effected, on attempting to introduce the catheter, it passed very readily into the bladder. The rationale of this must be obvious to every medical man.

When the bowels can be kept regular by the use of figs, prunes, cornmeal, or other articles of diet, not otherwise contradicted, it will serve a much better purpose than the employment of medicines, which must necessarily tend to weaken the tone of the alimentary canal, especially if their doses have to be augmented. But when these dietary articles fail in producing the desired end, medicines will be required, as Sulphate of Magnesia, Rhubarb, Extract of Butternut, etc. Preparations of Nux Vomica or Strychnia are peculiarly applicable in these cases; they may be added to the solvent or laxative medicines administered. The object is, not to purge, for this will weaken the patient, but to keep up as nearly as possible, a natural, healthy, daily discharge from the bowels, and for which purpose the doses of the laxative employed must be properly regulated. Fecal matter must not be allowed to accumulate in the rectum.

Injections, administered with an instrument having a rather short pipe or nozzle, will frequently be found to answer the indications much better than internal medicines,—and, where they are daily required, the addition of Iodide or Bromide of Potassium or of Ammonium, may serve a useful purpose. Very active injections are, as a general rule, to be avoided; the milder the injection, so as to effect the desired end, the better.

Partial retention of urine requires the use of the catheter, so as to procure a thorough evacuation of the bladder at least as often as once in every twenty-four hours; and, in cases, where several fluid-ounces are retained, the use of this instrument may be required two or three times during the above-named period. “This plan is to be pursued, probably, to the end of the patient’s life. It may be distressing to him to be thus dependent on the use of the catheter, but it is the least of two evils. The repeated introduction of it is an inconvenience, but it prevents misery and destruction. Without it, slow inflammation of the mucous membrane of the bladder, extending along the ureters to the kidneys, will supervene; abscess will form in the prostate; and probably stone in the bladder. But where the catheter is used regularly, these evils are at any rate delayed for a considerable time, and in by far the greater number of cases are prevented altogether.” (*Sir B. Brodie.*)

As to the kind of catheter to be employed, some medical men prefer the gum or flexible, and others the metallic. In these cases of partial retention, the gum catheter, with or without the iron-wire stilet, will be found to answer, in most cases; it is more easily introduced and there is less danger to be apprehended from it, than when the metallic one is used. It should be of a diameter suffi-

cient to fill the urethra without stretching it or causing pain: a smaller one will be liable to become entangled in some portion of the mucous lining membrane, or in the prostatic enlargement, and thereby not only fail in entering the bladder, but likewise cause more or less irritation, etc. If the stilet be used, it will be in those cases where the tumor forms a considerable projection into the bladder, and obstructs the entrance of the beak of the instrument into this organ. In such instances, the catheter will require a greater curve than usual, in order to enable it to pass over the obstruction, and the curvature necessary for this purpose may be given to the stilet. The degree of curvature required can only be ascertained by the physician, after a few trials. The same rules are to be followed in introducing the catheter, in difficult cases of partial retention of urine, as are hereafter named for its introduction in cases of complete retention.

In the use of gum catheters, whether introduced by the physician or patient, the latter should be provided with a number of them, and should keep them in a cool place, having each one mounted on a well-curved, stout iron stilet. When one is to be used, the curved stilet should be withdrawn, and a straight one of sufficient diameter to fill the canal of the catheter should be passed in it as far as to the commencement of the curved part, which gives greater firmness to the stem of the instrument thus filled. Then oil and introduce it, and, upon removing the straight iron stilet or support to the shaft of the instrument, the urine will flow. As the curved part tends to become straight after having been used, or when warmed, the instrument should be remounted upon the curved stilet as soon as it has been cleansed, and its internal walls have become dry. In some cases, I have found a catheter with only one orifice at its beak or extremity, to answer a much better purpose than the instrument ordinarily manufactured, with orifices upon the sides.

Some medical men prefer the silver catheter, and cases will, undoubtedly, be met with, in which it will be found necessary; but, beside being of more difficult introduction, especially when used by the patient, it is more liable to lacerate or puncture the urethra, or occasion hemorrhage, and when once introduced, it can not be so conveniently retained for any length of time, should this be necessary. The gum catheter, on the contrary, may, as in cases of complete retention, be allowed to remain for several days before withdrawing it.

In cases of partial retention of urine from enlarged prostate, the catheter will be required once or oftener, daily; but it should never

be introduced more frequently than is absolutely necessary. As long as there is pain and irritation of the bladder, or in the neighborhood of the prostate, and as long as the urine deposits aropy, tenacious, alkaline mucus, or, hemorrhage from the urethra is observed, the patient should continue under the immediate attendance of the physician. But in the absence of these symptoms, or of any other requiring personal medical assistance, the patient should be taught to introduce the catheter for himself, as soon as the physician has ascertained the degree of curvature necessary to give to the instrument, as well as the peculiar dexterity and management of it, suitable to each individual case; in all of which, the patient should be thoroughly instructed.

As a general rule, patients who are carefully instructed in this operation, pass the instrument with much greater facility than any second person could; as they soon learn the sensations produced by it in every part of the urethra, as well as the points where obstructions are encountered, and the peculiar tact and manœuvering required to pass the instrument by them. "Now, it is this continued use of the catheter, in those cases in which the patient is unable completely to empty the bladder by his own efforts, which constitutes the principal part of the treatment to be employed in ordinary cases of disease of the prostate gland. In some cases nothing more is required; and the patient who is dexterous in the use of the catheter, and who is careful never to neglect the regular introduction of it, passes through the remainder of his life, an invalid indeed, but with little or no actual suffering; and dies at last of some other disease, entirely independent of that which exists at the neck of the bladder." (*Sir B. Brodie.*)

Complete retention of urine also demands the employment of the catheter; and the elastic or gum instrument should, in my opinion, always have the preference over the silver one, wherever it can be successfully used; because, should it be desired to retain it for any length of time in the urethra, after having introduced it, a second operation is thus rendered unnecessary. But whichever instrument is employed, the physician should have on hand, a number of each kind, having different curvatures, in order to be prepared to meet the different cases which may be presented for treatment. These curvatures will vary from that given to the ordinary silver catheter to one at right angles, depending upon the degree of the enlargement and of the deviation of the urethral canal from its normal direction, and which can be determined only after one or more trials. Great care should be had that the last inch or two of the beak of the instrument be sufficiently curved; for, however well

the rest may be curved, if the end is straight, or even nearly so, it will be very difficult, if not absolutely impossible, to pass it into the bladder. In some cases, it may be required to employ a catheter twelve or fourteen inches long; as, for instance, when that portion of the urethra behind the triangular ligament is lengthened, as well as altered in its direction. All these catheters should be quite round at the point or beak.

Every physician knows that even when the urethral canal is free, difficulties are frequently encountered in attempting to pass the catheter into the bladder, and which must be greatly augmented when this canal is obstructed by tumors or enlargements; it is proper therefore, to know beforehand, whenever this can be done, the cause of these difficulties, in order that we may be prepared to overcome them by the correct means.

In the introduction of the catheter, no rudeness, no force, no violence must be attempted. If the urethra be irritable, spasm of its membranous portion will follow such a course; or, as frequently occurs with rough and inexperienced operators, the instrument may be made to pierce the wall of the urethra at some point, forming a false passage, and thus adding to the difficulties already existing to the passage of the catheter into the bladder, as well as originating a liability to the formation of abscess.

Dexterous and gentle manipulation is alone required; the catheter should be held rather loosely between the thumb and first two fingers of the right hand, at its upper or open end close to the ring; while the penis should be held between the fingers of the left hand,—the patient having previously placed himself in a recumbent posture, lying upon his back with his legs drawn up. Holding the straight part of the instrument in a horizontal position, and parallel with the line of the left groin, introduce the point or beak into the meatus urinarius, and carry it into the urethra as far as it will enter in this position; then, gently raise the handle a little, at the same time moving it to the median line of the body, which manœuver causes the point of the instrument to enter the subpubic curve. Next, gradually elevate the handle nearly at a right angle to the pubes, and, keeping the beak of the instrument closely along the upper part of the urethra so that it will slide closely under the pubic arch, slowly and gently depress the handle, (which may be done by placing a single finger on it) moving it downward toward the space between the patient's thighs. If this manipulation be dexterously performed, without force, the point of the instrument, if this be of the proper curve, will ride over the enlarged portion of the prostate and slide into the bladder.

Various other manœuvres may be required in difficult cases before the catheter can be made to enter the bladder. In some cases, where the gum catheter is employed, after advancing its point, as above stated, as far as the obstacle, it will pass into the bladder only upon withdrawing the stilet. Again, as the beak encounters the prostate, it may be made to slide into the bladder, by raising it or pushing it forward, either by pressure made on the perineum, or by means of a finger introduced into the rectum. Or, the operation may prove successful, if the concave surface of the instrument be kept closely but gently pressed against the pubic arch, while the handle is being depressed downward. Sometimes, it may be necessary to employ a longer catheter and one having a greater curve, in order that the beak may ride over the prostatic enlargement. And, if the tumor be so large as to completely block up the median portion of the passage, a small opening only being present at one side of the projection, it will be necessary, after having carried the beak as far as the obstacle will permit, to incline it to the right or left, that it may be enabled to enter such opening, and thereby reach the bladder. Other artifices may be required, but they can only be determined by practice, experience, good judgment, and a knowledge of the anatomy of the parts in health and in disease.

It may be proper to state here, that congestion of the prostate and engorgement of its vessels, which add to the volume of the already enlarged gland, is frequently the result of exposure to cold or dampness, as well as of various other causes. But whatever may be the cause, the congestion may be removed, at least sufficiently so to facilitate the introduction of the catheter, by immersing the whole body in a hot bath, or, (and which I prefer when it can be procured), by pounding fresh Stramonium Leaves to a pulp, adding hot water to the pulp; and applying it to the perineum, allowing it to remain on for twenty or thirty minutes, or even longer if necessary; this likewise relieves the distressing and uncontrollable paroxysms of straining to pass urine, from which patients frequently suffer. A fomentation of dried leaves of Stramonium and Lobelia in hot water, forms an inferior substitute for the preceding one.

If the attempt to pass the catheter into the bladder has proven successful, the next thing is to determine whether this viscus should be completely emptied or not. Instances have occurred in which an immediate and thorough evacuation of the contents of the bladder has been followed by depression, syncope, and death; and this result is more apt to occur in cases where the bladder has

been kept in a greatly distended condition for some time, from the retention, even when there has been a constant leakage or dribbling of urine. The rule to be governed by is, that in cases where retention of urine has remained for some time, or where there has been a constant dribbling of urine, the bladder being distended all the time, the withdrawal of the urine should be gradually accomplished, so that the bladder may be able to accommodate itself, by degrees, to the healthy condition of contraction. Therefore, in such cases, after some twenty or thirty ounces of urine have been removed, the catheter should be allowed to remain, placing a plug in its open end to prevent any further flow; in the course of half an hour, or an hour, some more may be allowed to flow out, and so on,—care being subsequently taken, in these instances, that the bladder be thoroughly emptied of its contents once or twice every day.

Another point to consider is, whether, in any case, the catheter should be removed after the bladder has been evacuated, or should be allowed to remain. In cases of urinary retention it is a very general circumstance, that after the withdrawal of the urine, the bladder soon becomes filled again, requiring the use of the catheter anew, within from three to six hours from its first introduction. Its re-introduction will increase any irritation already existing in the parts, and may also be found a much more difficult task than before. It is, therefore, a much better plan to allow the instrument to remain, plugging its open end so as to prevent the urine from trickling away, at the same time applying one of the above-named fomentations to the perineum to subdue any irritation which may be present. The instrument should be fixed, by tying or otherwise, so that its beak will not project into the bladder to create irritation, and the plug should be removed every few hours, as may be required, to admit the urine to flow out. This course will be still more strongly indicated if great difficulty was experienced in introducing the catheter at first. There may be cases met with, in which the physician would be justified in removing the instrument soon after the urinary evacuation, and which must, of course, be left to his judgment to decide; but, in the majority of cases, the rule above given will prove the safest and surest mode of procedure. As to the time during which the catheter may remain, it will differ according to circumstances, from twenty-four hours to three or four days, depending much upon the degree of contractile power resumed by the bladder. And, in all cases, this viscus will require to be artificially evacuated once or twice every day, until it has fully regained its power to normally effect this

evacuation. As with partial retention, after a suitable time, the patient may be instructed, so as to introduce the catheter himself.

If the mucus is very viscid and offensive, tepid water may be injected into the bladder by means of a catheter with double canals, washing it out, in this manner, as often as may become necessary. In such cases, it is better always to employ the double-channelled catheter instead of an ordinary one, after the first catheterism.

Where it has been necessary to allow a catheter to remain for some time in the urethra, I have met with very satisfactory results from the employment of an instrument made as follows: An ordinary silver catheter, but without any small holes or eyelets, has its closed end cut off so as to open this extremity; a round silver ball is carefully and accurately fitted to this open end, so that it may be withdrawn through the canal of the instrument by means of a stout flexible wire, which holds the ball in place (projecting out a short distance from the cut end of the catheter), by means of a cap and screw at the other end of the instrument. Having introduced this into the bladder, unscrew the cap, withdraw the ball, and pass in a gum catheter, which may, if necessary, be held in its place by means of a long wire stilet, while the silver catheter is being removed. The gum catheter may now be permitted to remain as long as may be desirable, but never to exceed two or three days.

Mr. H. Thompson has devised an instrument, as follows: "A full-sized catheter, of the No. 1 prostatic curve, but completely open at its extremity, as if the point were cut off; a flexible gum catheter of a size adapted to fill pretty accurately the channel of the silver catheter, is to be passed through this, just so far that the point of the flexible instrument protrudes, forming an obturator and point; this apparatus being passed down to the obstruction, and the silver catheter being held by the left hand, the flexible one may be gently pushed onward through the former, and may find its way into the bladder, when neither the silver nor the flexible instrument would pass alone."

Other forms of catheter have been devised by M. Mercier, one to be used as a last resort, when other catheters have failed to pass the obstruction, and another for the purpose of avoiding false passages. The reader will find an account of them in II. Thompson's monograph upon Diseases of the Prostate; it is unnecessary to describe them here, as they will seldom be required except in cases which have previously received unskillful treatment.

But, if no instrument can be passed into the bladder in the ordi-

nary way, and it is absolutely demanded that speedy relief to the patient suffering from urinary retention be afforded, what course is there to pursue? Such instances may occasionally be met with. The means which have been recommended are, forcible catheterism and puncture of the bladder. Of these, the first is considered

hæsafer operation, although either of them are liable to be followed by fatal results. A silver catheter of proper strength, having a conical form at its beak, is introduced as far as the enlarged prostate; the operator will then ascertain that the instrument is fairly within the urethra, by a finger passed into the rectum, also that it is in the median line of the body, at a proper distance from the pubic arch as well as from the rectum, and that its beak is against the prostate. Satisfied on these points, he will carefully, steadily, and firmly press the beak onward in the direction of the cavity of the bladder, gradually depressing the handle as the instrument advances, and ceasing all efforts as soon as no further obstacle is felt, and urine passes. It has also been recommended to perform this operation by means of a silver canula, having a curvature like that of a catheter, through which a trocar or cutting stilet is passed for the purpose of perforating the obstruction.

Whichever is used, (the catheter or canula), after it has entered the cavity of the bladder, it should be allowed to remain for about forty-eight hours, when a catheter should be introduced to preserve the opening thus made, and to favor the formation of a mucous membrane upon its walls. After which the aperture may be prevented from closing by occasional introductions of the catheter.

It usually happens that after having evacuated the bladder, in these cases of urinary retention, this organ does not readily recover its contractile power, and the use of the catheter will be required once or twice daily for several weeks, aided by such internal agents as will restore tone to the enfeebled or paralyzed organ, as Quinia, Strychnia, Ergot, Electro-magnetism, etc.

The operation for puncture of the bladder may be performed through the rectum, through the symphysis pubis, and above the pubes. These operations are very rarely demanded, though cases have occurred in which the patients' lives were thereby prolonged for several years. It is unnecessary to describe them here, as detailed accounts of them are given in the best surgical works.*

* Mr. H. Thompson describes these operations, in his work on Diseases of the Prostate, as follows:

"The supra-pubic, at one time regarded as the only possible mode of reaching the bladder from the surface in cases of enlarged prostate, is performed as follows: The patient being placed in a half-sitting, half-reclining position, and the

When the bladder becomes engorged with urine, the neck is dilated, and the surplus urine overflows and passes off involuntarily ;

pubes shaved, a vertical incision of the integument is made directly above the symphysis pubis, about an inch and a half or two inches in length at the surface; this is to be carried downward through the linea alba, so as just to admit the tip of the finger to recognize the distended bladder. Meantime, an assistant standing behind the patient, should press one of his hands firmly on either side, against the abdominal walls, in such a position as to steady the bladder. A straight, or a slightly-curved trocar (if the latter, the convexity of the curve should be upward), is then to be carried, with a very little inclination downward, into the bladder. The puncture should be made, not quite close to the pubes, or as the bladder contracts the opening will tend to recede downward behind the symphysis; nor should the distance from it at all exceed an inch, else the peritoneum will be endangered. When the distension is considerable, this membrane is carried two inches or more above the margin of the symphysis. In this case also it is better not to empty the viscus immediately when very large, in order to avoid the evils resulting from the sudden removal of pressure from the abdomen. After the operation the canula should be exchanged for a silver tube specially adapted to slide through it, secured by tapes and a T bandage, which may remain a variable length of time, at all events until lymph has been effused upon the edges of the wound, when it may be withdrawn, and an elastic gum catheter worn in its place, an instrument which is generally better tolerated by the bladder than one made of metal. * * *

"The puncture by rectum, commonly adopted in stricture, but which has also been resorted to in a few cases of retention with enlarged prostate, may be performed in the following manner: The rectum having been emptied, if necessary, by means of an enema, the patient is to be placed upon his back, in the position for lithotomy, and firmly held by two assistants, not tied. The surgeon is then to introduce the forefinger of his left hand into the bowel, and ascertain the limits of the prostate, defining its boundaries, if possible, particularly the posterior one. *Fluctuation should be felt there*, communicated through the contents of the bladder, from a tap, or from momentary pressure made on the hypogastric region; and the point at which it is most distinctly perceived in the median line selected. Any spot within fair reach of the finger, under the circumstances of retention and consequent distension of the parts, may be considered safe as regards the peritoneum. Having directed an assistant to support firmly the lower part of the abdomen with both hands, so as to press down and steady the bladder toward the rectum, a well-curved trocar, seven or eight inches long, should be carried along the finger, and carefully directed to the part indicated; the handle is then to be depressed, and the point carried upward through the coats of the rectum and bladder, until it is felt free in the cavity of the latter. The canula is to be carefully kept in its place while the trocar is withdrawn, and afterward retained there by means of a bandage and tapes" (He prefers Mr. Cock's instrument, the canula of which can have its extremity somewhat expanded after its introduction into the bladder, so as to lessen the danger of its slipping from this organ.)

The puncture through the pubic symphysis, he thus describes: "The patient should recline, and the trocar (a cylindrical one—an ordinary hydrocele trocar of middle size), should be introduced, whether after a small preliminary division of the integuments or without it, appears to be immaterial, about the center of the

this has been erroneously termed *Incontinence of Urine*, but it is simply *retention of urine with engorgement and overflow*, and requires the same treatment as recommended for retention, viz., the catheter.

Atony of the muscular coat of the bladder, in which this organ loses its muscular contractility to a greater or less degree, so that it becomes incapable of expelling the urine, even after this fluid has been withdrawn by catheterism, is frequently observed in cases of enlarged prostate. In most instances the regular evacuation of the bladder by catheterism, continued for ten or fifteen days, will be followed by a return of its contractile power; sometimes, however, the atonic condition will remain, and urine passes through the catheter, either by pressing upon the region of the bladder, through the abdominal walls, or, by the pressure exerted upon the bladder by the intestines while the patient is in an upright position. Remedial measures will then be required, although they will not invariably prove successful in removing this condition.

- Cold water suddenly applied to the thighs, the abdomen, or the back, will aid very much in facilitating the contractile efforts of the bladder; or, cold water may be injected into the bladder every day or two. A solution of Strychnia injected into the bladder, has also proved efficacious, after having been repeated several times; it must, however, be employed with judgment and carefulness. Internally, the remedies which have been found the most effectual, are, Strychnia, in doses of from one-tenth to one-fiftieth of a grain, repeated two or three times a day, carefully watching its effects, and ceasing its use when any untoward symptoms appear. Ergot of Rye, is another efficacious agent; it may be given in doses of from five to ten grains of the powder, repeated three times a day;

symphysis, reckoning from above downward, and in a direction at about right angles to the vertical axis of the body, (somewhat obliquely downward and backward toward the sacrum, varying the direction according to circumstances). A piece of flexible catheter is then to be introduced through the canula, and retained by a tape."

The puncture by rectum is the simplest and safest of these operations, when temporary relief only is intended. But it can not always be performed, as the enlargement of the prostate may be so great as to prevent the finger from reaching the tumid bladder behind it. The puncture above the pubes is more dangerous than the preceding one, especially among corpulent persons, although often successful, and affording a relief which has continued for several years; and it is to be preferred in those cases, where the catheter can not be introduced through the urethra, and where a new opening must be the patient's only resource for a considerable period of time. The puncture through the symphysis pubis, has not yet been sufficiently practised to develop its advantages or disadvantages.

or the tincture may be administered in doses of from half a fluidrachm to a fluidrachm; the use of this agent should not be too long continued, on account of its pernicious effects when taken uninterruptedly for a length of time. Cantharides, Extract of Arnica, and Tincture of Iron, have likewise proved efficacious.

The following preparation has been found to exert a most potent influence: Take of Strychnia one grain, of powdered Cantharides two grains, Extract of Arnica from forty-eight to eighty grains. Mix well and intimately together, and divide into twenty or twenty-four pills. The dose is one pill, repeated every eight hours; and their use should cease as soon as twitchings are observed, or when strangury occurs, or the stomach becomes irritable; commencing their employment again, in smaller doses, as soon as these effects have passed off. When indicated, a grain of Steel dust, or Oxide of Iron may be added to each pill.

Another excellent preparation is composed of Citrate of Iron and Strychnia three grains, Sulphate of Quinia one grain, Cantharides one-fourth of a grain, Extract of Arnica nine grains; mix, and divide into three pills, of which one pill is to be given every six or eight hours, as above.

Counter-irritation to the sacrum, as well as to the pubes, may frequently be beneficially associated with the above-named remedies; as, by sinapisms, Croton Oil Liniment, Firing, or Compound Tar Plaster, etc. I have found the addition of finely-powdered Arnica to the Compound Tar Plaster, very useful in obstinate cases. It has also been recommended to vesicate over various sites of the lumbar portion of the spinal column from time to time, each blister occupying a space of about one or two inches in diameter, over the vesicated surface of which, about one-eighth, one-sixth, or one-fourth of a grain of finely-powdered Strychnia should be sprinkled; one blister only should be formed at a time, for this purpose.

Electricity, or electro-galvanism is said to have answered an admirable purpose in several instances. The current may be passed from the lumbo-sacral region of the spinal column to the pubes and adjacent parts, and to the perineum. A gentle current may likewise be passed from the lumbo-sacral region of the spinal column, to the neck of the bladder, or as near to it as can be reached by the urethral conductor.

In the treatment of the difficulty under consideration, the digestive organs and bowels must be carefully attended to; employing a nourishing but easily digestible diet, and promoting regular daily alvine evacuations by articles of diet, injections, etc.; avoiding active catharsis or drastic purgation as much as possible.

Inflammation of the Bladder, Irritability of the Bladder, and Incontinence of Urine, which frequently attend enlarged prostate, must, when present, be treated as already laid down under their respective heads.

Hemorrhage from the prostate may occur spontaneously, or may be due to the introduction of an instrument into the urethra, or to its retention for some time. Unless profuse, little else will be required than rest in the recumbent position; otherwise, it must be treated upon the principles laid down under the head of *Hemorrhage from the Bladder*. Also see *Phosphatic Deposits*, page 945.

4. The operations which have been recommended for prostatic enlargement and tumors are as follows:

a. Compression has been employed by many surgeons; its mechanism is two-fold, to render the urethral canal rectilinear, its deviation being one of the frequent results of prostatic enlargements, and to change the vitality of the organ by modifying its circulation, and thus promoting discussion or absorption. For this purpose large elastic and metallic catheters have been employed; instruments having several branches are to be introduced with the branches closed or lying together, and as soon as these reach the neck of the bladder, they are to be separated, and compress the abnormal projections; also elastic tubes, which, when introduced as far as the vesical neck, are to be distended by forcing water into them.

Compression is a painful method, is very difficult to support by the patient, is apt to give rise to great irritation of the parts, and is generally attended with no desirable results.

b. Incision has also been employed, but it seems to be more applicable to those muscular bar-like obstructions which are sometimes met with at the neck of the bladder; and, in which cases, when properly performed, it appears to have afforded much relief to the patient from the distressing symptoms which had not yielded to the several means previously pursued.

M. Mercier, a French surgeon, dwells especially upon these obstructions, and advises to incise at one, two, or three places, for which purpose he has devised several instruments, which may be reduced to a bent sound, in the interior of which is a cutting-blade, which incises the bar, either from behind forward, from in front backward, or by a to and fro motion. Various other instruments somewhat similar in construction have been employed by French surgeons. Incisions seem to have another object, that of deeply *scarifying* the prostatic tissue. This method is based upon the fact

that after the operation of lithotomy, the prostate has rather a tendency to atrophy than to hypertrophy.

Incisions of the prostate constitute a very uncertain method; when of limited extent, their effect is rendered null by their rapid cicatrization; and when deep, they are liable to cause hemorrhage, inflammation, or other serious symptoms. Their employment should be confined only to well-ascertained cases of bar at the neck of the bladder.

Excisions, which are only a variety of incision, has for its object the removal of a portion of the bar, especially when this is wide and rounded, or, of one of the abnormal projections of the prostatic lobes. Several instruments have been invented for this purpose. M. Mercier employs a kind of lithotrite with two branches; the bar is seized between the branches, they being separated, then by closing them the excision is accomplished.

Cauterization, which has also been advised in the treatment of prostatic enlargement, is of very little efficacy, besides being of very difficult application.

Crushing is another operation which has been attempted; the projecting tumor is embraced between the blades of a lithotomy forceps, and is crushed or torn, so as to develop sphacelus in the part.

Ligation, is another difficult and very limited operation, though if it can be accomplished, it is the least dangerous of any of the mechanical means above referred to, and may prove successful in removing polypoid tumors coming from the median portion of the prostate.

All these mechanical means which have been proposed for the treatment of prostatic tumors are very difficult, and very limited in their application, because of the depth of the gland, and the shallowness of the surrounding urethral space, and their results are, as yet, very problematical.

CHRONIC DISEASES OF THE EAR.

ANATOMY OF THE EAR.*

USES OF THE DIFFERENT PARTS OF THE ORGAN OF HEARING.

1. The *auricle* has two uses, viz.: to receive and reflect sonorous undulations, and, up to a certain point, direct them into the auditory canal; thus, the undulations which strike upon the concha, are re-

* Before entering into a description of Chronic Diseases of the Ear, it may be of some utility to briefly refer to the anatomy of this organ. The auditory apparatus, consisting of many parts, has been, for the sake of description divided into three parts, viz., the external ear, the middle ear, and the internal ear.

I. The EXTERNAL EAR consists of the following parts, viz.:

1. The *auricle*, or expanded portion, also called *pinna*, and *pavilion*, is a thin, transversely flattened, semi-oval, fibro-cartilaginous appendage, wider above than below, continuous with the neighboring parts, free above, below, and behind, situated on each side of the lateral region of the head, below the temple, behind the cheek, and in front of the mastoid process. Its external face is inclined forward, and is concave throughout most of its extent. The inequalities caused by the eminences and depressions of the outer surface of the auricle, also exist in its fibro-cartilage. This fibro-cartilage is fixed around the auditory canal by three ligaments.

2. The *helix* is a fold, or half-circular prominence, found on the outer, posterior, and superior edge or boundary of the auricle. It commences at the center of the concha, above and somewhat behind the boundary of the external meatus, passes along the outer margin of the auricle, and gradually becomes thin, narrow and fleshy, losing itself in the lobule.

3. The *antihelix* is another prominent ridge, arising in front by two ridges from behind the anterior curvature of the helix; it proceeds at first longitudinal, parallel to the helix, then obliquely from behind forward, describing a circuit around the concha, and terminating in the antitragus. Of the two ridges at its commencement, the inferior one is narrow, more acutely prominent, partly concealed under the helix, and proceeding horizontally forward, while the superior one is larger, obtuse, and directed obliquely forward in such a manner as to form, with the inferior one, a small triangular cavity, called the *fossa of the antihelix*, or the *fossa navicularis*.

flected upon the tragus, which in turn reflects them into the auditory canal. And, notwithstanding we may occasionally encounter

4. The *fossa of the helix*, (*fossa innominata*), is the narrow, curved groove situated between the helix and antihelix.

5. The *concha* is the deep, capacious cavity, looking obliquely outward and forward, transversely elongated, somewhat divided into two parts by the commencement of the helix, narrower above, and triangular or funnel-shaped from without inward, where it is continuous with the meatus auditorius or external auditory canal. The cartilage of the concha is enveloped by a fine skin; the subjacent cellular tissue contains little or no adipose matter; and this part readily becomes deeply and extensively ecchymosed by severe frictions and bruises.

6. The *tragus* is a small, flattened, irregularly triangular eminence, adherent at its base to the skin of the face, with its apex or free edge looking obliquely inward and backward; it is situated above and in advance of the lobule in front of the concha, as well as of the meatus auditorius, and below the anterior part of the helix, from which it is separated by a small notch. Its under surface, especially at the apex, is usually covered with a tuft of hairs, more particularly in advanced life.

7. The *antitragus* is another eminence of somewhat similar form to that of the tragus, and which is situated directly opposite the tragus, from which it is separated by a deep notch (*incisura intertragica*), and at the superior and anterior portion of the lobule.

8. The *lobule* is the inferior, dependent part of the ear, situated immediately below the antitragus, it consists of tough cellular tissue, with a small quantity of adipose substance, and is softer and less elastic than the rest of the auricle. Females wear rings in this part of the ear.

9. Under the skin and on the outer surface of the cartilage, are four small muscles, called the *intrinsic muscles*, but their presence is not constant with man; they are the helix minor, the helix major, the tragus, and the antitragus; also, the transversus auriculæ, on the cranial surface of the auricle. There is also another set of muscles, called the *extrinsic*, which are attached to the head, and move the whole of the auricle; they are generally rudimentary, being mere analogues of larger muscles in some of the mammalia. They are, the *Attolens aurem*, or superior auriculæ, inserted into the upper and anterior part of the concha; the *Attrahens aurem*, or anterior auriculæ, inserted in front of the helix; and the *Retrahens aurem*, or posterior auriculæ, inserted into the back part of the concha.

10. The *auditory canal* or *meatus auditorius externus*, is a canal about an inch and a quarter, or an inch and a half in length, which extends transversely from the concha to the *membrana tympani*. Its direction from the concha inwardly is, at first, a little forward and upward, then backward and inward, and again downward, forward, and inward. Externally, the meatus is of an oval shape, but it becomes circular toward its inner extremity. About one-third of the external part of the auditory canal consists partly of cartilage and partly of fibro-cellular tissue, which renders it moveable to a certain extent, and very slightly dilatable; the rest of the canal has bony walls. The superior and posterior walls of the meatus, are somewhat concave; and the superior wall is somewhat shorter than the inferior. There is only a thin lamina of bone between the posterior wall, and the mastoid cells. In front, the meatus is protected from the introduction of foreign bodies, by the tragus. The diameter of the external

persons who, having lost their auricles, are still able to hear, yet there is no doubt that delicacy of hearing greatly depends upon the

auditory canal, varies in different persons, from half an inch to one-fourth of an inch, being, however, narrower near its middle portion than at its extremities. Its tympanal extremity presents a well-marked obliquity passing from above, forward and downward.

At the entrance of the external auditory canal and on the margin of the meatus are numerous glands furnishing fine hairs, called *vibrissæ*, which point toward the center of the canal, and which serve to prevent the introduction of foreign bodies into the ear. These hairs become very abundant as the person advances in years. These hairs, when falling loose, and becoming intermingled with the wax or cerumen, frequently give rise to ceruminous concretions which obstruct the passage of the auditory canal, giving rise to deafness in a greater or less degree, and chronic inflammation of the neighboring tissues, as well as perforation of the tympanal membrane.

The tissues which line the walls of the external meatus auditorius, are 1st. The epidermis which forms the outermost layer of the walls of the canal, as well as of the tympanal membrane. 2d. The dermis, which underlies the epidermis throughout its whole extent, and which gives insertion at certain parts, above referred to, to fine, short hairs, and which likewise gives passage to the ducts of the ceruminous glands. As the dermis advances inwardly, it becomes extremely sensible. 3d. The periosteum covering the bone, and the perichondrium.

11. In the cellular tissue situated beneath the dermis, and chiefly in the outer half of the membranous portion of the meatus, are numerous glands, over two thousand, which secrete the cerumen or wax of the ear. These *ceruminous glands* are more abundant posteriorly, and the cerumen secreted by them forms a ring or band passing around the external part of the tube of the canal, about six lines in width and one line in thickness. This wax is of a brownish-yellow color, or nearly black when old, and its bitter taste and adhesiveness is well calculated to arrest particles of dust which may enter the canal, as well as to prevent insects from crawling therein. The ceruminous secretion may be increased in quantity, by certain inflammations of the parts; it may likewise be diminished under the influence of certain pathological conditions.

THE MIDDLE EAR OR TYMPANUM is an irregular, narrow cavity, situated within the petrous bone, between the external auditory canal and the outer wall of the labyrinth, having an oblique direction inward and forward; it is somewhat wedge-shaped, being narrow below and in front, and broad above and behind, its longest diameter from before backward being from six to nine lines, its diameter vertically about three lines, and its transverse diameter about two or three lines.

The cavity of the tympanum presents six faces or sides: 1. The superior wall, which is formed by a layer of bone, separating this cavity from that of the cerebrum, and through which bone diseases of the tympanum advance, when they affect the brain. 2. The inferior wall, which presents a fissure or slit, about a line in length, called the *Glasserian fissure*, traversed by a fibrous band called the tendon of the anterior muscle of the malleus, and a small canal giving passage to the chorda tympani nerve. 3. The external wall, formed principally by the membrana tympani. 4. The internal wall, which has a vertical direction, and looks outwardly; it presents a reniform opening which leads from the tympanum into the vestibule, having its convex border upward, and its long diameter directed horizontally, and which is called *Fenestra ovalis*; it receives the base of the stapes.

presence of these appendages and their stretching or degree of projection outwardly.

The fenestra ovalis is not completely closed by the base of the stapes, which is inserted by a kind of synovial articular capsule, a kind of circular narrow strip which is probably subject to all the diseases of the larger articulations.

Above this fenestra is the *Aqueduct of Fallopius*, which gives passage to the facial portion of the seventh pair of nerves; below this is the *Promontory*, formed by the first external turn of the cochlea, and a part of the vestibule; below the promontory is an oval aperture placed at the bottom of a funnel-shaped depression leading into the cochlea, and called the *Fenestra Rotunda*, which is separated from the fenestra ovalis by the rounded eminence of the promontory; the fenestra rotunda is closed by a membrane which is concave toward the tympanum, and convex toward the cochlea, and which has been termed *membrana tympani secundaria*. Behind the fenestra ovalis, and in front of the vertical portion of the Aqueduct of Fallopius, may be observed a small conical eminence, called the *Pyramid*; in its apex there is a depression which leads into an opening giving insertion to the *Stapedius Muscle*. 5. The anterior wall, is wider above than below, and presents the internal tympanic orifice of the *Eustachian tube*. 6. The posterior wall is also wider above than below, and presents an opening of communication with the *mastoid cells*.

We will now examine more particularly some of the parts of the middle ear referred to in the preceding section, and with which it is important that the practitioner should be acquainted, as the Mastoid Cells, the Membrana Tympani, the Ossicles, and the Eustachian Tube.

THE MASTOID CELLS. At the upper part of the posterior wall of the cavity of the tympanum, is a large, irregular sinus, and sometimes several smaller apertures, which lead into canals which communicate with the interior of the mastoid process. This process contains in its interior an infinite number of compartments, formed of bony lamellæ, recalling to mind the spongy tissue of bones, and which are termed the mastoid cells. All these bony lamellæ are covered by a very delicate mucous membrane (resembling a true periosteum) which is continuous with that lining the cavity of the tympanum. As these cells communicate freely with the tympanic cavity, inflammation attacking this cavity may extend to, or exert an unfavorable influence upon, them.

THE MEMBRANA TYMPANI, OR DRUM MEMBRANE. This membrane separates the inner extremity of the external auditory canal from the cavity of the tympanum; it is a very dry, thin, semi-transparent or translucent membrane, irregularly oval in shape, rather broader above than below, and directed from above very obliquely downward and inward, forming an acute angle with the inferior wall of the external auditory canal, and an obtuse angle of 130° to 140° with its superior wall in the adult; with the new-born child it is slightly oblique. The shape of the membrane varies from nearly circular to elliptical, according to the age of the person, as well as its degree of obliquity, which assumes a more horizontal direction with very young persons. Its long or obliquely-vertical diameter is about two-fifths of an inch; its circumference is thick, firm, somewhat denser and whiter than the rest of the membrane, and is inserted in a well-marked groove upon an elevated ridge at the tympanal margin of the bony meatus, in a manner somewhat resembling the setting of a crystal in the besil of a watch. This circular groove occupies about five-sixths of the circumference of the inner or tympanal extremity of the external auditory canal, the remaining upper sixth, where

The second and most important use of the auricle is to receive and transmit sounds. Savart has shown that when waves of sound

the malleus joins the membrana tympani, being smooth instead of grooved. Internally, where it corresponds to the handle of the malleus, the membrana tympani is convex; externally, where it terminates the external meatus, it is concave.

According to Toynbee, the membrana tympani is composed of four extremely thin layers, viz.: 1, the *epidermis* or *external layer*, which is a continuation of the epidermis of the external meatus; it is very thin, and so transparent that the layer beneath it can be seen distinctly through its substance; on its outer side it presents a very smooth, reflecting surface, and at its anterior and inferior part, there may generally be seen a triangular shining spot.

2. The *dermis* or *dermoid layer* is a continuation of the dermis of the external auditory canal; it is situated immediately underneath the epidermis, which, indeed, it secretes, is very thin and transparent, and is well supplied with blood-vessels, which can not be seen with the naked eye, except when they are enlarged, giving a red appearance to the surface of the membrane; it is also furnished with nerves which render it exquisitely sensible.

3. The *fibrous layer* is composed of two laminae, which may be readily separated from each other. The external lamina is situated directly beneath the dermoid layer, and has been named the *radiate fibrous lamina*, because its fibres radiate from the malleus to be attached to the white, dense, cartilaginous or ligamentous ring, forming the thick and firm circumference of the membrana tympani. These fibres proceed from the sides and the extremity of the malleus to the cartilaginous ring, for about the inferior half of the membrane; in the superior half, these fibres pass across the external portion of the malleus, taking their course in front of the processus brevis, and are inserted into the periosteum of the upper part of the external meatus, of which they are a continuation.

The internal lamina, called the *circular fibrous lamina*, passes, for the most part, behind the handle of the malleus, and is united by fine cellular tissue to the radiating layer in front of it. This lamina consists of circular fibres, which are firm and strong at the circumference, but so attenuated toward the center, as to be detected only by careful observation; it has no connection with the cartilaginous ring, but is continuous with the periosteal lining of the tympanic cavity.

4. The *mucous layer*, or *membrane* forming the inner covering of the membrana tympani, is very thin, and is a continuation of the mucous lining of the tympanic cavity; it can be discerned with difficulty.

The membrana tympani is highly sensitive, the slightest touch producing most acute pain; its thinnest parts, where it is more generally ruptured by accident or disease, are, about midway between the points of the malleus downward and forward in the anterior portion, and downward and backward in the posterior portion. The office of the membrana tympani appears to be to receive and convey sounds to the ossicles, and thence to the labyrinth; to modify the influence of loud sounds, and to render the ear more susceptible to the influence of delicate ones.

OSSICLES OF THE TYMPANUM. The tympanic cavity of the ear, from the membrana tympani to the fenestra ovalis, is traversed by a chain of movable ossicles (minute bones), which articulate with each other by means of a little synovial and ligamentous apparatus. These bones, are three in number, some writers say four, and are as follows:

come in contact with membranes of the nature and density of this appendage, they resound and transmit the sound. Now the promi-

1. The *malleus* or hammer, named from its fancied resemblance to a hammer, is the largest of these bones and is situated more anteriorly than the incus; it consists of a head, neck, handle or manubrium, and two processes. The *head* is the large upper extremity of the bone, located in the upper and anterior part of the cavity of the tympanum, which extends above the *membrana tympani*, it is irregularly oval, and articulates posteriorly with the incus, being free in the rest of its extent. The *neck* is the narrow contracted part just beneath the head, and immediately below this is a bulb or prominence to which the various processes are attached. The *manubrium* or *handle* is a long, tapering process, flattened from within outward, and slightly curving forward at its extremity. It passes downward and backward between the two fibrous layers of the *membrana tympani*, and is the chief object on which the eye first rests in examining the ear. The *processus gracilis*, or *long process*, is a long, slender process, which proceeds at a right angle from the prominence below the neck, in a direction forward and outward to the Glasserian fissure, where it is attached near the edge of the tympanic ring. It affords attachment to the anterior mallei muscle, or *Laxator tympani*. The *processus brevis* or *short process* is a slight conical projection arising from the upper end of the handle, and lies in contact with the *membrana tympani*. It affords attachment to the internal mallei muscle, or *Tensor tympani*.

2. The *incus* or anvil, which is of an irregular shape, somewhat resembling a bicuspid tooth, with two roots, widely separated from each other; it consists of a body and two processes. The *body* is rather quadrilateral, and compressed laterally; its crown or summit is concave, and articulates with a corresponding convex surface upon the head of the malleus. The *short process*, is of a conical shape, is directed horizontally backward, and is attached by ligamentous fibres to the roof of the tympanum, near the orifice leading into the mastoid cells. The *long process* passes nearly at right angles from the short process, and in a direction with that of the handle of the malleus, behind which it is situated, bending inward and terminating in the *os orbiculare*, which articulates, toward the inner wall of the tympanum, with the head of the stapes.

3. The *os orbiculare* or *lenticular process*, is a small lenticular bone, situated between the long process of the incus and the superior and external extremity of the stapes; it is united to the process of the incus in the adult, but forms a separate bone in the fetus. In size it is equal to a small grain of sand.

4. The *stapes* or *stirrup*, so called from its resemblance to this article, consists of a head, neck, two branches, and a base. The *head* presents a depression which articulates with the *os orbiculare*. The *neck* is the constricted part of the bone below the head, and receives the insertion of the *Stapedius* muscle. The *two branches*, one of which is longer than the other, diverge from the neck, and connect at their extremities with the base. The *base* is a flattened oval-shaped plate, which forms the foot of the stirrup, and is fixed into the opening of the vestibule.

All these small bones are connected with each other, and with the tympanum by ligaments, their articular surfaces being furnished with cartilage and synovial membranes. The muscles which move them are the *stapedius* and the *tensor tympani*; the *stapedius* pulls the head of the stapes upward and backward; the *tensor tympani* draws the malleus and the *membrana tympani* inward and forward.

nences and ridges of the auricle are so numerous and diversified, that at whatever part the sonorous waves strike them, they will

The EUSTACHIAN TUBE is a somewhat trumpet-shaped canal from an inch and a half to two inches in length, through which a communication is kept up between the tympanum and the cavity of the fauces; its small extremity, or intra-tympanic orifice opens into the cavity of the tympanum, from which it proceeds, gradually increasing in diameter, obliquely downward, inward and forward to the superior and lateral part of the pharynx behind the posterior orifice of the inferior meatus of the nasal fossa, behind and on a line with the inferior turbinated bone. Its faucial or guttural orifice, called pavilion, is fibro-cartilaginous, larger than at any other part of the canal, bell or funnel-shaped, and will admit the introduction of a writing quill, while a very fine bristle can hardly pass through its bony portion, which is about a quarter of a line in diameter. The Eustachian tube consists of an osseous, and a fibro-cartilaginous portion.

The *osseous portion* (excavated in the thickness of the temporal bone, between the petrous and squamous portions, above the carotid canal from which it is separated by a very thin plate of bone, and below the canal which receives the malleus), opens into the tympanic cavity by an orifice which is situated below the processus cochleariformis. This orifice is about two-fifths of a line in its transverse diameter, and about one-fifth in its vertical.

This portion is slightly compressed from without inward, is from six to eight lines in length, conical; the wide extremity of the cone corresponding to the tympanum, the narrow extremity opening into the fibro-cartilaginous portion, at its origin, and which orifice is quite round, having a diameter of about a quarter of a line. The internal walls of the osseous portion are lined by an extremely thin fibro-mucous membrane, very similar to that lining the tympanic cavity.

The *fibro-cartilaginous portion* commences at its attachment to the jagged margin at the extremity of the osseous portion, which is usually the narrowest part of the tube, barely large enough to admit a good sized bristle. From this point it proceeds downward and inward, gradually dilating as it advances, forming a second elliptical cone, resembling a straight trumpet, the large bell or funnel-shaped extremity of which opens behind the posterior nares, as stated above, where it presents a thick, round, projecting lip or margin. The fibro-cartilaginous portion of the tube is from an inch to an inch and a quarter in length; the trumpet or funnel-shaped faucial orifice of the Eustachian tube is nearly half an inch long, and its lower margin is slightly below the floor of the posterior nares; this orifice is always closed in a state of rest, and is opened by the Tensor and Levator palati during the act of swallowing.

This portion of the tube is formed by the union of two triangular cartilages, of unequal size; the smallest, situated inwardly, is united to the osseous portion by its summit, to the internal wing of the pterygoid process by its base, and gives attachment to the Tensor palati muscle; the other cartilage, much larger and thicker, is likewise attached to the osseous portion of the tube by its summit, and forms at its base a kind of horn, to which is attached the Levator palati. These two muscles form, as it were, a kind of sphincter around the faucial orifice of the Eustachian tube, and this disposition of them will enable us to explain the cause of certain difficulties or symptoms which may follow the operation of catheterism. Thus,

a. With certain persons, as soon as the catheter touches the pituitary mem-

always or nearly always be perpendicular to the tangent of one of these prominences or depressions. Thus then the auricle receives

brane, spasmodic contractions occur in the upper portion of the velum palati; now, during these violent contractions, the muscles of the palate having their fulcrum at the faucial orifice of the tube, completely close it, so that the catheter can not enter.

b. If this spasmodic contraction occurs at the instant the catheter passes into this orifice, the instrument will be suddenly expelled therefrom, and its beak will fall in the pharynx; thereby rendering it necessary to repeat the manœuver.

c. If, in order to enter the catheter, notwithstanding these contractions, the medical man makes a little resistance, the beak of the instrument will lacerate the mucous membrane, and an emphysema will be spontaneously produced during the movements of deglutition, or even with the first insufflation.

A mucous membrane lines the interior of the whole Eustachian tube, which is a continuation of that of the nasal fossa, and of the cavity of the pharynx, and before penetrating therein it forms a thick and soft cushion around the faucial orifice, which contains small glands secreting a mucus analogous to that from the nostrils; hardly has it advanced within the tube, than it becomes much thinner, acquires greater consistence, and gradually assumes that peculiar epithelial-like appearance, which characterizes the internal membrane of the tympanum. Throughout its whole tract, from its faucial orifice to its tympanic extremity, the mucous membrane is very vascular, and is provided with vibratile cilia; it also contains in its substance muciparous follicles, and it is to inflammation of them with hypertrophy, in obstinate catarrhs, that thickenings, strictures, and other morbid changes of this membrane are due.

III. The INTERNAL EAR or LABYRINTH is situated in the petrous portion of the temporal bone, between the tympanic cavity and the internal auditory canal; it is very complicated in its form; and its position is such that the Vestibule, and the Cochlea are opposite to the membrana tympani, and the Semi-circular canals are posterior to it; it commences at the fenestra ovalis, and consists of the three following parts:

1. The *vestibule* is a small, irregular cavity, ovoid from before backward, flattened from side to side, or from without inward, and situated centrally and slightly outwardly in the labyrinth, immediately behind the fenestra ovalis; its greatest or transverse diameter averaging about one-sixth of an inch. It has three dilatations, called ventricles or horns, one anterior and superior, and two posterior and inferior. On its outer or tympanic wall is the fenestra ovalis, closed by the base of the stapes; its inner wall is perforated at its anterior and inferior part by several minute holes for the passage of filaments of the portio mollis or auditory nerve; at the back part of the inner wall is the orifice of the Aquæductus vestibuli or canal of Cotunnus; on the superior and posterior side of the vestibule are the five orifices of the semi-circular canals; in front is the oval orifice of the external scala of the cochlea, etc.

2. The *Semi-circular canals*, which form the posterior part of the labyrinth, are three osseous tubes, situated in the temporal bone, above and behind the vestibule, into which they open by both extremities; there are, however, but five orifices to be observed in this cavity, and which is owing to the fact that two of these canals have but one common orifice. Two of these canals have their arches vertical or turned upward, one being superior, the other posterior; the third or shortest, is external and horizontal, its arch being directed outward and back-

the undulations, reflects some of them, and transmits the most of them through the air in the external auditory canal to the membrana tympanum, and thence to the aural bones.

ward. These canals describe the greater part of an irregular circle, are compressed from side to side, are about one-twentieth of an inch in diameter, and present each, (with the exception of the posterior extremity of the external or horizontal canal), a dilatation of the end of the tubes to more than twice their diameter, and which dilated extremities are termed *ampulla*.

3. The *Cochlea*, so named from its bearing some resemblance to a snail shell, forms the anterior part of the labyrinth, and commences at the anterior part of the vestibule. It is a conical tube, placed almost horizontally in front of the vestibule, and having the length of about one inch and a half, measured along its outer wall; the canal winds spirally round a central pillar of bone, called the axis or modiolus, around which it describes two turns and a half, gradually diminishing in size from the base to the summit, where it is closed forming a cul-de-sac. The first turn of the tube of the cochlea produces that convexity upon the inner wall of the tympanum, which is called the *promontory*.

The interior of the spiral canal is divided into two scalæ or passages by a thin osseous and membranous lamina, the lamina spiralis, which winds spirally round the modiolus in the direction of the canal; and upon this lamina the nerve tubules are distributed. The two scalæ are thus completely separated from each other, communicating superiorly by means of an opening common to both, the *helicotrema*. Of the two scalæ, one, which is internal or posterior, is situated at the base of the cochlea, is larger, shorter, and at first a little straight, and commences at the fenestra rotunda; at its inferior part is the orifice of the aqueduct of the cochlea. The other scalæ, external or anterior, is narrower and longer and commences in the vestibule by an oval orifice. It is through this that the vestibular liquid penetrates into the scalæ of the cochlea,—a very fine fibrous membrane, and which is intimately adherent to the bones, lines all the cavities of the labyrinth, the internal surface of which secretes the liquor Cotunni, and which liquor exactly fills all the labyrinthian cavities, in which we find neither air nor emptiness.

The *membranous labyrinth* is a closed membranous sac, smaller than the osseous labyrinth, having the same general form as the vestibule and semilunar canals, in which it is enclosed, and separated from their lining membrane by liquor of Cotunni. The *vestibular portion* of this labyrinth consists of two sacs called the Utricle and the Sacculus. The *utricle* is the larger of the two, it is elongated, compressed laterally, is situated in the superior and posterior part of the vestibule, being in contact with the superior cresta vestibuli, and its cavity communicates, posteriorly, with the membranous semilunar canals by five apertures. The walls of this sac have numerous filaments of the auditory nerve distributed upon them. The smaller vestibular sac is the *sacculus*, which is round, situated in the hemispherical cavity of the vestibule, and has apparently no direct communication with any other part; it receives numerous nervous filaments which enter from the bottom of the depression in which it is contained. It contains a limpid fluid, and is said to have so much firmness, that when opened with the point of a lancet, it will retain its form.

The *Membranous Semicircular Canals* are smaller in diameter than the osseous canals, but resemble them in number, shape and general form; they are hollow,

2. *The external Auditory Canal* directly continues the ærial waves through the air it encloses; its walls conduct the sonorous waves, transmitted by the auricle, to the membrana tympani; and the column of air contained in it, re-echoes and augments the intensity of the sound.—To properly fulfill its functions, certain conditions of this canal are required; its curvature is of service, and exists in all animals furnished with such a canal; if it be too large, or too narrow, it gives rise to a deficiency in the delicacy of hearing. A certain amount of cerumen is required to keep the canal properly moistened, but, too great an abundance, or an entire absence of it, interferes with the transmission of the sound-waves,—the latter condition may, however, be frequently remedied by dropping into it

open by five orifices into the utricle, and have ampullæ at their extremities the same as the osseous canals.

The membranous labyrinth is retained in its position by means of the numerous nervous filaments which pass through the minute openings on the inner wall to be distributed to the utricle, the sacculus, and to the ampulla of each canal. Its walls are transparent, and consist of three layers, within which is contained a limpid serous fluid, liquor of Scarpa or endo-lymph, which fills the membranous labyrinth, and two minute, granular, calcareous bodies suspended in this liquor, and called *otoconites* or *otoliths*, one being in the utricle, and the other in the sacculus. They appear to be almost universally present in the ear of the mammalia, and are probably in some way connected with the function of hearing.

IV. NERVES OF THE AUDITORY APPARATUS. The Auditory Nerve is the *portio mollis* of the seventh pair of nerves, emanating from them after they have reached the meatus auditorius internus; it is the special nerve of the sense of hearing, and divides, at the lower part of the internal auditory meatus, into two branches, the cochlear, and the vestibular. The *vestibular nerve* is situated more posteriorly than the cochlear, and is subdivided into a superior, middle, and inferior branch. The *superior branch* is the largest, and divides into numerous minute filaments, which after entering the vestibule are distributed to the utricle and to the ampulla of the external and superior semicircular canals. The *middle branch* sends off numerous filaments which enter the vestibule below the superior branch and are distributed to the sacculus. The *inferior branch* is the smallest of the three, it passes backward to the posterior wall of the vestibule, and gives off filaments which are distributed to the ampulla of the posterior semicircular canal. After these nervous filaments have entered the ampullæ and the sacculi, they radiate in all directions, forming loops and a kind of network, and finally terminate upon the inner surface of these membranes in minute papillæ, somewhat like those of the retina.

The large, anterior, cochlear nerve, divides into numerous filaments at the base of the modiolus, ascend along its canals, and form a plexus containing ganglion cells between the osseous plates of the spiral lamina, at the edge of which they terminate, by a very free anastomosis, in minute fibrillæ, and finally end in delicate papillæ in the membranous part of the spiral lamina.

The *Arteries* of the labyrinth are derived principally from the auditory branch of the superior cerebellar artery.—The most important vein of the ear is the deep-seated auricular, located in front of the tragus.

a few drops of some fatty substance. Deafness is the result of the obliteration of this canal.

3. The *solid walls of the Cranium* aid in the transmission of sound, as may be proven by holding a watch between the teeth. When we close the ears, we, nevertheless, hear the voice of a person near by; and if we place a watch against or near the head, first, in front, and then behind, we will ascertain that the posterior part transmits the sound-waves much better than the anterior.

4. The *Membrana Tympani*, or *Drum Membrane*, is present in all animals with ærial audition. In animals who lead a subterranean life it is very oblique, and nearly horizontal with the mole. Its inclination not only increases its extent, but also changes the direction and measure of the sonorous waves. It receives these waves, either through the air in the external meatus, or directly along the walls of this canal, and by the shock communicated to it, vibrates, the same as the head of a drum when it is made to receive a blow.

It is likewise susceptible of another very different movement, which is impressed upon it by the movements of the chain of ossicles under the influence of muscular contractions. This second movement, known as tension and relaxation of the *membrana tympani*, is somewhat passive in man, as it results only from the action of the ossicles. With some animals it will be active, as their drum membrane is of a muscular character; while with others the tension and relaxation are due to the variable pressure of the air in the interior as well as in the exterior parts of the ear.

In man, the tension may occur by the tensor tympani, or by the stapedius muscle, when this is present, that is to say by a power which acts at one or the other extremity of the chain, and relaxation is then simply an effect of elasticity, and is not active. Arnold states that the otic ganglion presides over the movements of these two muscles, the same as the ophthalmic ganglion presides over the movements of the iris; so that there is an analogy between the iris and the drum membrane.

The *membrana tympani*, according to Bichat, is made tense for weak sounds, and is relaxed for strong sounds. On the contrary, however, Savart states that the membrane is relaxed for the perception of weak sounds, and becomes tense for loud sounds; also that when the membrane becomes accidentally and forcibly stretched by rarification of the air of the tympanum, or by condensation of the external air, the faculty of hearing feeble sounds is lost, loud ones only being heard; in other words the hearing is diminished. We can satisfy ourselves of this, by closing the mouth and nose, and then making a strong expiration, which condenses

the air in the tympanic cavity—or, by a strong and continued inspiration, which rarifies the air in this cavity. In these two easily repeated experiments, we hear badly, the hearing is obtuse, because the membrane is made tense outwardly during the expiration, and inwardly during the inspiration.

Muller thinks that certain cases of partial deafness are due to too great a tension of the drum membrane; this circumstance may be of value to bear in mind in the diagnosis of diseases of the ear, which are sometimes so obscure. This excessive tension of the membrane may be occasioned by obstruction of the Eustachian tube, in which the air dilates under the heat of the body, or else becomes partially resorbed, the membrane being strongly stretched either outwardly or inwardly. It may also be occasioned by contraction of the tensor tympani. Perforation of the membrana tympani, or of the mastoid process would be useful in the first case (that is, if the tube be obliterated) but of no service in the last, and this will, probably, explain the opposite results following this operation.

It is probable that during a very loud sound, the tensor muscle is put in action by a reflex movement, similar to that which happens to the iris and to the orbicular muscles of the eyelids under the influence of a very strong and bright light. In this case, the irritation is transmitted to the sensorial nerves of the brain, and from the brain to the motor nerves. Consequently, it is a probable hypothesis, that when a very intense noise strikes the ear, the muscle of the tympanum may control the amount of sound-waves that pass to the labyrinth, and thus moderate the hearing, by its reflex movement. Mr. Toynbee observes, "I think it may be fairly inferred, that the function of the tensor tympani muscles is to protect the membrana tympani and the labyrinth from injury during loud sounds; while the stapedius muscle places these structures in a position to be impressed by the most delicate vibrations; and it would appear to be brought into action during the process of listening."

The integrity of the drum membrane is not absolutely essential to the mechanism of hearing; many individuals in whom it has been accidentally ruptured, are able to pass cigar smoke through the ears, without being deprived of the faculty of hearing. If, with a perforation, there also exists a thickness or other abnormal condition of the membrane, then deafness will almost invariably be present.

5. The *Tympanum* or *Drum*. We have seen that variability of tension of the membrana tympani is necessary for the adaptation of hearing to the variable intensity of sounds. Now, to effect this

variability of tension, it is required that the partition or drum membrane be placed between two columns of air, and consequently that this fluid be contained in the tympanic cavity.—Sound, having reached the membrana tympani, is transmitted to the internal wall of the tympanum, by the air contained in this cavity, and by the ossicles.

All possible conditions are combined in order that the vibrations communicated by the drum membrane be transmitted, without any loss, to the fenestra ovalis along the chain of ossicles. These are solid, unattached to the bones of the cranium, and are enveloped on all sides with air; and, it is known, that a solid body transmits sound more readily when it is not communicated to the surrounding atmosphere. The membrana tympani, then, transmits the sound-wave to the handle of the malleus, from this to the stapes and to the membrane of the fenestra ovalis.

6. The *Eustachian Tube* has had many uses attributed to it; thus, Muncie maintained that it was necessary to keep up an equal density between the external and internal air, in order that the latter transmit the vibrations; Muller has objected to this opinion, because unequal density of layers of air only occasions a slight loss of the force of sound. Henle states that the faucial aperture is analogous to holes pierced in the sound-board of a violin, and which are necessary for the formation of a full sound, and there is resonance at the same time of the board, of the instrument, and of the air contained in its interior. Muller admits this fact.

The mucus secreted in the tympanic cavity is evacuated through the Eustachian tube, and when this is retained or accumulates, it forms an obstruction to the free passage of air through the tube, and deafness is the result. But the principal use of this tube is to give a free passage to part of the air of the tympanic cavity, consequently, favoring tension of the drum membrane, and maintaining it in equilibrium with the air exterior to it.

The Eustachian tube is generally closed at its faucial orifice, except during deglutition, when it is opened by the tensor, and levator palati muscles. Toynbee remarks: "As during the act of deglutition the tensor and levator palati muscles contract, it is evident that whenever that act is performed, the Eustachian tube must be opened; and inasmuch as there is no apparatus by which the faucial orifice of the tube can be kept open, its lips must fall together, and the orifice close as soon as the muscles cease their action. During the few moments that the faucial muscles are brought into play in the process of deglutition, air can either enter or recede from the tympanic cavity, and thus be always of the same density as the outer

air. The reasons why the Eustachian tube is closed, save during the momentary act of deglutition, are, first, that the tympanum may be generally a closed cavity, so that the sonorous vibrations reaching it may be concentrated upon the membrane of the fenestra rotunda; and second, that, as especially pointed out by Dr. Jago, sounds may be prevented entering the tympanum from the fauces." He further states, that whenever the Eustachian tube becomes impervious, the air in the tympanic cavity becomes partially exhausted or absorbed. "The effect is to produce an increased concavity in the external surface of the membrana tympani; a forcing inward of the chain of ossicles; pressure on the contents of the labyrinth; and a very serious diminution of the hearing power."

7. The *Mastoid Cells* appear to be merely an appendage to the tympanic cavity, being for the organ of hearing what the sinuses are for the olfactory organ. Their development in feline animals and night-birds, in which they extend into the occipital bone and the temporal, indicates that they contribute to increase the intensity of sound.

8. *Fenestra Ovalis* and *Fenestra Rotunda*. The sonorous vibrations having reached the internal wall of the tympanum, may be transmitted to the labyrinth by two routes: as by

a. The fenestra ovalis which, by means of the chain of ossicles, makes the lining membrane closing it vibrate, and, consequently the vestibular liquid.

b. The membrane which closes the fenestra rotunda, or membrana tympani secundaria.

There has been a diversity of opinions as to whether sound is transmitted by both, or only one of these passages. Pathology has shown that destruction of the ossicles will sometimes result in the abolishment of hearing, and at other times will only feebly diminish it; it is probable therefore that both of these fenestræ have the power of propagating sonorous vibrations. As to which of them transmits sound the best, Muneke decides in favor of the fenestra ovalis to which an osseous chain conveys sounds; Muller also adopted this opinion.—What is remarkable in this matter, is, that both fenestræ are not indispensable to ærial audition; frogs have the f. ovalis but not the f. rotunda, a manifest proof of the superiority of the former.

M. Auzoux gives an explanation of the use of the fenestra rotunda, of the following purport: At the instant when the plate or base of the stapes, put in motion by the sonorous vibrations, dips or sinks down in the fenestra ovalis, the labyrinthian liquid yields to the pressure thus made upon it; but this liquid exactly fills the canals

and the scalæ of the labyrinth, so that there is no vacuum; and the osseous walls resist this pressure. The membrane of the fenestra rotunda, pressed from within outward by the reflux of the liquid (through the orifice of communication of the two scalæ), yields, becomes tense within the limits of its elasticity, making, so to speak, a hernia on the side of the tympanum; consequently, the capacity of the inferior scala is momentarily enlarged, to the extent to which the small portion of liquid displaced has yielded when put in motion by the shock or pressure of the stapes. As soon as this pressure ceases, the membrane of the fenestra rotunda, from its own elasticity, returns to its original condition, and the labyrinthian liquid displaced an instant for the accomplishment of the function (that is, concussion of the nervous extremities), also resumes its primitive situation.

9. The *Liquid of the Vestibule*, and the *Semicircular Canals*. The greater part of the sonorous undulations pass, then, by the fenestra ovalis; there, they impress the liquid, which communicates its vibrations to the vestibular and cochlear nerves.

The complication of this passage through a layer of liquid before encountering the nerve, is a fact worthy the attention of physiologists. Let us observe, at first, that this disposition being common to all atmospheric and aquatic animals, is, for that reason, fundamental, and of the highest importance for the function.—The presence of an intermediary liquid being, if not indispensable, at least very useful; the concussion communicated by a liquid to the nerve being more favorable for its delicate pulp. Beside, according to Breschet, the membranous sacs or tubes of the vestibule may vibrate; this vibration is rendered more easy for them by their position between two liquids which sustain them.—If the vibration of sound passed directly from the air to the nerve, the sudden impression would be painful for this soft and delicate pulp.

Muller states that the intensity of sound is slightly augmented by the direction of the curvature of the canals, and, according to him, the osseous portion of the canals appears to be accessory, for with the noisy lamprey we find only membranous tubes or canals.

10. The *Cochlea*. M. Flouren's researches have shown that the cochlea has not so great an importance as the vestibule, since it is absent in entire classes of animals; it is, however, a very useful means of improvement. To understand the manner in which the sonorous vibrations are conveyed to the cochlea, we must bear in mind that they may reach it by two passages, viz.: a. By the water of the labyrinth, (perilymph), which moves freely in the communicating vessel, represented by the vestibule, and the cochlear scalæ.

b. By the solid walls of the cranium. All these vibrations are transmitted through the modiolus, the spiral lamina, and the osseous plate which envelops the scalæ.

It may naturally be asked if the concussion follows a successive and progressive course along the liquid of the scalæ, or along the modiolus and the spiral lamina, from the vestibule, to the apex of the cochlea? This can not be; the concussion is communicated so readily from the liquids to the solids that the shock is communicated at once in every direction, without going through the entire length of the canals.

We are aware, with Muller, that the convolutions of the cochlea have for their object, by confining the canal in a small space, the inducing a simultaneous vibration or concussion upon the whole nervous surface.

The lamina spiralis is also, probably, designed to present a large surface upon which the numerous filaments of the cochlear nerve are expanded, like the cords on a key-board.

Muller has offered the following considerations: The cochlea is adapted to receive at the same time, the sonorous vibrations coming from the labyrinth and from the walls of the cranium, for its spiral lamina, supports the auditory nerve, communicates with the labyrinthine perilymph and with the bony parts of the cochlea and of the cranium, and, on the contrary, the membranous labyrinth, which is free and floating in fluid, is only adapted to transmit to the vestibular nerve the vibrations communicated through the medium of the liquid. And since the cochlea possesses the two means of receiving the vibrations through the solids and the liquids, it is a more perfect organ of reinforcement than the vestibule.

As to the aqueducts, they have no part in hearing; they do not serve to evacuate the fullness or overflow of the liquid, during the vibratory concussion, as Cotunni and Meckel believe. Breschet has demonstrated that these fissures are associated simply with the evolution of the auditory organ.

No satisfactory solution of the perception of different sounds and their degrees of intensity have yet been given, though many hypotheses have been advanced by physiologists.*

* In the selection and preparation of matter furnishing the history, description, causes, and symptoms of aural maladies, as well as the remarks introductory thereto, I am greatly indebted to Triquet more especially, to Toynbee, Wilde, and Von Trœltzsch, also to Itard, Kramer, Bonnafont, Muller, Meniere, Valeroux, etc.

GENERAL CAUSES OF DISEASES OF THE EAR.

Acquired deafness is due to two causes, viz.: predisposing, and efficient.

Among the *predisposing causes* it will be found that males are more subject to those diseases of the ear occasioning deafness, than females, and which is undoubtedly owing to their being more exposed to the action of cold, moisture, atmospheric influences, etc., which give rise to catarrhs and inflammations of the air passages, Eustachian tube, tympanic cavity, and other parts of the ear. The action of cold is very prostrating; it interferes with the free circulation of the blood in the capillary vessels, so that the parts affected by it contract and present an appearance characterizing either an absence of blood in the tissues, or a stasis, being pale in the first instance, and purplish in the latter; it likewise lessens the sensibility of the parts, as well as retards or arrests their secretions. If the cold be severe, the consequent degree of depression will be in accordance therewith, and, if not carried to too great an extreme, will be followed by a corresponding powerful reaction, resulting in pain, redness, increased heat, and other symptoms indicating inflammatory action.

The resisting power of organs to the influence of cold, is, to a certain extent, due to their being well enveloped in adipose and cellular tissue, and in being furnished with an abundance of blood; the ear, however, has only a minimum amount of such protection, its more important parts being encased in osseous structure, and hence it is more disposed to inflammation when improperly exposed to a cold atmosphere, cold draughts of air, or draughts of air when the system is warmed by exercise, etc., as well as to the influence of cold water or other fluids entering the ear, and imprudent applications of cold water to the head.

Deafness may be acquired at any period of life from infancy to old age, depending upon the abnormal lesions producing it; thus, young children often labor under external or internal otitis, with denudation of the bones, caries, necrosis, perforation of the membrana tympani, abscess of the mastoid process, and caries of the mastoid process, which lesions are generally the sequelæ of certain fevers, especially eruptive fevers. Two additional causes may be met with among very young infants, viz., exposures to cold, and convulsions. Among youth and adults, frequent catarrhal attacks, extending into the Eustachian tube, the tympanic cavity, or into

the external auditory canal, as well as otitis developed during, or following a severe febrile attack, as, for instance, typhoid fever, may ultimately occasion deafness. Old persons are more disposed to deafness originating from morbid changes in the internal ear, as, absence of the liquor of Cotunnii, congestions of the neurilemma of the auditory nerve, as well as abnormal changes in the sensibility of this nerve.

Deafness may also be hereditary or transmitted from parent to child; thus, we sometimes meet with parents becoming deaf at a certain age, whose offspring also become deaf at about the same age, and under similar circumstances. In these cases, the prognosis is almost invariably unfavorable.

Deafness is much more common in the North, or, in cold and moist climates; for these agents acting either singly or together, produce unfavorable influences upon the tissues of the external auditory canal, and upon the membrana tympani, rendering this membrane less apt to transmit the sonorous vibrations; beside which, they occasion inflammations which may attack this membrane and the tissues of the external auditory canal, or which may extend into the Eustachian tube, and to the tympanic cavity, as may frequently be observed in inflammation of the naso-pharyngeal mucous membrane. On this account it is better to undertake the treatment of deafness from these causes, in warm and dry seasons, instead of during the winters. Deafness in warm climates, and especially in places along the sea-coast is more commonly due to rheumatic affections of the fibrous tissue which enter into the composition of the auditory apparatus.

Persons of sedentary professions, and those much occupied in long-continued mental exercises, are liable to become deaf, especially about the middle period of life, from hyperæmia of the auditory apparatus, which may be cœtaneous with cerebral congestion; those, likewise, whose avocations require them to be exposed to cold, moisture, atmospheric changes, etc., are equally liable to diseases of the ear, as draymen, coachmen, carpenters, house-painters, masons, bleachers, day-laborers, boatmen, farm-laborers, etc.

Again, those who dwell or work in the midst of noise, especially if this be constantly monotonous, are very subject to deafness occasioned by a diminution of the sensibility of the auditory nerve, from the constant and repeated concussions, and incessant irritations upon this delicate organ. Those who work near steam-engines, are very apt to be hard of hearing, if not quite deaf; and artillery-men are always more or less deaf, which is often due to rupture of the membrana tympani from the severe sonorous concussions occasioned

by the firing of cannon. These constant noises act both by the shock they impart to the whole organism, especially when they are powerful, and by the impressions they produce on the organ of hearing.

In adult and old age, those of a sanguine temperament are more subject to deafness. Persons of this temperament who constantly present red cheeks, injected eyes, short necks, large chest, full and strong pulse, are more especially liable to what is called "nervous deafness," and which may be due to a congestion of the labyrinth, of the neurilemma of the auditory nerve, or, of that part of the encephalon from which this nerve arises.—Next to the sanguine, the lymphatic temperament is liable to deafness. Among children, especially, of a lymphatic and scrofulous temperament, who are pale, with soft flesh, white, slightly œdematous skin, thick lips, broad, flat nose, blue eyes, and congestion of the glands of the neck, deafness is to be feared, as they are very subject to discharges from the ear, and which, if neglected, will certainly occasion a more or less complete loss of hearing. With this class of children there is a tendency to suppuration, which becomes developed under the influence of the slightest cause and continues inexhaustible. The deafness observed among them is often due to internal or external otitis, which ultimately extends into the tympanum; sometimes, however, it is owing to catarrhal inflammation of the Eustachian tube.

The nervous temperament comes next in order, as regards liability to deafness, and which deafness is ordinarily due to vital lesions of the auditory nerve.—Lastly, the nervo-bilious, or melancholic temperament is subject to tinnitus aurium, and a more or less complete loss of hearing. But, whatever may be the predisposing cause to diseases of the ear, the liability to them will depend upon the character, duration and intensity of the efficient causes, and the degree of resisting power of the system.

The *efficient causes* are both local, and general. The principal ones among the local efficient causes, are, cold and moisture, heretofore referred to; these are not only predisposing causes, favoring the development of diseases of the ear, and rendering them more difficult of cure, but they frequently are, of themselves, sufficient to produce deafness very rapidly, as may often be witnessed among persons living in places where they are exposed to sudden changes of temperature, or of the wind, etc. Diseases of the throat, the result of cold, and especially that which occurs during the presence of scarlatina, catarrh, influenza, measles, diphtheria, laryngitis, etc., are very fruitful sources of aural affections; as, the

diseased condition of the mucous membrane of the throat, lips, nostrils, or eyes, may be propagated through the Eustachian tube to the mucous membrane of the tympanum. The mucous membrane lining all these organs is but a continuation of one membrane, which even extends into the lungs and stomach, and which will account for the readiness with which disease at one portion of it may be transmitted to some other, even to that lining the middle ear.

The next in order among the local efficient causes are blows or falls upon the head, and all circumstances which may produce concussion of the brain; in which cases, the deafness may be symptomatic of a cerebral lesion, its prognosis resting upon that of the brain affection, or, it may be the consequence of a concussion of the auditory nerve, somewhat analagous to amaurosis caused by blows upon the eye, and, like the amaurosis, it may resist all methods of treatment. The common practice of boxing or pulling the ears, or of introducing pins, ear-spoons, or other foreign bodies within the external meatus is very improper, as inflammation, terminating in deafness may thereby be produced; I have known the drum membrane to become ruptured, in several instances, where the children had been severely boxed on the ears.

Among the general efficient causes, is, the scorbutic diathesis, in which there is a tendency to a morbid change in all the plastic functions of the system, and especially in the fluids, and which condition is not only favorable to, but may actually determine effusions in the ear,—deafness frequently being due to an effusion of blood in the internal and middle ear.

Cancer may develop itself either in the neighborhood of, or directly in, the auditory apparatus, and interfere with, or completely abolish the hearing, but there is no special action of cancer in the development of aural diseases.—Deafness may occasionally be due to gout influencing some part of the auditory organs, or, it may with still greater probability be occasioned by syphilis, which locates itself wherever there is any fibrous tissue, as, in the derma, periosteum, articulations, cellular tissues, parenchymatous tissues, as the liver, testes, etc., and also in the neurilemma, and which may, in like manner, locate itself in the bones of the ear, in the periosteum lining the osseous cavities of this organ, and in the auditory nerve, or some of its ramifications, producing lesions incompatible with hearing. But cases of deafness due to these causes are extremely rare. Still more seldom is deafness due to the presence of tubercles in any part of the ear.

Acute diseases, as, typhoid fever, small-pox, scarlatina, measles, etc., are apt to terminate in a purulent diathesis of the economy,

frequently giving rise to suppurative discharges from the ear, (as well as suppurative inflammation of the parotid glands, of the bronchia, pleura, etc.), and which aural discharges may ultimately occasion deafness.

Among persons of advanced years, deafness generally comes on gradually; at first, conversation at the usual distance can not be heard, the distance of hearing lessens by degrees, slight noises are not heard, and finally, the person, in order to hear, requires those with whom he converses to repeat their sentences, and to elevate their voices, and so on, until ultimately the deafness becomes complete. But, the deafness may develop itself more rapidly, under the influence of a severe acute attack, external or internal otitis, acute catarrh, etc. The duration of the deafness is generally quite lengthy, perhaps several years. Deafness in old age has been shown by Mr. Toynbee, not to depend upon a gradual and natural decay of the power of the organs of hearing, but upon "the influences to which aged persons are frequently subjected, namely, the prolonged stay in warm rooms, the avoidance of the open air, the cessation from bodily exercise, the want of attention to diet and to the healthy performance of the functions of the skin." The internal auditory apparatus being almost entirely concealed in a bony receptacle, and having but little connection with the rest of the economy, as a general thing, we can treat its diseases only by feeble and indirect means of action.

GENERAL SYMPTOMS OF DISEASES OF THE EAR.

The symptoms of aural affections are divided into Subjective, or certain sensations experienced by the patient, and Objective, or certain morbid changes observed by the physician, in the form, color, texture, consistence, vascularity, and the more or less ready penetration of air and fluids in the different parts composing the organ of hearing. Both orders of symptoms should be very attentively investigated, in order to aid us in forming a correct diagnosis, prognosis, and course of treatment.

If it be desirable to treat diseases of the ear with skill and efficiency, it is highly important that a correct diagnosis be arrived at by the practitioner; and this can only be attained by instituting as thorough an examination as possible of the several parts of the ear, and of the symptoms present, and by ascertaining all the important circumstances associated with the case before us.

We will, therefore, first ascertain the name of the patient, age, occupation, temperament, usual state of health, present state of

health, condition of tongue, stomach, liver, kidneys, bowels, pulse, etc.; whether subject to cutaneous diseases, syphilis, rheumatism, scrofula, etc.; whether any relatives have been subject to deafness or diseases of the ear, and which of them; when the present affection was first observed, and to what cause it was attributed; what symptoms have from time to time been observed; whether the disease has progressed gradually or rapidly; whether the symptoms were constant, or appeared at regular or irregular intervals; whether they came on gradually or suddenly; whether they (deafness in particular) have been or are aggravated by cold, cold and damp weather, mental excitement, physical fatigue, mastication, etc.; what conditions of air, weather, position, and the system, effects an apparent improvement in them; and whether during an exposure to loud noises, noise of machinery or mills in motion, traveling in coaches or railroad cars, walking through a crowded street, etc., or, whether after a full meal, the hearing is increased or diminished.

Having procured satisfactory replies, we then commence a further investigation of the

I. SUBJECTIVE SYMPTOMS.

1. *Deafness* presents itself in various degrees, from cophosis or complete absence of hearing to dysecœa or dullness of hearing. In dysecœa the patient still hears, but less distinctly and readily than in the normal state; as commonly termed, he is said to be "hard of hearing." In a more advanced degree, the most elevated tones of the voice can hardly excite a confused sensation. Having reached this degree, the deafness approximates cophosis.

For a long time, aurists have endeavored to ascertain the best method of determining the degree of hearing with the different persons falling under their observation. Generally, a patient believes his hearing to be still good, as long as he can continue his social relations in a convenient manner and sustain a conversation. The human voice is thus taken as a standard of comparison; but this could only be admitted if either every person, or any particular individual, always spoke in the same tone, with the same force, the same thrill, and accurately in the same direction toward the ear of the patient; and these conditions do not admit of being fulfilled. Patients who hear very badly with one ear, often think that they still hear perfectly well with the other, and therefore consider any further proof of this quite superfluous.

Again, a person may hear the human voice tolerably well, and yet be wholly unable to hear another noise, as, for instance, the

ticking of a watch; and, on the contrary, certain persons who can still hear the watch, are entirely insensible to the human voice. The facility with which the voice, articulated in a more or less distinct manner, and at a greater or less distance, may be heard, is, then, not a certain measure for the various changes which the function of hearing may undergo; for the ear is not sensible to all sounds, though of the same force, so that we can not with absolute certainty conclude, from an increased susceptibility for a definite sound, as that of a watch, that a precisely proportionate increase of capability of hearing the human voice exists. Various instruments have been formed for the purpose of determining the degree of hearing, but, as "the works of the watch always give a *uniform sound*, the *distance* of which from the ear to be investigated always admits of being *accurately defined*, and which may always be presented to the ear in the *same direction*," these several instruments have been set aside, and the watch substituted in their stead.

As watches vary in their sounds, some ticking louder than others, it is very difficult to form a correct idea of the degree of hearing, or hearing distance of deaf patients, reported by writers, unless there be universally recognized by the whole profession, a *standard normal distance of hearing distinctly*, and counting the ticking of a watch. In order to obtain this desideratum, I had (including myself) ten apparently healthy persons, who had not complained of any difficulty of hearing, to test, each, the hearing distance of his own watch, as well as of the watches of the others, and the result is given below. Although the measurements are not given exact up to the very inch or its parts, (in some cases, an inch or so being dropped, and in others added), yet the figures and allowances made are considered sufficiently correct for all practical purposes.

Each watch was held, in the hand of a person, on a level with the ear of the listener, the latter of whom gradually increased the distance between his ear and the watch, until he reached his limit of distinct hearing,—then, by means of a graduated tape, the measurement was taken from the watch to the prominence of the malar bone of the right side; the right ear being, in each instance, the one directed toward the watch.

From the following, the average or *standard normal distance* at which the ticking of a watch may be heard, may be assumed as 12.5 feet, or 150 inches, or 381 centimetres.

Therefore, taking 12.5 feet as the *standard normal distance of hearing* the ticking of a watch, we can readily determine the *standard limit of hearing* (distinctly) with any watch whatever, provided, the normal distance at which the watch used can be heard, has

first been ascertained; and which may be effected by a trial with ten or twelve healthy persons who have not complained of, nor detected any difficulty of hearing, and accepting, as the normal distance at which said watch can be heard, the greatest distance at which the majority of the listeners can distinctly hear and count its ticking.

NUMBER OF PERSON.	Number of each Watch, and the Hearing Distance.

Average distance of hearing with each watch.	160.5	214.5	94.5	140.0	94.5	78.5	160.5	56.5	94.5	149.0
	16.05	21.45	9.45	14.0	9.45	7.85	16.05	5.65	9.45	14.9

I. The rule by which to make the calculation is as follows: *As the normal distance at which the watch employed can be heard, is to the standard normal distance of hearing, so is the distance at which the patient can hear the watch employed, to his standard limit of distinct hearing, or standard hearing distance.**

1. If the normal distance of hearing a watch is 3 feet, and a patient can only hear it at 3 inches, what is his standard limit of hearing?

First, in this case, reduce the feet to inches, then,

$$\begin{array}{ccccccc} \text{inches.} & & \text{inches.} & & \text{inches.} & & \text{inches.} \\ 36 & : & 150 & : : & 3 & : & 12\frac{1}{2} \end{array}$$

2. If the normal distance of hearing a watch is 7 feet, and a patient can only hear it at 2 feet, what is his standard limit of hearing?

$$\begin{array}{ccccccc} \text{feet.} & & \text{feet.} & \text{inches.} & & \text{feet.} & & \text{feet.} \\ 7 & : & 12 & . & 6 & : : & 2 & : & 3\frac{1}{7} \end{array}$$

* *Standard limit of hearing* is the distance at which the patient would hear a watch, the standard normal distance of hearing of which is 12.5 feet.

3. If a watch can be normally heard at 20 feet, and a patient can only hear it at 6 inches, what is his standard limit of hearing?

inches.	:	inches.	:	inches.	:	inches.
240	:	150	:	6	:	$3\frac{3}{4}$

II. The rule by which to determine the distance at which a particular watch may be heard by a patient, his standard limit of hearing being given, is as follows: *As the standard normal distance of hearing is to the normal distance at which a particular watch can be heard, so is the standard limit of hearing in a patient (as given by a writer) to the distance at which said patient can hear the particular watch.*

3. The normal distance of hearing my watch is 20 feet, at what distance can it be heard by a patient whose standard limit of hearing is given as $3\frac{3}{4}$ inches?

inches.	:	inches.	:	inches.	:	inches.
150	:	240	:	$3\frac{3}{4}$:	6

4. The normal distance of hearing a physician's watch is 7 feet, at what distance can it be heard by a patient whose standard limit of hearing is given as $3\frac{1}{4}$ feet?

feet.	:	feet.	:	feet.	:	feet.
$12\frac{1}{2}$:	7	:	$3\frac{1}{4}$:	2

A writer may, therefore, give, when describing the degree of his patient's hearing, either the standard limit of hearing, or the actual distance at which his own watch can be heard by the patient. In the latter case always naming the normal distance at which his watch can be heard.

By the above means a degree of uniformity is attained, and the degree of deafness of all reported patients, as well as their subsequent improvement in hearing, can be approximatively ascertained, sufficiently exact for all practical purposes.*

* Instead of the above, we may, as is done with vision, determine the Acuteness of Hearing, instead of the hearing distances, thus: Let the normal Acuteness of Hearing, 12.5 feet, as ascertained by the means named above, be represented by 1; then in the first example given above the Acuteness of Hearing will be twelve and one-half one hundred and fifty inches, equal to one-twelfth; and in the second example, it will be five one-seventeenth and one-half or about plus one-third.

Ex. The normal distance of hearing my watch is 20 feet, at what distance can it be heard by a patient whose Acuteness of Hearing is given as one-sixth?

One-sixth of 12.5 feet is 25 inches, which is the standard limit of hearing of the patient, then by Rule II above given,

inches.	:	inches.	:	inches.	:	inches.
150	:	240	:	25	:	40

When it is desired to estimate a very advanced degree of dullness of hearing, a watch should be employed that can be heard at a considerable distance by a sound ear. The watch should be approached gradually to the ear, instead of being withdrawn from it, until it gets within the hearing point at which the tickings can be accurately counted, and the intervals between these sounds be perceived. The hearing should be tested with the mouth open as well as closed; also before and after the inflation of the tympanum; and the experiment should be conducted in a room as still as possible. The watch should be held directly opposite the ear and on a level with it. Persons who can still hear the elevated tones of the voice at a short distance from the ear, say about eighteen inches, may hear the ticking of a watch in contact with the ear; but those who can hear the watch at a distance of one-third of an inch, one-half of an inch, or one and a half inches may be able to follow a conversation at some distance, and without any effort.

In repeating the trial of the hearing distance of a patient, in order to determine the progress of his case, it "must always be made under the same circumstances, internal as well as external; always in the same room, and during the same degree of surrounding stillness, as well as of the mental and bodily repose of the patient; either always before or after a syringing, or sitting before the vapor or air apparatus; and with the watch in the same direction toward the ear, etc." (*Kramer.*)

According to the degree of deafness, etc., the watch should be applied as named above, or, both before and behind the auricle, or to the forehead, or, against the auricle, or be held gently between the teeth of the patient, etc.

2. *Pain*, (with the exception of otalgia or neuralgia of the ear, in which the pain comes on by paroxysms, without any trace of inflammation of the membranes, and rapidly attains its height, as well as vanishes suddenly), is almost invariably indicative of an inflammatory condition of the organ. Otalgia may be due to the presence of a carious tooth, and will disappear with the removal of the tooth.

Pain, is a symptom observed in all inflammations of the external, middle, and internal ear. In each of these cases, its seat and its nature are invariable, and demand an attentive examination.

In inflammation of the external auditory canal, whether this inflammation be due to the presence of a foreign body, or originates from cold, the seat of the pain is the tragus and the small region contiguous to it.

In inflammation of the tympanum, and of the cells, the seat of the pain is at the base of the mastoid process, and at the root of the neck.

In inflammation of the membrana tympani, the patient complains of pain in the superior part of the helix, and deeply within the external canal.

In inflammations of the internal ear, the corresponding region of the cranium is more particularly the seat of the pain, as, the forehead, the temples, or the occiput. In otalgia the pain is violent and by paroxysms; in all inflammations it is continuous with a paroxysm in the after part of the day, and especially during the night; sharp and severe, diffusive-like, in inflammation of the auditory canal, it is pungent in inflammation of the drum membrane, pulsating or throbbing when the tympanum is inflamed, and lancinating, or as if some foreign body were attempting to pass through, when the mastoid cells are attacked.

In inflammation of the labyrinth the pain somewhat resembles that of encephalitis. The patient utters sharp screams, and becomes delirious in the first stage, which is soon followed by coma, if the treatment employed does not speedily afford relief.

In the chronic state, similar pains are experienced, but much less severe than in the acute. In chronic catarrhal inflammation of the external auditory canal, and which terminates by suppuration, there remains a feeling of uneasiness or painfulness, and we may frequently excite pain, by even lightly pressing upon the conglobate gland (sub-lobular) which is almost always increased in size.

In chronic inflammation of the tympanum, there is more a sense of fullness than of real pain; and in old inflammations of the labyrinth, there is cephalalgia, which persists for a long time; and when, exhausted by the time, it finally disappears, the morbid changes which follow, and which will be hereafter referred to, under "Nervous Deafness," are of such a nature that we should be very cautious in our prognosis. Thus, in certain amauroses, we observe the pain, acute at the commencement, soon yield to a deceitful calm, to a feeling of well-being which induces the patient to hope for an immediate amelioration; but the duration of this hope will not be very long, for at this period of the disease, the sight is lost, more generally, permanently. So it is with the ear, certain forms of nervous deafness, are, in reality, what might be termed incurable amaurosis of the ear.

3. *Erethism*, or *augmentation of hearing*. *Paracusis Acris*, is a morbid phenomenon met with principally during acute inflammatory

attacks of the membrana tympani, of the labyrinth, and at the commencement of nervous deafness, at least in many instances.

In acute inflammation of the drum membrane, this augmentation of the sensibility of the ear is sometimes such, that the least noise gives rise to most violent pains, so that the patients are frequently obliged to tightly close their ears to prevent the painful vibrations of the suffering organ.

By the side of this erethism of the hearing, we may bring in contrast with it an opposite phenomenon; *torpor* of the ear, *Paracusis Perversa*, or its insensibility to its natural excitants, the voice, moderate sounds, etc. In this state, loud noises only, such as thunder, artillery-firing, noise of large clocks, of trumpets, drums, rolling of coaches, etc., may arouse a transient sensibility of the auditory apparatus, so that the patient can hear ordinary sounds and hold conversation only during the presence of these loud sounds.

Paracusis, or *depravation of hearing*. *Paracusis Duplicata*, is a singular phenomenon rarely met with in certain forms of deafness, particularly in the nervous; the patient hearing at the same instant two or several discordant sounds.

4. *Tinnitus Aurium* is the name given to certain peculiar sounds which many patients laboring under aural affections, complain of hearing, or of being annoyed with; these sounds are variously described as a ringing or tinkling in the ears, a singing in the ears, or noises like whistling, hissing, rushing of water, buzzing of bees, the singing of a tea-kettle, rustling of trees, a blowing sound, a fluttering sound, etc. These sounds exist alone, or they may be combined with others heard by the patient, or which he imagines he hears. All these internal noises are sometimes so annoying that the patient, deprived of his sleep by them, regards them as the cause of his deafness, and imagines that he would be well if all this internal uproar could be stopped. Unfortunately this is not the case, for certain remedies which lessen or momentarily remove the tinnitus, have no effect whatever in improving the hearing; and, after all, there is nothing surprising in this, since this symptom is due to the acute or chronic morbid changes of the tympanum, or of the labyrinth.

All these noises accompany a depravation, or a partial loss of hearing, and are termed tinnitus aurium; their tone may be grave, or more or less acute, in which latter case a patient may believe he hears, and actually may hear continued whistlings, hissings, or some analogous sound. In describing these abnormal noises, patients generally compare them to other sounds with which they are more familiar; thus, domestics imagine they hear the ringing of bells, ticking of clocks, singing of tea-kettles, etc.; workmen in

large factories the noise of steam machinery; artillery-men, the noise of cannon; sailors, the whistling of the wind, or the roaring of the waves, etc.

In our inquiries concerning this symptom, we should ascertain the peculiar character of it; whether only one or several kinds of noise are experienced; whether they are heard at stated times, or all the time; under what circumstances or conditions they diminish or pass away; whether the tinnitus exists in both ears, or only in one; and whether they are referred by the patient merely to the affected ear or ears, or appear to exist in the interior of the head.

Tinnitus aurium may accompany disease of the auditory apparatus, or it may be present with diseases of other parts than the ear. We will examine each of these conditions, in order to have a proper understanding of them.

A. TINNITUS ACCOMPANYING DISEASE OF THE AUDITORY APPARATUS.

a. Tinnitus accompanying a lesion of the external auditory canal. In this rank may be placed, an agglutination of the hairs, *vibrissæ*, which are within the external orifice of the canal. With some persons, these hairs may be very numerous, and then a small quantity of cerumen will suffice to agglutinate them and form a small barrier closing the entrance of the meatus, leaving, however, minute openings or fissures among the hairs composing it, through which the air may pass in and out of the canal. Now, the little column of air which has penetrated within the auditory canal, will, from the warmth of the parts, soon have its temperature above that of the external temperature, and, as in all places where there is a circulation established between unequal temperatures of air, the warm air will be replaced by a column of cold. Thus there is established through the minute openings among the agglutinated hairs, a series of small currents of air; and these currents taking opposite directions, and the ærial molecules coming into collision with each other, give rise to a noise or tinnitus very annoying to the patient. This tinnitus may be cured with wonderful facility, if we are fully aware of its cause.

Another cause of tinnitus aurium is, the accumulation of a greater or less quantity of cerumen, in the deeper parts of the external auditory canal, near the drum membrane; the tinnitus being produced by a mechanism analogous to the one preceding. The capacity of the canal being diminished, from the accumulation of wax, a free circulation of air therein becomes more difficult, and a series of small currents is formed between the warm air passing out, and the cold air which enters at each instant with the sonorous vi-

brations. Itard regarded this tinnitus as being produced by the breaking or division of the column of air (occurring at the moment when this column, having passed within the canal, reaches the constricted or obstructed part), in order that it may pass through an orifice of much less diameter than its own. The causes of the preceding sounds may be readily detected by an attentive examination of the auditory canal made with the assistance of an ear speculum.

Indeed, any mechanical obstacle to the free circulation of air in the ear may cause tinnitus, upon the same principle that a murmuring or whistling is heard in a well-heated room, into which the external air passes only through a small opening. So, if we place the extremity of a finger in the meatus, or apply the hollow of the hand over the concha, an unpleasant murmuring or tinnitus will be produced.—Foreign bodies in the canal, as peas, beans, glass, marbles, beads, etc., or bodies spontaneously developed in this canal, may give rise to these various noises, and in a similar manner.

b. Tinnitus accompanying inflammation of the membrana tympani. Here the tinnitus does not present exactly the same characters as those of the preceding; it is more acute and at the same time more painful; sometimes it is likened to the falling of water, or to the loud pumping of a steam-engine, or to the roaring of waves; frequently, especially in the milder acute forms, or in the chronic stage, it is somewhat like a metallic tinkling. Its cause is not known, unless, indeed, it be due to the increased flow of blood in this highly delicate and sensitive membrane; and which is heard in a similar manner to the placental, chlorotic, or aneurismal souffle, though from the situation and condition of the parts, with much greater intensity. However, inflammation of the drum membrane is very seldom met with separately; it is frequently, if not always, accompanied with a catarrhal inflammation of the tympanum, and which will be considered hereafter. A remarkable and interesting point connected with inflammation of the drum membrane, is, that upon perforation of the membrane the noises cease at once.

c. Tinnitus accompanying catarrhal inflammation of the Eustachian tube and of the tympanum. In these affections we know that there is always a more or less profuse secretion of mucus. Now, this excess of mucus, secreted within the tympanic cavity will flow with more or less difficulty through the tube, and, during inspiration, mastication, or deglutition, the air in its effort to penetrate into the tympanic cavity through the tube, will cause noises analogous to those made during its passage through the bronchial tubes when these are obstructed with similar matters. The same effect is con-

stantly occurring in catarrhal discharges from the pharynx or nasal fossæ, either during the whole course of the inflammation, or only at certain periods, when, the obstruction being considerable, some of the mucus is forced into the Eustachian tube by the excretive efforts. But if, instead of simply obstructing the guttural canal of the ear, these mucus discharges completely fill it up, then deafness succeeds the tinnitus, and does not readily disappear. We may obtain an analogous effect in the auditory canal, by firmly and deeply inserting the end of a finger therein, so as to completely close this canal, then the tinnitus, caused by the presence of mucus, will cease or diminish, and the hearing will become more obtuse.

d. Tinnitus accompanying nervous deafness, is one of its most frequent symptoms, and for which many hypotheses have been presented. If, by an attentive examination we ascertain that the external auditory canal is not closed by cerumenous masses; that the Eustachian tube is not obstructed by mucus matters; that the middle ear does not contain a collection of mucus, sanguine, or purulent matters, we usually conclude that the tinnitus resides in the brain or in the auditory nerve. The antecedents of the patient, other concomitant or general symptoms, such as a severe fever at a recent or late period, the age especially, will be valuable information to resolve the difficulties of differential diagnosis, and we may thus be enabled to determine that the cause of the tinnitus resides in the auditory nerve itself, which may receive the morbid concussion from congestion or inflammation of its own tissue, or this pathological concussion may be communicated to it by the inflamed neighboring tissues.

Duverney believes that these sounds are due to a greater determination of blood in the arterial capillaries of the cochlea and of the semi-circular canals, and this afflux causes a vibration of the last divisions of the auditory nerve. Now, vibrations of the ramifications of the auditory nerve, whatever may be their cause, determines the production of sound, and whoever is the subject of it will hear noises of divers kinds and intensity. In the normal state, the nervous pulp or the auditory retina is gently agitated by oscillation of the liquor of Cotunnus produced by the base of the stapes, itself obedient to the vibrations of the membrana tympani.

But if, under the influence of inflammation of the labyrinthine cavities, the sanguineous circulation determines to the capillaries, which irrigate the frail and soft ramifications of the auditory nerve, increasing their activity, we can conceive that the result will be a vibration in the nervous filaments, and that this pathological vibration must give rise to abnormal sounds, the same as the physiological undulations of the liquor Cotunnus will produce in the normal

state, sound, properly so called. From this ingenious idea, the formation of abnormal sounds or acoustic anomalies, which are but tinnitus in its various forms, is made known to us in its fullest details by the key-board hypothesis of Leclat, which rests wholly upon the anatomical disposition of the nervous filaments which are distributed to the spiral lamina of the cochlea.

This spiral lamina having a triangular form, and diminishing in width from the base to the apex, the nervous filaments exposed at its surface must, consequently, be smaller in length as they occupy a more elevated position. Leclat compares this arrangement to that observed in the strings of a harpsichord, and, according to this truly seductive hypothesis, sounds should be more or less grave or acute according to the part of the spiral lamina set in vibration by the undulations of the liquor Cotunnii. So, according to this writer, grave sounds result from vibration of the inferior cords of the spiral lamina, acute ones from vibration of the more elevated nervous filaments.

This theory has been rejected by all physiologists, who have regarded it as a fancy of the mind; but as the auditory apparatus has been compared to that of certain stringed instruments, the explanation of Leclat merits a serious examination. Let us suppose that a simple sanguineous congestion, or else an inflammation, affects the largest portion or the base of the key-board represented by the spiral lamina, the nervous strings will be vibrated by the acceleration of the movement of the blood in the capillaries, and the tinnitus caused by this inflammation will have a grave pitch; if, on the contrary, the inflammation affects the more elevated strings, instead of the tinnitus being grave, the patient will hear sharp sounds, whistlings, etc., and these sounds will be more acute as they are nearer the summit of the key-board.

Labyrinthine and cochlear inflammations, as well as inflammation of the auditory nerve itself, from its origin at the fourth ventricle to its termination, have been demonstrated by numerous dissections; and it is sufficient that there exist a congestion, inflammation, or even excitation of the auditory nerve, in the cranium or in the labyrinth, in order that tinnitus may be produced. So that we may accept Leclat's theory of tinnitus in nervous deafness, based as it is on the most rigorous proof,—normal and pathological anatomy.

Saissy has met with a curious variety of tinnitus, which he calls "whirling sound," and considers to be owing to the entrance of air into the cochlea, and to its passage through the spirals of this part. This phenomenon could not be produced, unless one of the

fenestræ being destroyed, the liquor of Cotunnus flowed out, and its absence was replaced by the air of the tympanum. Now, the pathological anatomy of nervous deafness has shown a destruction of the membranes of the fenestræ, or else, luxation of the stapes, either of which conditions may give rise to this curious phenomenon.

Thus then, congestions, inflammations, etc., of the deeply-seated parts of the acoustic organ, as well as anything that will cause abnormal vibrations of the auditory retina, will give a satisfactory explanation of the tinnitus, and abnormal noises which are heard under these pathological conditions.

Triquet also describes a species of tinnitus which is insupportable from its persistency, and which destroys the charms of society, renders life joyless and full of bitterness, causing men to renounce their business, to become melancholy, and even to commit suicide. It has, very probably, been heretofore associated with nervous deafness. He says, for a long time I have remarked that, in certain cases of tinnitus in which the Eustachian tube, the tympanum, and the auditory canal were healthy, a very strong lens of three to four inches focus, aided by the speculum and a reflector, has, when examining that point of the membrana tympani which gives attachment to the handle of the malleus, revealed considerable vascular redness of this handle and of that portion of the membrane surrounding it, as well as minute intermittent oscillations of the drum membrane at this same point, beating synchronously with the pulse.

Having had an opportunity of examining the ear of a patient affected with, well-marked deafness, a discharge, insupportable tinnitus, and destruction of the membrana tympani as well as of the ossicles, Triquet observed a reddish projection on the sides of the promontory, and which appeared to be the stapes remaining in place, pressing in its fenestra; the mucous membrane was red and fungous. At the inferior and anterior part of the internal wall of the tympanum, he noticed particularly a nipple-like projection about the size of a pin's head, a true hypertrophy of the mucous membrane; it was red and shining, and had pulsatory movements which were synchronous with the patient's pulse, and, on compressing the corresponding carotid, its pulsatory movements as well as the tinnitus ceased, and the hearing became better. This projection was touched with a solution of perchloride of iron, 25° B., and disappeared in the course of eight days, together with the tinnitus. Other similar cases were cured after a period of three or four weeks, applying the solution every two or three days. Here then is a fine

capillary plexus, which, from inflammation in different parts of the acoustic apparatus, becomes abnormally developed, elevating the mucous membrane in which it is diffused, in the same manner as the small vessels which nourish arterial and cutaneous erectile tumors.

When the drum membrane is destroyed we may readily observe the condition referred to, but when this membrane is entire we can only establish the diagnosis by induction. There is one sign, however, which Triquet considers pathognomonic, and that is the redness and vascularity of the handle of the malleus, heretofore described. Whenever this symptom exists, we may affirm that the patient is tormented by tinnitus, and that this tinnitus is due to an abnormal development of the capillary plexus, a consequence of chronic inflammation. It may also be observed that tinnitus, due to the cause under consideration, is tumultuously augmented on the least exercise, or under the influence of the slightest emotions. In these cases, when the drum membrane is entire, he applies, by means of a capillary tube properly placed, a few drops of the solution of perchloride of iron on this membrane along the course of the handle of the malleus. He also proposes compression, and even ligation of the small arterial vessels which penetrate into the tympanum and labyrinth.

He further says,—“If all the other means fail, such as catheterism of the tubes, local and general venesections, drastic purgatives, and especially aloetics, cold affusions on the head and neck, cauterization over the mastoid process, seton to the nape of the neck, and Faradization; if my patient was especially a victim to these insupportable aural noises which produce a deep melancholy, despair, and suicide, I would, at first, attempt compression of the anterior and posterior auricular arteries, and even the ligation of this last, which is undoubtedly the most important, as it furnishes the stylo-mastoid branch, which is the true artery of the internal ear.

“I would act thus with the firm conviction of curing the patient, or at least of affording him great relief, without exposing him to any serious danger, experience having shown that compression and even ligation of the auricular arteries presents no inconvenience.”

B. TINNITUS ACCOMPANYING OTHER DISEASES THAN THOSE OF THE EAR.

The diseases in which tinnitus may exist, without any aural affection being present, are, anemia, chlorosis, excessive uterine hemorrhages, hysteria, hypochondria, eruptive fevers, at their commencement and sometimes during their whole course, cerebral congestion, apoplexy, and other diseases of the brain in which

there is no symptom present of diseases of the ear, etc. There are also other abnormal sounds, a kind of roaring or blowing noise due to the pulsations of dilated or aneurismal arteries situated within the neighborhood of the auditory apparatus, for instance, in the vessels of the neck, and of which several instances have been recorded. In these cases, if we can compress the affected artery, the sounds will cease while the compression lasts.

Sometimes, these noises in the ear, may be due to strong mental impression, a great fright, intense excitement, excessive fatigue, etc.

As to the *diagnosis* of these varieties of tinnitus, it will be the same as that of the diseases of which the tinnitus is only a symptom, and which will be noticed hereafter.—As to *treatment*, a few words may be said here by way of anticipation. Generally, patients who are subject to tinnitus, become so tormented by it, that they are willing to pursue any treatment, however severe, as the moxa, seton, or cauterization, if the slightest hopes of relief thereby be held out to them; and in these cases, it may often be required to use some means for its diminution or removal, more especially when it is not connected with any disease of the ear.

When the tinnitus is due to ceruminous obstructions in the external auditory canal, these should be removed by injections of warm water, as described hereafter.—When it is owing to an obstruction of the median ear, catheterism of the Eustachian tubes, followed by injections of medicated vapor or fluids, is the only mode of treatment.—If it be caused by inflammation of the tympanum and its membrane, antiphlogistic medication will be required, as, leeches to the ear, and the internal use of Tinctures of Aconite, Black Cohosh, Gelseminum, Veratrum, St. John's Wort, Arnica, etc. Wilde speaks of the Tincture of Arnica as being the only medicine which, as far as he knew, exerted any beneficial influence in tinnitus; he recommends fifteen drops of the tincture in a tablespoonful of the Infusion of Arnica, and some cordial tincture, or aromatic wine, three times a day, gradually increasing the dose a drop or two daily, until it produces headache or giddiness, when the dose should at once be lessened, or the medicine be omitted for a short time. I have found very excellent results from the Tincture of Black Cohosh used in a similar manner.—Tinnitus accompanying nervous deafness, must be treated by means indicated by the general symptoms present, and which will be considered hereafter.

If, after a general survey of the disease, and of the patient, we have reason to believe that the tinnitus is due to a too considerable determination of blood to the head, purgatives, irritating pediluvia, spirit vapor bath, frictions upon the surface of the body, and tepid water upon the head and neck, once or twice a day, will be found very serviceable; should these fail, the practitioner may add to them, cupping behind the ears, and scarifications of the small veins of the auricle. Sometimes, when not contra-indicated, douches of cold water to the head, instead of tepid, will be found more efficient.

In the tinnitus accompanying nervous deafness, douches of the Vapor of Ether, or of Chloroform, have often given a transitory relief for a longer or shorter period; but it must be remembered that serious lesions of the internal auditory apparatus may be present in the disease termed "Nervous Deafness;" and as these lesions are more commonly the result of an old chronic inflammation, neither an antispasmodic like ether, nor an excitant like chloroform, can afford any temporary cure or permanent relief.

When the tinnitus is associated with cerebral congestions, of which it is the precursory symptom, as, apoplexy, softening of the brain, paralysis, etc., these diseases only are to be treated; the tinnitus will disappear with them. The same may be said when it is present in anemia, chlorosis, uterine hemorrhage, etc.—Tinnitus due to strong mental excitements, or to mental alienation, must be treated both mentally and therapeutically according to the circumstances and conditions attending each particular case, and which will frequently require great tact and judgment on the part of the practitioner.

Sometimes, tinnitus, even when it is not of long standing, and is not complicated with deafness, resists the best directed treatment, and the patient will have to submit to it, unless he is willing to follow the advice of Itard, which is to cover or disguise the internal, real, or imaginary sound by an analogous external one and equally continual. And it is worthy of remark that the external noise thus made, which ought necessarily to be more intense than the morbid tinnitus, in the place of preventing sleep, will induce it and render it profound.

When deafness has continued for a long time, or is very considerable, a change in the *character of the voice* will be observed; and this will occur without any disease of the internal parts of the mouth and throat, or of the organs concerned in the mechanism of speech. The voice becomes harsh, discordant, monotonous, with a peculiar twang resembling that which has been termed, though im-

properly, "speaking through the nose." Sometimes the tone of the voice is quite loud, the patient speaks as though he was out of breath, and with a blowing or whistling sound; the sounds gradually acquire a more guttural tone, and utterance becomes indistinct. The prognosis in cases of this kind is by no means favorable, especially when the mouth and parts around the naso-pharyngeal cavity, and in the nares present a normal appearance.

II. OBJECTIVE, OR ANATOMICAL SYMPTOMS.

After having finished an investigation of the Subjective symptoms, it is of the highest importance that the practitioner carefully and thoroughly examines the morbid changes undergone by the different parts of the ear, for it is only by this course that he can obtain any information calculated to give as much precision as possible to his diagnosis. Without this precision, the treatment will be empirical and hazardous. We will, therefore, point out what parts are to be examined, and how their examination must be made.

1. *Examination of the Auricle, and adjacent external parts.* The patient is to be seated in a chair with a high back to it, against which he may rest his head, or, if the back be not sufficiently elevated for this purpose, he may rest his head against a wall, or have it supported by an assistant. If the day be a fine one, and the sunlight good, he should be seated near a window so that the rays of the sun may fall directly upon the parts of the ear under examination. These preparations being made, we request the patient to incline his head, to the extent required, toward the shoulder opposite the ear to be examined; which inclination exposes the ear more directly to the physician's sight, and to the luminous rays. He should also be requested to keep as still as possible while the examination is going on. The physician now carefully observes the condition of the auricle, the concha, the external meatus, the cerumen, and the vibrissæ; also, of the mastoid process, and the subparotid region corresponding to the fissures of Santorini, through which pus, enclosed in the external auditory canal, may filter.

In examining the auricle we must observe its color; it may be very pale, or white, as with chlorotic or anemic persons, those of strumous constitution, or those who are fatigued or exhausted. It may, on the contrary, be reddish, or purplish, as with plethoric individuals; with these, the veins of the auricle are generally apparent, delineated in bluish or purplish relief, and these particulars

have their importance. Indeed, congestion of the auricle of the ear is almost always an indication of congestion of parts deeper situated, and it is often the case, that deafness is owing to no other cause than hyperæmia of the internal ear, and which has been cured by plunging the ear in water as hot as could be borne, and then scarifying the veins of the auricle or over the mastoid process, and thus procuring a sufficient flow of blood.

The form of the auricle is next to be noticed; in the normal state it should have the form of an ear-trumpet; its prominences should be well marked; it ought to be wide at its mouth, somewhat bell-shaped, and the concha should be large and funnel-shaped; the external meatus should be readily brought to view, not being obstructed by the tragus. It is of considerable importance in the mechanism of hearing, that the auricle presents all its normal anatomical forms and conditions.

The auricle should be moderately thick, but thin enough to possess complete translucency, and with sufficient resistance to preserve its form; these points demand a close attention, for the auricle is not only designed to collect sonorous undulations, but likewise to increase their intensity by its vibrations. Any cause that will alter its consistence, its thickness, its flexibility, and consequently its elasticity, will thereby interfere with one of the acts of the function of hearing, and produce a hardness or dullness of hearing.—If the prominences and depressions of the auricle are absent, or abnormal in their character, sound-waves are imperfectly or not at all collected; if the auricle be too thick, or soft, its vibration will be more or less deficient in proportion to the degree of these changes.

The consistence of the auricle should not be too hard nor too soft; as either will interfere with its elasticity and vibrating power, as well as its function of conveying sounds to the outer meatus.—Its temperature should be especially remarked; in certain forms of nervous deafness when the auricle is congested, and when it is the seat of some local inflammation, as erysipelas, eczema, impetigo, etc., its temperature will be found considerably elevated.—The angle of insertion which the auricle forms posteriorly with the cranium, should be noticed. It should not lie close toward the head, as that would interfere with its facility for catching sound; it ought to stand out a little forming an angle with the posterior part of the cranium of about forty, forty-five, or fifty degrees.

As we proceed in our examination, all the different morbid symptoms and conditions should be written down, so that nothing may be forgotten in forming a diagnosis, prognosis, and treatment; and

also that as the treatment progresses, we may refer to our notes to learn the degree of improvement, from time to time.—The upper extremity of the helix should be taken between the thumb and index finger of one hand, and be drawn upward, backward, and outward, while the thumb or fingers of the opposite hand, placed in front of the tragus, should draw it sufficiently forward and slightly downward, to expose a considerable portion of the outer third of the external meatus auditorius. And while holding it in this position, the patient should be requested to open and shut his mouth, and to perform the act of swallowing; if any pain is caused by these movements, it should be carefully noted. Wilde also recommends firm and deep pressure with a finger “upon the movable root of the *tragus*, and backward into the depression between it and the articulation of the jaw. While the finger is retained in this position the patient should be desired to open and shut the mouth, and the amount of pain or inconvenience experienced by pressure in those two different positions of the jaw accurately noted. The middle and forefingers should likewise be inserted deeply behind the ramus of the jaw toward the styloid process, and notice taken of the sensations there experienced.”

The ear-gorget, or semi-speculum auris of Wilde, will be found very useful in the examination of the outer part of the external canal. The entrance to this canal is protected by two opercular projections, the tragus and the antitragus. These projections serve to indicate the orifice of the auditory canal, which they protect, and, in the normal state and with young persons, without interfering with the functions of this apparatus. But with old persons, these membranous parts becoming flaccid and participating in the general relaxation of all the tissues, it sometimes happens that they fall down upon the auditory meatus and completely cover it, somewhat like a snuff-box is covered by its lid. This point should be recollected in the examination of old persons, with whom dullness of hearing or even deafness, may be due to this cause alone.

The disposition and condition of the hairs just within the entrance of the meatus should be noticed. In crossing one another, and in becoming agglutinated to each other by means of the cerumen, they may form at the entrance of the canal, a net-work, and a kind of barrier to the introduction of foreign bodies; this agglutination may become so extensive as to present an impediment to the entrance of air and sound. Some writers have attributed another use to them, that of finely dividing or sifting the air which enters the auditory canal, and modifying its cold and moist qualities. This is a view which is not without some foundation. All animal tissues

possess some caloric, and the air which passes through the barrier formed by these hairs at the entrance of the external meatus, must experience an elevation of temperature, and thus produce a less painful impression upon the membrana tympani. If the hairs are few, or absent, the cold and moist air coming in contact with the drum membrane, would become a cause of deafness.

If we are led to believe that inflammation is present, we should especially examine the *mastoid process*, as to its color, form, size, temperature, etc. A couple of fingers should explore its entire surface, making very firm and strong pressure upon all parts of it, to ascertain if the cells composing it contain any abnormal collection of fluid, whether serous, sanguine, or purulent. The depth and duration of any pitting made by this pressure, as well as the degree of œdema or swelling of the soft parts and integuments, will aid considerably in forming a diagnosis. Sometimes, percussion of the mastoid process, will afford some valuable information. A similar examination should also be made of the sterno-mastoid muscle from its insertion to one-third its distance downward, as well as at its origin at the clavicle; for, collections of pus may be frequently found at these different places, which, having their commencing point in an abscess of the tympanic cavity, have penetrated, under the deep surface of the sterno-mastoid muscle through a perforation, or kind of fissure of the process of the same name.—Immediately behind the auricle, and over the center of the mastoid process, is a small gland, about as large as a horse-bean, and of similar shape; this gland is sometimes the seat of severe neuralgic pain, and also swells, and becomes painful upon pressure, during inflammatory attacks.

2. *Examination of the External Auditory Canal.* In examining the auditory canal, and previous to employing the speculum auris, we should observe any abnormal changes, either in quantity or quality, which the wax or cerumen may have undergone. Thus, the cerumen may be absent, which is one cause or rather a complication of certain kinds of deafness; in this case, the meatus will be dry, and the little layer of cerumen, which, in the normal state lines its inferior two-thirds, can not be seen. This state of dryness of the meatus is one of the worst signs that we can ascertain by a simple exterior examination with the eye alone.

When the auditory canal is the seat of a catarrhal otitis, with inflammation of the ceruminous glands, the wax assumes characters different from those which it presents in the normal state; it will be serous, fluid, less yellowish, of a dark-brown or blackish color, and fetid. All these morbid changes may be verified without the

aid of the speculum. At the same time, under the influence of the irritation, we may observe that these glands become more prominent or hypertrophied, giving to the walls of the canal a characteristic dull aspect.

We now proceed to the examination of the deeper parts of the external auditory canal. This canal is from an inch and a quarter to an inch and a half in length, and consists of an osseous, and a cartilaginous portion, the entire length of which must be examined, as well as the outer surface of the *membrana tympani*. When the canal is of large diameter, by straitening it in the manner presently to be described, its whole extent may, under a good light, be explored without the aid of a speculum; but as it is generally rather narrow, an ear speculum will be required, of which instrument, among the several models that have been presented to the profession, I prefer Wilde's, though Töynbee's, and Holcomb's porcelain ones will be found useful in many cases. An aurist should have a full set of each. The ordinary two-valved, hinge-moving speculum is used by many, and is highly recommended by Triquet; that it may prove serviceable is undoubtedly true, but I seldom make use of it.

As the external auditory canal is not a strait but curvilinear tube, it must be rendered as strait as possible in using the speculum, and which may be accomplished in the following manner: With the fingers of one hand seize the auricle at its superior posterior part, and gently draw it upward, backward and slightly outward, and with the other hand introduce the speculum, taking care to have the sett ready so that the most suitable size may be selected. (If the examination is made without a speculum, a finger of the hand not employed in drawing upon the auricle, may draw the tragus outward and to one side, so as to expose the canal to illumination and inspection.)

In conducting the examination of the auditory canal, whether with or without the aid of a speculum, we should select a place, as for instance near a window, where a full stream of strong light can fall upon the *membrana tympani*; the best light is that in which the sun's rays fall obliquely into the speculum. The patient's head, in this examination, will have to be strongly inclined toward the opposite shoulder, the physician placing it in such a position as will enable him the more readily to obtain a clear and distinct view of the *membrana tympani*, and other parts brought into view, being very careful to keep his own head out of the light. The speculum must be passed in the canal as far as it will go without producing pain, and without force, for no dilata-

tion of any account can be produced, and this only at the outer cartilaginous portion of the meatus. Then by moving the patient's head slightly in the required direction, and rotating or moving the end of the speculum gently about, every part of the membrana tympani, and of the auditory canal may be distinctly seen. During the examination the head of the physician should be somewhat higher than that of the patient.

Sunlight is decidedly superior to any other in making this examination, and should always be had recourse to in operations in the vicinity of the tympanic membrane. But, in *the examination*, it can not always be made available, and artificial light will then have to be employed. Various lamps, etc., have been contrived for this purpose, which it is unnecessary to enumerate here; I have found the best artificial light to be that from a coal-oil lamp, having a slightly concave silver reflector on one side of it, and a plate of glass tinted with neutral blue, four or six inches square, on the opposite side. (This lamp should be made so as to be readily held in the hand, or be placed upon a table, as may be desired, and it may likewise be used for examinations with the ophthalmoscope and the laryngoscope.) However, the practitioner can not make as accurate and satisfactory an examination by artificial as by sunlight, for the different shades of vascularity, polish, transparency, etc., of parts, can not be thereby detected.

Again, an examination of the membrana tympani is not always so easy as one might believe, and especially in those cases where the obliquity of its direction is such as to be nearly horizontal; and, in other instances, it will be necessary to completely remove all obstructions in the canal, by means of an injection of warm water, in order to see the whole extent of the drum membrane, its color, normal transparency, morbid lesions, etc. Sometimes, the wax, muco-purulent matter, or other impediment that might obstruct our view, "may be gently removed with a small spatula, or a probe rolled round with cotton, as syringing is apt to increase the vascularity, and so mask the natural appearances." (*Wilde.*)

Another method of illuminating the ear for purposes of examination and applying medicines, is to have a plain or slightly concave mirror attached to an upright rod by means of a sliding rod, in such a manner that the mirror may be movable in every direction. This rod may be attached to some portion of the window-frame, or be placed upon a table near the window. Seating the patient about ten or twelve feet from the mirror, this is moved about until the rays of the sun received upon it are reflected immediately upon the ear, and through the ear speculum upon the

membrana tympani. This method is preferable to direct sun light or to artificial light. By means of a magnifying lens, of two and a half inches focus, held between the thumb and index finger, the meatus will be seen considerably enlarged, and a thorough examination may be made of the membrana tympani.—A new aural speculum named “Hutchinson’s, Clark’s Illuminator,” will prove a very useful instrument in nearly all examinations of the drum-membrane.—Von Troltsch suggests the use of a concave mirror of about six inches focus, with a central orifice, similar to the ophthalmoscope, for throwing light through the speculum upon the tympanum; I have used one with great advantage.

In the *healthy state* the appearance of the membrana tympani has been variously described by authors. Triquet states that it presents the appearance of a small thin web, transparent, of a pearly color, and slightly bluish with brilliant irised reflections; in its center is a kind of penumbra, an obscure point, which corresponds to the insertion of the malleus. The circumference of the membrane is a little more obscure than the other parts. Toynbee states that the outermost layer of the membrane is very smooth, and capable of reflecting light, and there is usually seen at its anterior and inferior part a triangular shining spot.

The following general description of its appearance may be of some value to the reader. The drum membrane is polished, shining, diaphanous or semi-transparent, clear, and brilliant, or occasionally of a yellow-gray tint, somewhat the color of gold-beater’s skin, or thin-sheet gutta percha, except toward its superior attachment, and along the line of insertion of the handle of the malleus; it presents an irregularly curved surface; is divided by a white streak thickened above and narrow below, except at its extremity, which is slightly enlarged and indented into a navel-like depression, or umbilicated. This white line is the manubrium of the malleus proceeding from the upper attachment of the membrane downward, somewhat backward, and a little inward, to a point slightly below the center of the membrane, which is thus divided into an anterior, posterior, and an inferior portion. The anterior part of the membrane is thin, almost transparent, or as clear as fine gold beater’s skin, highly polished, and generally convex, a speck of bright light being reflected from its most convex and prominent part; this is not always in the center of the anterior part, but is often seen beneath it, (a triangular shining spot at its anterior inferior part),—this may be called the anterior vibrating portion. Sometimes the short process of the malleus may be seen as a small

round dot above the manubrium, where the membrane curves off into the roof of the meatus.

Below and behind the malleus, the membrane is also thin, clear, and glistening, but not quite so diaphanous. Beneath the point of the malleus it is flat, and behind it rather concave, but not always so; spots of reflected light are not usually present in these parts when normal. Superiorly, from about the upper half of the malleus, the membrane becomes gradually denser until it is quite white; it also forms concave curves from the upper part of the malleus, the posterior one being deepest and whitest. Above, the membrane forms a gradually-vaulted curve into the roof of the external meatus, with the lining of which it is imperceptibly blended; while, in front, below, and partly behind, there is a sharp, well-defined line of demarcation between it and the meatus, and sometimes a slight, whitish, thickening.

In examining the *membrana tympani*, we must observe "its superficial color, its degree of opacity or transparency, its tenuity or thickening, its vascularity, and the arrangement and position of its vessels in every part,—its tension, flexibility, polish, curvature, and its position as regards the interior of the cavity of which it forms the outward boundary,—and also the direction and projection of the handle of the malleus; and the characters of the membrane, both above and below the attachment of this bone, should be carefully observed. While the membrane is thus within the field of the speculum, the patient should be desired to try and press air into the drum by holding the nose, shutting the mouth, and making a forced expiration. This manœuvre should be resorted to several times, if the first be ineffectual, as some degree of tact on the part of the patient is necessary to test the experiment. The sound thus produced is a sort of a *thug*, and very much resembles that of a dried bladder suddenly inflated with air.—When the tympanum is inflated, the whole of the anterior and lower portion of the *membrana tympani* is bulged outward, and the speck of light appears as if spread over a large surface, or is entirely lost for the moment.—While the air is thus pressed into the drum we should note accurately whether the membrane vibrates, or its tensility is altered, and if so, whether it regains its original position suddenly or gradually. The patient's own sensations should likewise be taken into account in this matter. It is also necessary carefully to observe the degree of vascularity produced by this inflation, as well as the course and position of the vessels which cause such vascularity, for even in several healthy ears, if this experiment is made two or three times, we seldom fail to recognize one or two vessels becoming filled

with red blood along the course of the malleus; and if a small aperture exists in the membrane which may have previously escaped the eye, we may then readily detect it both by sight and hearing. By this means we often discover a perforation, which, from its minuteness, or owing to the part being thickened or coated with discharge, had not been noticed during the ocular inspection. If such exist, we shall then see its open, everted lips, sometimes pressing out mucous discharge, and also hear a peculiar whistling sound which the air makes in passing through this narrow aperture. There are, however, some cases of perforate membrana tympani, where, from obstruction in the upper part of the Eustachian tube, or granulations in the middle ear, this can not be effected. If the patient be able to thus inflate the tympanum, we may then remove the speculum, and, by means of an ear-stethoscope (otoscope), ascertain the peculiarity of sound which is thus produced in the middle ear, (the same method of inflation being again had recourse to), whether the ordinary rush of normal air, or a prolonged squealing or gurgling sound,—such as might be caused by any contraction in, or thickening of, the walls of the Eustachian tube, or by dryness, or by accumulation of mucus either in it or in the cavity of the tympanum,—is heard. The stethoscope should also be applied over the mastoid process, and the same series of observations made upon the sounds, if any, produced there; but these latter can seldom be heard distinctly.” (*Wilde*.) If the patient can not thus inflate the tympanic cavity, there may be some obstruction in the Eustachian tube, in which case, if there be no acute inflammation of the tube or tympanum, we may inflate it artificially by injecting air, as hereafter described.

Under the influence of disease, the membrana tympani may present various appearances; it may become white and thick, from disease or decomposition, and sometimes the outermost layers can be removed in an unbroken scale. It may be collapsed, (indicative that the Eustachian tubes are obstructed so that air can not reach the tympanic cavity), entire, or ruptured; granular and vascular; mottled red and white; opaque and vascular; pinkish, thickened; pearl-colored, unpolished, thickened; whitish, thick, succulent and vascular; white and opaque in nervous deafness; sometimes the shining surface will be hazy and opaque, or as white as parchment, the handle of the malleus being discerned with varying degrees of distinctness, or ceasing to be visible at all; an opaque crescent may be observed on its lower edge; or, it may be covered by yellow lymph, wax, pus, or blood, etc. Occasionally, a ray of sunlight striking upon some of the irregularities of the eurved surface of the

membrane, gives the appearance of a perforation when none exists,—hence care must be exercised not to take the reflection of a ray of light for a hole or perforation.

When the mucous layer is diseased, it becomes thickened, vascular, villous, and even pulpy; in cases when this layer is intensely vascular, the other layers may remain as transparent as natural, (the epidermis being polished), while the inflamed mucous lining may be seen through these layers of a pinkish color.—When the proper fibrous membrane is inflamed, it will sometimes present one uniform sheet of bright red, and often, several small vessels, superficial to the general redness, and radiating from the center to the circumference, may be seen.—The cartilaginous or ligamentous ring can frequently be distinguished from the rest of the membrane, but, in disease, it becomes very manifest, frequently presenting a bright vascular zone when the rest of the membrane is not affected; it is also the seat of an isolated dense opacity at the inferior attachment of the membrane, resembling a crescentic white band, about a line in breadth, somewhat like the arcus senilis.

In the examination of the tympanic membrane the introduction of a probe to press against it, is very rarely required, as any perforation of the membrane can almost invariably be ascertained without the use of this instrument; but in the few cases in which its use might possibly be justified, it should be introduced very lightly and carefully, avoiding much pressure, and never without having the membrane fairly within view, as, otherwise, it will not only cause or increase pain, but may produce a perforation where none existed before.

Having carefully surveyed the *membrana tympani*, we withdraw the speculum slowly, at the same time examining the auditory canal, its form, curvature, color, polish, vascularity, and its secretion.

“Redness of the lining membrane of the external auditory canal is present both in acute and chronic inflammation; the vessels are abnormally developed, their calibre being increased by a foreign stimulus,—in the natural state, hardly perceptible with the aid of magnifiers, they become visible to the naked eye from inflammatory influences. The walls of the meatus are naturally of a pale rose color, but become more or less deep red from inflammation. With this vascularity, more or less tumefaction appears, the lining membrane seeming to be converted into a net-work of anastomosing vessels, and the walls almost come in contact with each other. In this case, the patient experiences a sensation as if a foreign body was in the ear, similar to that experienced in conjunctivitis. In the

chronic state the redness is not so deep, or is of a whitish rose color, with less vascularity and less tumefaction.

"If the vascular redness and the tumefaction continue and resolution is not effected, ecchymoses will be observed both on the walls of the meatus and on the tympanic membrane; they may be small, resembling flea-bites, or may attain a still larger size. In certain cases, where the mucous membrane appears raised, by pricking it with a fine needle, a small drop of blood will flow out, showing a subepidermic effusion.—If the disease be not checked in its progress, the reddish tint of the ecchymosis will become obscure red, brownish-red, grayish-red, and we will then have a purulent spot; suppuration or an abscess is developed under the epithelium. If the inflammation still continues the abscess will discharge itself into the auditory canal. If this abscess is developed in the thickness of the membranous layers composing the membrana tympani, the case will be still more serious, as a perforation is inevitable.

"When the walls of the auditory canal have suppurated for a long time, adhesions may be established between the drum membrane and the ossicles, and between these organs and the promontory; when the ossicles have become displaced, various adhesions may occur,—the luxated ossicles adhere to each other and fall into the tympanic cavity, and the drum membrane becomes shrunken. The case is then incurable.—Ulcerations may exist in the auditory canal from the preceding morbid changes; if they are simple and not extensive they are soon cured; if they are connected with a scrofulous or other diathesis, the appropriate constitutional remedies must be given. A slight ulceration of the drum membrane, following a simple catarrhal inflammation, generally heals readily. If it results from a scrofulous inflammation, it will be more serious and less amenable to treatment. If the ulcer be large, it will be impossible to heal it, and the perforation resulting from it will render the tympanum liable to disease.

"In certain subacute affections, a gangrenous layer forms and more or less of the membrane sloughs off; this occurs more particularly in small-pox, scarlatina, typhoid fever, and measles. From this results a loss of substance in the auditory canal and in the tympanic membrane. In the auditory canal this loss is not so serious, as reparation usually takes place. But if a portion of the drum membrane is destroyed, and the progress of the ulceration was from within outward, it becomes a more serious matter, and the ulceration increases daily; and, if to any extent, reparation becomes impossible. These ulcers usually occupy the center of this membrane at a point corresponding to the handle of the malleus. Sometimes,

the ossicles are removed by the suppuration, the stapes alone remaining in place; the liquids escape; the contact of air dries the parts; the auditory nerve loses its properties, and an incurable and complete deafness occurs. These are, however, not common, a reddish fungosity is usually developed, while the stapes alone remains in its place, so that the deafness is only partial.—When these ulcerations and gangrenous conditions have a tendency to heal, fleshy granulations will be seen on the surface of the membranes affected by them. Sometimes, and more especially when the ulceration is very small, and is seated at the circumference of the drum membrane, cicatrization unexpectedly occurs; when it is seated at the center, it becomes more serious.

“Opacities are a necessary consequence of the morbid changes just noticed; the inflammation has left between the layers a plasma, which is sometimes absorbed, and often remains indefinitely. More or less insensibility of the part is another consequence of these morbid changes; the walls of the auditory canal and drum membrane generally so extremely sensible, even when touched with a blunt probe covered with a little cotton, no longer experience any tickling sensation or pain.—Changes of form are likewise frequently undergone; the drum membrane loses its normal external concavity, and becomes flat; sometimes, it presents two lateral oblique surfaces, and on the sharp edge which separates them is inserted the handle of the malleus,—in this case, we may rest assured that the ossicles are anchylosed to a greater or less extent.

“The preceding conditions can not exist without more or less considerable hypertrophy or thickening of the affected tissues. The drum membrane, so thin and delicate, in the normal state, becomes vascular and thickens; at the point which corresponds to the handle of the malleus we observe an umbilication.—Inflammation gives rise to thickening, this causes the walls of the meatus to approach each other and lessen its calibre so that we can hardly perceive the drum membrane through it. The shrunken or atrophied membrana tympani somewhat resembles the eye of an ant. When the thickening amounts to induration of the tissues, the progress of the waves of sound, as well as the secretion of cerumen, are interfered with, and the parts become more disposed to renewed inflammatory attacks. If the drum membrane is indurated, we will have reason to believe that the induration extends more deeply and that the ossicles are likewise anchylosed. Softening sometimes follows induration, especially in strumous constitutions.” (*Triquet*.)

It must be remembered, in all instances, that an inflammatory or other disease developed in one of the tissues of the ear may invade

several others at the same time. The disease may commence in one of the tissues, and sooner or later involve the neighboring parts. It is by no means uncommon for a simple catarrhal or rheumatic external otitis to extend even into the internal ear.

3. *Examination of the Middle Ear.* In this examination the organs to be examined are inaccessible to the sight, and we can only form a more or less complete idea of their conditions by certain manœuvres or operations, as, by inflating the tympanum, catheterism of the Eustachian tube, douches of air vapor, or fluids into the tympanic cavity, and auscultation and percussion of the mastoid process.

However, before proceeding with any of these operations, the physician should examine the throat and fauces, to ascertain the condition of the parts there, and by means of a rhinoscope, he may likewise discover the condition of the parts situated behind and above the uvula and around the posterior nares. We should introduce the index finger into the mouth, and press firmly upon the palatine arch opposite the orifices of the Eustachian tubes, in an upward and outward direction, and observe whether it gives rise to pain or inconvenience at that part, or in the tympanum, and the character as well as the degree of the pain. The mucous membrane of the nose should likewise be thoroughly examined, using Wilde's ear gorget to aid in the examination. Disease of any of these parts, it must be recollected, may extend into the Eustachian tube and tympanic cavity, as the membrane lining them is one and continuous. Should there be enlarged tonsils, granular or simple erythematous inflammation, etc., of the nasopharyngeal cavity, and deafness be present, it will be proper to suspect that this inflammation, etc., has extended even into the tympanum; and, before undertaking any treatment for the affection of the ear, we should first treat the pharyngeal disease.

It occasionally happens that the tympanic cavity may be explored directly with the aid of a speculum, but this is only when the membrana tympani has been destroyed. And even then the examination is nearly always incomplete, from the presence of fungous growths in the tympanum, filling its cavity so that we merely see a reddish mass in the midst of which we can distinguish nothing. Generally, in these cases, the ossicles have become displaced or removed. Fortunately, destruction of the tympanal membrane is not a very common thing, and the greater part of patients affected with deafness have the membrane intact.

We now proceed to ascertain whether the Eustachian tube is free, so as to allow the passage of air into the tympanic cavity,

and also permit the discharges from this cavity to be conveyed to the pharynx. This may be effected in two ways, as follows:

a. *Exploration with the Otoscope.* Having placed one extremity of a Toynbee's Otoscope into the patient's ear, and the other into the ear of the examiner, being careful that no portion of the tube touches any neighboring body, request the patient to close his lips and hold his nostrils, and then make a forced expiration; the air, finding no other outlet, will be compelled to pass into the Eustachian tube, and as it enters the tympanic cavity and strikes against the inner surface of the drum membrane, the examiner will hear a *thug* like sound, or a faint blowing sound, depending upon the free condition of the tube and cavity from mucous matters. Or, instead of the forced expiration, the patient, having the nostrils and mouth closed, as above-named, may be requested to swallow a little saliva—he will then hear a *thug* like sound, and experience a sensation of fullness in the ear, while, at the same time, the examiner will distinctly hear a faint, liquid-like, crackling sound; or, if the mucous membrane of the tympanum be thick, the sound will resemble a gentle flapping.

If no sound be heard by either the patient or the physician, if no sensation of fullness in the ear be experienced by the former, and if the membrana tympani is not seen (through the speculum) to move, when these endeavors to inflate the cavity are attempted, then the second method of examination may be undertaken.

b. *Exploration with the Eustachian catheter.* Having selected the silver catheter to be used (Toynbee's or Wilde's are generally preferred, and if used in cold weather should be warmed), and seated the patient in a high back chair, or in some position where the head can rest and be properly supported, and where he can face the light, the operator, holding the catheter between the thumb, index and middle fingers of the right hand, somewhat in the manner of holding a bistoury or a pen, and standing in front of the patient, whose head he steadies with the left hand, will introduce the beak or point of the instrument, looking downward, into the nostril, and glide it quickly, but without employing any force, backward and by the side of the *septum nasi*, carrying it onward until the curved end reaches the faucial cavity, when it is to be pressed backward against the mucous membrane of the posterior part of the fauces; then draw it slightly forward, and rotate it outwardly, so that the extremity may turn upward and catch the orifice of the Eustachian tube, which can be distinctly felt, and will prevent the further rotation of the instrument. Now press the instrument backward and slightly outward, when it will be felt to engage in the mouth

of the tube. If the aperture be missed, the end of the catheter may again be carried against the back of the pharynx, and manœvered as before; or, by feeling for the opening by slightly pushing it in and out. With a little careful and dexterous manipulation, the catheter will almost find its own way into the tube, in most instances; sometimes, however, its introduction will be found quite difficult. During the operation the patient must not move nor speak; and the few tears which may frequently be seen, are the result of irritation and not of pain. The operation produces rather an unpleasant sensation; and should any irritation be caused at the tip or anterior extremity of the nose, this may be pressed upward with the left hand, so as to remove it from contact with the catheter.*

*Notwithstanding, as a general rule, that catheterism of the Eustachian tube may be readily accomplished, yet, difficulties as well as accidents will sometimes attend the operation. Thus, extreme timidity of the patient, or obstinacy in children, may require the use of chloroform. The nasal fossæ may be exceedingly narrow, so that a catheter of very small diameter and slight curve can alone be used, and which must be gently introduced under the lower turbinated bone, with its apex directed toward the external wall of the fossa. Sometimes, the narrowness may be so great that the catheter becomes arrested, on reaching the middle of the nasal fossa, between the septum and the turbinated bone, or between this bone and the upper jaw. Should this occur, the extremity of the instrument being properly directed, it will be necessary to withdraw it, and, after the patient has had a few minutes' rest, again attempt its introduction. Difficulties may also arise from excessive narrowness of the inferior nasal fossa, the result of chronic inflammatory thickening of the mucous membrane; from polypi or fleshy vegetations; from hypertrophy, or a greater or less unnatural elongation of the lower turbinate bone, with a faulty direction of the curve; from deviation of the septum of the nasal fossæ; from exostosis from the lower turbinated bone, or from the ascending process of the superior maxillary bone. An extreme sensibility of the pituitary membrane, and the pain produced by the least touch, also constitute a serious difficulty. Again, if the catheter be too large, have too great a curve, be improperly introduced, or have a wrong direction given to it, either of these will create a difficulty.

The local accidents arising from the operation, are,—1. Laceration of the inferior part of the nasal canal, causing slight pain, and a drop or two of blood; this is of little importance, unless the hemorrhage be profuse. 2. The pituitary membrane may be so excessively sensible as to cause great pain, constant sneezing, or excessive lachrymation; this last symptom causes no pain, although quite unpleasant, and soon passes off,—still some caution should be used in performing the operation in persons subject to diseases of the eye. 3. In subjects, in whom, as the result of repeated attacks of coryza, the mucous membrane will be red and inflated, and as it were, studded with papillæ full of blood, so that mere contact of the instrument will occasion epistaxis, which, however, may always be arrested by the inspiration of a little cold water, or astringent solution. 4. The operation may be disturbed by a nervous cough, but this is of no importance. 5. Spasmodic contraction of the orifice of the Eustachian tube at the moment the catheter is about to enter it, is not uncommon where patients have had re-

The rule just given for the introduction of the Eustachian tube is the general one. There may, however, be exceptions, as for

peated attacks of quinsy, where there is a simple or chronic granular pharyngitis, and where there is hypertrophy of the tonsils. Sometimes, especially with nervous subjects, as soon as the catheter touches the pituitary membrane, the velum palati is convulsively drawn upward. During these violent contractions, whatever be their cause, the peristaphyline muscles, inserted near the mouth of the Eustachian tube, completely effuse the opening, so that an instrument can not pass it without effort. If this spasmodic contraction occurs only at the moment when the catheter enters the tube, the point is expelled and falls into the pharynx, and the operation must be repeated. 6. If the operator employs too much force to overcome the contraction of the muscles, the mucous membrane may be torn, so as to give rise to the production of emphysema at the first attempt at deglutition or at inspiration. If the patient make a sudden movement of deglutition, or if the aurist wish to blow in a little air for the purpose of exploring the tube, the patient falls as if struck by lightning; he raises his hand to his neck; the eye is haggard, the face congested, the mouth open, and the voice lost. The symptoms resemble those of œdema of the glottis in its last stage. On forcibly drawing down the tongue with the finger, there is perceived to be considerable emphysema, raising the whole of the mucous membrane of the pharynx and even invading the larynx, especially the arytaeno-epiglottic folds. It is requisite only to tear with the nail of the finger which holds down the tongue, one of the emphysematous projections of the mucous membrane; the air escapes, and the patient recovers. Death has occurred from this cause. 7. Simple insufflation with an India-rubber bag, or the pumping of air into the Eustachian tube, may rupture the membrana tympani, more especially when there is chronic inflammation of this membrane. 8. When too frequently repeated, catheterism of the Eustachian tube, irritates the mucous membrane, and may give rise to traumatic inflammation, diminishing its density. And, sometimes, even the introduction of a small catheter may give rise to a painful inflammation, which may extend to the cavity of the tympanum.

The general accidents following catheterism of the Eustachian tube are: rigors and fever; facial neuralgia; obstinate headache; and an increase of the deafness, or of the noises in the ears, for the relief of which the operation has been undertaken. Suspension of the treatment is generally sufficient to arrest these accidents. (*Triquet.*)

Toynbee also observes, that in making a few puffs into the catheter, it will sometimes be the case that no air will be heard to enter, "the mucous membrane (at the faucial extremity of the Eustachian tube), being too thick to allow it to pass; and, under such circumstances, it is unwise to attempt to force the air into the tympanum. Great mischief has frequently resulted from such a proceeding; the mucous membrane having been lacerated, and the air been driven into the submucous tissue, causing extensive emphysema. Nay, still more serious results have occurred, the patient having been killed instantaneously, perhaps through the effusion of air through the fenestra rotunda (the membrane having been lacerated) into the labyrinth, and the shock upon the nervous system causing instant death. Nor need it be a source of surprise that the effusion of air into the labyrinth should prove fatal, since even the forcible distension of the tympanum, while blowing the nose, frequently produces giddiness by pressure upon the labyrinth."

instance, it may be required to pass the catheter through the nostril with the beak directed upward, both in introducing and withdrawing it; or the instrument may require to be gently rotated between the fingers, so as to find the way for itself, without any force being employed. Sometimes, if the patient makes a movement of swallowing, at the time the beak is being turned outward and upward, it will be involuntarily thrown into the orifice of the Eustachian tube. Again, it will sometimes be almost if not quite impossible to introduce the catheter into the mouth of the tube, unless we place it there with the aid of a pharyngoscope to guide us.

Wilde recommends to have the beak turned downward and rather outward into the angle between the floor and external wall of the nares, as it is passed rapidly over the nasal floor.

Triquet introduces the catheter directly into the inferior meatus, with its concavity looking upward and outward, the beak resting slightly against the external wall, (engaging, as it advances, deeply beneath the inferior turbinated bone), and its back or concavity in contact with the septum or partition; if it be slowly and gently carried on in this position, without using any force or violence, the posterior extremity of the inferior meatus is reached, and the point of the instrument, finding a natural groove along this inferior meatus, must, he says, infallibly and readily engage in the faucial orifice of the Eustachian tube which lies immediately behind this extremity of the inferior meatus. Sometimes, a slight turn of the instrument may be necessary to engage it. If an obstacle is encountered during the passage of the catheter through the nostril, it must be passed or overcome by slight lateral movements, without any rudeness or force. He prefers this method, which avoids giving rise to efforts at swallowing, or vomiting, as well as to spasmodic action of the pendulous veil of the palate, because, he says, the instrument reaches the orifice of the tube without having been able to touch this veil, or the pharynx.

Too slender a catheter is useless, as its calibre is too small to be of any service, either in removing mucus collections by insufflation, or in injecting medicated fluids; beside, it is more apt to injure the mucous membrane. Too large a catheter either can not be passed, with most patients, or else it may luxate or break the lower inferior turbinated bone, and terribly lacerate the mucous membrane. A catheter which has its beak too much curved is liable to the same objections. A medium-sized catheter, with a large orifice, a slightly curved beak, and a kind of olivary enlargement to round off this extremity, so as to avoid bruising or wounding the mucous membrane and to enable it to glide easily under the

small circular projection formed by the inferior turbinated bone, is the best. A practitioner, should, however, have several of different sizes.

The best time for the operation is before breakfast, or three or four hours after eating; or, the patient may be requested to omit the meal previous to the operation. The instrument should always be warmed, and anointed with glycerin, or white of egg. Sometimes it will be necessary to overcome excessive tenderness or sensibility of the mucous membrane, by several preparatory sittings, accustoming it gradually to contact with these instruments. Among refractory children, where catheterism of the tube is positively necessary, chloroform may be given to procure the required immobility, but it will not be necessary to produce complete anæsthesia.

The instrument being properly introduced into the mouth of the Eustachian tube, we are now prepared to explore this canal, or to treat it therapeutically with medicated vapors, fluids, etc.; if the latter, it will be proper, in most instances, to firmly secure the catheter by means of a frontlet bandage with a pair of forceps attached, which should be placed upon the forehead previous to the introduction of the catheter. If the former, this bandage may be dispensed with, at least when Toynbee's otoscope and explorer are used. The aurist will merely have to transfer the catheter to his left hand, and while holding it lightly, so as not to cause pain to the patient (as the use of the frontlet invariably does), insert into the dilated end of that instrument the small end of the explorer, (or, of the syringe, etc.).

The physician will place the other end of the explorer in his mouth, holding the catheter in place with the other hand constantly applied to it; then, adjusting the otoscope with the other hand (that is, having one extremity in his patient's ear, and the other in his own), he will gently blow through the explorer, and at the same time listen through the otoscope, to ascertain whether the air enters the ear, and if it does, what is the peculiar sound it produces. If the tympanum be unobstructed by mucus, the air is heard to pass in a stream against the inner surface of the membrana tympani, but when mucus is present, a peculiar gurgling is heard; and if the mucous membrane itself is thickened, a peculiar squeak or bubbling is also perceptible. It is better to make only a few successive puffs, attentively listening during each; but it is not advisable to blow forcibly into the ear. (*Toynbee*.) Wilde states, that in a healthy ear, with a free tube, when a stream of air is passed into the tympanum, it impinges upon the inner wall of the membrana tympani

with a peculiar *thug*, followed by a continuous rustling sound, which is very remarkable, is the normal or natural sound, and is not very easily forgotten when once heard.

When a puff or douche of air is passed into the tympanic cavity with a certain degree of impulse, through a catheter introduced into the Eustachian tube, a crepitation will be heard through the otoscope, which is either strong or feeble, with or without much bubbling or rattling, dry or moist, cavernous or veiled. If the tube be large, the sound will be strong, and resemble that of a heavy rain falling through dry leaves.—If there be an accumulation of mucus in the tube or in the tympanum, or, if the tube be strictured, the sound will be feeble and intermittent; the current of air will pass through these mucous secretions with more or less difficulty, and the bubbles of air will rupture, one after the other, and at long intervals.—The crepitation will be dry, when the mucous membrane lining the tube is dry, like parchment, and which condition is a cause of deafness.—It will be sonorous or cavernous when the membranes which separate the cells of the mastoid process have been destroyed by an internal otitis with suppuration, thus converting this process into a large cavity communicating with the tympanum, and swelling the sounds which are produced there, somewhat like cavities in the lung.—When the tympanic cavity is filled, either by an effusion of blood, by mucous secretions, or by pus, the crepitation will be veiled or muffled.—When the tube is wholly obstructed, or obliterated, the air not being able to penetrate into the drum, this cavity gives no sound during the operation of insufflation; and when this is the case, it is unwise and even dangerous to attempt to force air into the tympanum, as the result may be laceration of the mucous membrane with extensive emphysema, laceration of the membrane of the fenestra rotunda, consequent effusion of air into the labyrinth, and death.

“If when a jet of air is made to enter the tympanic cavity, we succeed in getting a clear view of the drum membrane through a speculum, it will be observed to press outward the anterior and lower portion of this membrane,—that which is most vibratory and placed opposite the stream of air,—and also that it at the same time renders the upper and posterior part of the membrane slightly vascular.” (*Wilde*.)

With regard to the introduction of medicated vapors, etc., after the Eustachian tube has been introduced, I will refer to it hereafter, when treating of the diseases in which such vapors, etc., are recommended.

It may be proper to state here, that *in removing the catheter from*

the Eustachian tube and nostril, we must be as careful and as delicate as when introducing it; we first, gently remove it from the blades of the forceps of the frontlet bandage, if one be used; and then slightly drawing the tube forward a short distance, to free it from the Eustachian orifice, we rotate it so that the beak or extremity will be downward, which we can determine by the position of the ring at the other (outer) end, and then rapidly withdraw it from the nostril, without using the slightest degree of force in so doing.

4. *Examination of the Internal Ear.* Here we have no direct nor indirect method of ascertaining the morbid changes to which deafness may be due; as this portion of the ear is deeply situated in a bony receptacle, concealed from sight and from the various means of exploration. It is only by exclusion, and by the impossibility of connecting the morbid symptoms of the disease with a lesion either of the external or internal ear, that we may be able to decide whether there is a lesion of these deeper parts of the ear, the existence of which we can not directly verify. Diagnosis by exclusion does not belong only to the ears, we find it made use of in the investigation of a large number of diseases.

Diagnosis by exclusion is not, then, a mark of inferiority peculiar only to the examination of diseases of the ear; it is the consequence of one of the difficulties of our art,—a difficulty which is met with in other diseases than those of the ear, but more especially here on account of the situation of this apparatus in the thickness of the petrous portion of the temporal bone.

However, there is a method of ascertaining if the internal ear is capable of fulfilling its functions, or in other words, if the vitality of the auditory nerve is not abolished, and that is catheterism of the tympanum. Between the tympanal membrane and the labyrinthine cavities are a non-interrupted chain of ossicles, serving to transmit, in part, the impression of the sonorous vibrations of the membrana tympani to the liquid contained in the vestibule, the semicircular canals, and the cochlea. From this disposition, it will be seen that if we concuss the drum membrane at the point of insertion of the malleus, by means of a blunt probe, the whole chain of ossicles is thereby put in motion; and through the stapes to the fenestra ovalis and the liquor Cotunnii; so that, if the auditory nerve has not lost the faculty of being impressed by sonorous vibrations, the patient may experience a sense of confused hearing. We term this operation, “catheterism of the drum membrane,” and it should be performed with a very delicate blunt probe, having its concussing extremity covered with cotton. From this examination we can

determine whether there is any encouragement to undertake treatment of the case so examined.*

* M. Gendrin recommends auscultation as a means of facilitating the diagnosis of the deep-seated portions of the ear; the auscultation may be either *mediate* or *immediate*, and the patient's nares should be closed.—In the physiological condition every *expiration* produces in the tympanum a deep, gentle, distant *bruit de souffle*, which passes away before the end of the expiratory movement. If the *membrana tympani* is perforated, this sound becomes acute, dry, sometimes even sibilant, and is more prolonged. When the *Eustachian tube* is narrowed, it becomes intermittent, consisting of several successive *souffles* which are usually accompanied with bullar crepitation due to mucosities. Crepitation may be heard when there is caries of the internal ear, or when there is a collection of matter in the middle ear, or in the mastoid cells, in communication with the tympanum and the open tube; but here the crepitations are deep and moist. Coughing renders these abnormal sounds shorter and more clear, so that they are more easily recognized.

Inspiration, in a sound ear, does not give rise to any perceptible sonorous vibrations; but if the membrane is pierced, the Eustachian tube remaining pervious, a very sharp sibilant *souffle*, mingled with moist crepitation, is heard, the patient himself often being conscious of the sound.

The *voice*, heard in the ear, appears deeper and slightly vibrating, and is interrupted by frequent and sudden intermissions. When the Eustachian tube is narrowed, or the tympanum is filled with mucosities, by pus or by a central exostosis of the petrous bone, the sound of the voice degenerates into a confused and inarticulate murmur. It is not heard when the tube is obstructed; and it becomes whistling, and accompanied by crepitating bullæ, when the membrane is ruptured. In the normal state, the *labial hissing* is transmitted by the ear like a distant acute *sibilant souffle*. It is much weakened or almost silent when the Eustachian tube is narrowed, and is not heard at all when this is obstructed. When the membrane is destroyed, the tube remaining free, the hissing becomes very acute, and is so near that the patient seems to be whistling in one's ear. In most cases the abnormal sounds may be verified by a comparative auscultation of both ears, as it is rare to find the same degree of the lesion in the two. (*Brit. and For. Med. Chir. Rev.*, Jan. 1857, p. 272.)

"A watch placed between the teeth, so as to touch them, is *not* heard by the person whose deafness is caused by lesion of the auditory nerve or brain. The sound is conveyed by the bones of the head to the sentient portions of the ear, and is distinctly audible when the nervous apparatus is in order. This test will serve to separate a small class of cases of deafness, in which *no benefit can be derived from Eustachian catheterism*.

"If the tick of the watch be heard, and the external auditory passage, as well as the *membrana tympani* be found healthy, negative evidence is afforded that either the Eustachian tube or the middle ear is at fault. To complete the evidence, let the patient close his mouth and nostrils, and then make the movement of swallowing; if the tube be healthy, he will distinctly hear the air move in the ear with a kind of thug and producing a feeling of fullness, which is at once removed on swallowing with the nostrils unclosed. If there is mucus in the tubes, the patient will feel a gurgling in the ear, the result of air breaking in bubbles in the secretion; if the tube is obstructed, no sensation or sound will be experienced." *D. Hodyson*.

THERAPEUTICS OF DISEASES OF THE EAR.

As the theurapeutics of aural affections are not generally well understood, it may not be improper, previous to a description of the causes, symptoms, treatment, etc., of the various lesions of the auditory apparatus, to make a few remarks relative thereto, which will be equally applicable to both the acute and chronic forms. Aural therapeutics, if properly understood, can not materially differ from that of other diseases, at least so far as concerns the influence of depletives, counter-irritants, antiphlogistics, medicines which act specially on mucous or serous tissues, etc.; and the same class of medicines indicated in certain forms of disease in any organ of the system, will be found fully as useful in similar diseases of the ear, the only difference being, perhaps, in the mode of administration. —For convenience, aural therapeutics may be divided into two classes, the first, comprising general medication; the second local application.

I. GENERAL MEDICATION.

1. *Alteratives*, or those remedial agents which determine normal changes in the living solids and fluids of the economy, without occasioning any remarkable evacuation of the secretions or excretions; and which class of medicines will frequently be found of great value in the treatment of chronic affections of the ear. Alteratives may be of a stimulating, sedative, tonic, antistrumous, or antisyphilitic character; and, in the treatment of disease, that kind of alteratives should be selected, which will be the best suited to the temperament of the patient, and to the character which the symptoms of his disease present. And as the greater part of patients having disease of the ears, are of a strumous habit, it will be proper to select those agents which are termed antistrumous, or antiscrofulous, etc.; and if there is an abnormal activity, or depression in the vital condition of the tissues affected, a sedative, or a stimulant should be associated with the antiscrofulous agent, unless we can procure one already possessing stimulant or sedative antiscrofulous properties.

Among the agents used as alteratives are the preparations of Iodine and Bromine; of which the best are Iodide of Iron, Iodide of Iron and Manganese, (*tonics*), Iodide of Potassium, Iodide of Ammonium, Tincture of Iodine, (*stimulants*) and Bromide

of Ammonium, (*sedative*); the vegetable alterative preparations which have been found the most efficacious are, Compound Syrup of Aralia, (*stimulant*), Compound Syrup of Queen's Root, (*stimulant and diuretic*), Compound Syrup of Poke, (*sedative*), Compound Syrup of Turkey Corn, (*sedative and tonic*), Compound Syrup of Yellow Dock, Compound Tincture of Corydalis, (*tonics and cholagogues*), etc. An excellent preparation for children to use on their bread instead of butter, is made as follows: Take of fresh Butter four ounces, Iodide of Potassium one grain, Bromide of Potassium three grains, Chloride of Sodium (*salt*) half a drachm, mix thoroughly together.

As the system, after a time, becomes accustomed to the continued use of one alterative preparation, which thereby loses its remedial influence, it will be better to occasionally change or alternate the administration of these agents.

2. *Purgatives*, are generally of more value in acute inflammations than in chronic. Laxatives are preferable, as a general thing, in chronic affections, merely to prevent the bowels from becoming constipated, or irregular in action; occasionally, however, more active measures may be required. The purgatives preferred are the Oleo-resin of Blue Flag, Resin of Podophyllum, and in some cases, Aloes; or, the various pills into which these articles, together with Scammony, etc., enter. Rhubarb and Ginger, or Rhubarb and Sulphur, are excellent for strumous children with soft flesh, and torpid or impaired digestive functions. When there are morbid accumulations in the intestines, the neutral salts may frequently be used with advantage, as, Sulphate of Magnesia, Citrate of Magnesia, Sulphate of Soda, Seidlitz powders, etc.; however, the character of the laxative or purgative will depend upon certain circumstances attending the disease, and which have been referred to, heretofore.

3. *Emetics* are useful to dislodge unhealthy matters from the stomach; to stimulate the nervous energy of this organ when there is a tendency to dyspeptic complication; to cause a determination to the surface; and to impart a healthy shock to the general nervous system. They will be found useful more especially in lymphatic, bilious, and torpid constitutions; but should be avoided as much as possible in aural diseases, among those of full habit or of great nervous irritability.

4. *Diaphoretics* appear to be more useful in catarrhal or rheumatic affections of the auditory apparatus, as well as among aural patients of full habit; obstinate headache, accompanying old chronic inflammations of the labyrinth, are frequently relieved by a profuse perspiration. Diaphoretics may be said to include all the

means of exciting a determination to the skin, from bathing and friction, warm infusions, and sudorific tinctures, to the hot air bath.

5. In addition to the above, will be required, agents which exert a more special influence upon *mucous tissues*; those which more powerfully affect *serous tissues*; *antisyphilitics*, when deafness is due to the action of the syphilitic virus upon the membranes and bones of this complicated organ; *chalybeates*, when it is due to chloro-anæmia, etc.

II. LOCAL MEDICATION.

1. *Injections of Medicated Fluids or Vapors, into the Tympanic Cavity.* For the purpose of removing obstructions, mucous accumulations, etc., in the Eustachian tube and tympanum, injections of warm water have been recommended. They may be introduced by means of an ordinary syringe, after the Eustachian catheter has been passed into the orifice of the tube, by the means named on page 1235, and fixed by the frontlet bandage. This operation, so highly recommended by some writers, is really of but little service, and is seldom required; when performed, the fluid regurgitates into the throat, and is apt to occasion irritation.

The mucous membrane of the Eustachian tubes, being similar to that of the nostrils, may like it, secrete mucus in abnormal quantity, when exposed to inflammatory influences, and this mucus, like that of the nose, may become quite hard, very adherent, and only capable of being detached after having been moistened with warm water. At the junction of the osseous and cartilaginous, or narrowest part of these tubes, which is only about one-fiftieth of an inch, or a quarter of a line in diameter, a very small quantity of dry, hard, and adherent mucus at this point, would cause an obliteration of the canal, and occasion a rapid and complete deafness. Here is one of the few cases in which injections of warm fluid would be of service. But where there is only a thick and viscid mucus adhering to the ossicles, fenestra, etc., causing dullness of hearing, tinnitus, etc., injections of air or vapor will be found to answer a much better purpose.

The injection of medicated vapors for the purpose of altering the condition of the mucous membrane of the tympanum, or stimulating the nervous expansion on its surface, will frequently be found serviceable in the treatment of diseases of the middle ear. Various agents have been used for this purpose, as, for subacute or chronic catarrhal inflammations of the middle ear, the vapor from

infusions of Elder Flowers, Sassafras Bark, Flowers of St. John's Wort, Flowers of Marygold; the vapors of Benzoin, Tolu, Myrrh, Tar, Sweet Gum, etc., to stimulate the nervous filaments in old cases of nervous deafness; and the vapors of solutions of Iodine, Iodide of Ammonium, Hydrochlorate of Ammonia, Bromide of Ammonium, etc., to act as local deobstruents, discutients, or detergents. In nervous deafness, ethers, and medicated vapors act only through the intermedium of the membranes of the fenestræ ovalis and rotunda.

A very simple apparatus is required for this purpose; a glass flask capable of holding about a quart of fluid, has about one-third of its capacity, (*i. e.* 10 or 11 fluidounces) filled with the infusion or solution to be employed; this is placed upon a shallow sand-bath, over a spirit-lamp. A cork is fitted into the mouth of the flask having three orifices in it; *one* for a thermometer, which should pass far enough down into the bottle to have its bulb immersed in the solution; *the second*, for a glass tube to pass through, having one extremity nearly in contact with the bottom of the flask, and its other extremity communicating with an elastic tube the further extremity of which is attached to a bellows, an elastic bag, or which may be held in the mouth of the operator; *the third* orifice is for a piece of glass tubing, entering only a short distance within the flask; and to the outer end of which tube is attached an elastic tube, the further extremity of which is fastened upon the Eustachian catheter. These elastic tubes need not be over two feet, or two feet and a half in length.

It is used as follows: The Eustachian tube having been properly introduced, and fixed by the frontlet bandage, and the solution in the flask being sufficiently heated to give off vapors, the operator, either by means of the bellows, etc., or by simply blowing into the elastic tube leading to the long piece of glass tubing, forces a current of air into the fluid in the flask which displaces, and forces a portion of the vapor in the flask, to enter the short piece of glass tubing, pass along the elastic tube and catheter, and be expelled into the Eustachian tube and tympanic cavity. A continuation of the supply of air from the mouth or bellows, will keep up the supply of vapor upon the affected *parts* as long as may be desired. Care must be taken with regard to the temperature, which may be regulated by the thermometer, and which should be mild, halituous, and convey no sensation of burning or scalding.

For the injection of Ether, Chloroform, and other very volatile substances into the ear, urethra, etc. I have found the following apparatus very useful; it consists of an ordinary silver syringe

about six inches in length and half an inch in diameter. Close to the nozzle end of the barrel is an aperture into which the neck of a small vial or glass flask may be screwed; and a delicate valve is attached to the barrel-end of the nozzle, which will allow air to be expelled when the piston is pushed down, but will permit none to enter when it is drawn outwardly. The glass flask has a metallic band with male screw threads attached to its neck so as to fit the female screw in the aperture of the barrel: and a delicate valve is also placed within the neck, to allow the vapor from the fluid contained in it to escape into the barrel of the syringe, but not to return again into the flask. If necessary another valve may be placed in the piston head, similar to those in small air pumps. Through a short tube leading from the nozzle of the syringe to the properly introduced Eustachian catheter, the vapors may be injected into the tympanum without any trouble. A cloth wet with warm water and applied around the glass flask will cause the ethereal vapors to rise. I have used such a syringe for the last six years.—A somewhat similar but cheaper arrangement may be made, substituting a vulcanized rubber ball for the piston, and hard rubber for the barrel and nozzle.

Vapor of medicines may be introduced into the tympanum in very many instances, without the aid of the Eustachian catheter. Thus, by means of medicated cigarettes, one of which the patient is to smoke, (or by directly filling the mouth with the vapor, from the prescribed article, by means of suction or otherwise), and when the mouth is filled with the smoke or vapor, the patient keeping his mouth closed, and also holding his nostrils closed, will either make a strong expiration in order to force some of the vapor into the tympanum, or, (and which will usually succeed much better after a few trials), while keeping the mouth and nostrils closed, he may attempt to swallow some of the vapor, simultaneously making an effort to cause a crackling sound in the ears. And this may be repeated as often as deemed necessary.

Preparations of Opium, as Laudanum, etc., should never be placed in the ear, and especially the middle ear; their action is dangerous, and they have even caused death. Ether, or Chloroform, are not proper agents to introduce into the external or middle ear, except in vapor or very much diluted; otherwise, they produce irritation, a sensation of violent burning, with more or less severe pains. Violent and painful irritations in these parts may rapidly extend to the brain and give rise to serious consequences, as the brain is only separated from the ear by a thin lamina of bone, thinner than an egg shell. Ether dropped into the ear was for a time highly

lauded for deafness, but it was found to produce serious cerebral disorders. Miss Cleret, who it was pretended had made the discovery, used it for her own deafness, and eventually became insane. Triquet recommends warm solutions of Tannin, Sulphate of Copper, and Benzoic Acid, in Glycerin; and Alum, and Sal Ammoniac, in water, as injections into the middle ear, or, to be dropped into the external; of course, they should not be too strong.* He also proscribes Nitrate of Silver, and Sulphate of Zinc, as being very painful and giving rise to serious symptoms, although, he uses Solution of Chloride of Zinc in polypus, etc.

The following preparations for injecting into the ear have been recommended by European aurists, and will often be found very advantageous, when properly applied:

Injections of Caustic Potassa. In cases where the diagnosis leads us to believe that the mucous membrane of the Eustachian tubes or of the tympanum, is in a mammillated condition, and especially among patients whose deafness is consecutive upon typhoid fever, M Marc d'Espine recommends the injection of a solution of caustic potassa into the middle ear, thus,—to a concentrated Aqueous Solution of Caustic Potassa, add twenty or thirty times its volume of water, or sufficient to impart a slight tingling sensation to the tongue, when the diluted solution is applied to it. This done, we take up in a pipette, syringe, or other small tube, fifteen or twenty drops of the diluted solution, and, by means of a caoutchouc vapor ball, we insufflate or blow into the middle ear, through the Eustachian catheter previously introduced into the pharyngeal orifice of the tube, the desired quantity of the solution. At first, this will be only four or five drops repeated every other day, and gradually increased to eight or ten drops, ceasing, when the tubes and tympanum are filled with mucous sounds during the insufflation. When the operation has favorably succeeded, the patient will complain of a sense of heat with formication or tingling in the ear. The pain is slight, and soon disappears, though occasionally it continues until bed-time. On the first day, if the pain should prove too severe, it will be prudent to inject into one ear only. If, at the

* In acute catarrhal inflammation of the ear, Triquet recommends, after the pain has been removed by leeches, poultices, and injections of infusion of black tea, and when a discharge only remains,—to inject with, *R.* Rose-water one hundred parts, Honey of Roses thirty parts, Sulphate of Copper one part; mix. If this is not well borne, replace it for some days with an infusion of Elder, or Melilot, or with warm Tar-water, and then use the following: *R.* Sugar of Lead four and a half grains, Honey of Roses seven and a half drachms, Rosewater three ounces; mix.

commencement, the tubes are filled with mucous sounds in the expiratory efforts, or during insufflation, we should, for a week or two, be satisfied with the employment of injections of dry air, or a few drops of ether or chloroform may be added to it to render it slightly excitant. The dryest tubes soon become moist under the action of the potassa, as may be perceived in the mucus rattling sounds produced during the insufflation. The pain occasioned by this injection is not followed by any inflammatory symptoms; and no inconvenience results from its continued employment. Tinnitus frequently ceases while it is being used. Several injections may be required in order to effect a satisfactory result; sometimes, only one.

Injections of Iodine. Take of Tincture of Iodine ten grains, Iodide of Potassium one grain, Distilled Water one hundred grains; mix. This injection acts locally upon the membrana tympani, as, in thickening, a mammillated or fungous condition of it, etc.; beside, the heat of the cavity into which it is injected is sufficient to volatilize a small quantity of the iodine in this fluid, and this vapor, by its excitant properties, may stimulate the nervous membrane of the labyrinth, and even the auditory nerve itself,—being an energetic means of awakening the sensibility of this organ when the deafness is really due to a want of excitability. These injections are generally very painful, requiring great courage and determination on the part of the patient to submit to, and support them. The above-named solution should be diluted with one-third, two-thirds, or one-fourth its volume of water, before using it, according to the susceptibility of the ear.

Injections of vapor of Ether, or of Chloroform. Injections of air with chloroform added to it, may be employed concurrently with the potassa injections to modify the vital properties of the organs of the ear; these injections of ether or chloroform may be useful in cases where there is a paralysis of the acoustic nerve; they are of great service when the deafness is accompanied with tinnitus. To use them, we place some Acetic Ether or Chloroform, (say, commencing with one-fourth of a drachm, and at different times, from a drachm to a drachm and a half), in a hollow ball of India rubber, furnished with a metallic tap, or stop-cock; the heat of the hand applied over the ball is sufficient to volatilize the liquid. The outer extremity of the tap is placed in the opening of the Eustachian catheter previously introduced into the orifice of the tube, the tap is opened and a simple pressure upon the ball expels the vapor into the cavities of the ear.

Injections of Strychnia. If Ether or Chloroform fail, we may try

Strychnia, Nux Vomica, Veratria, etc. In obstinate and desperate cases, all means are legitimate, which are not injurious. Injections of Strychnia may be made of two strengths, thus:—No. 1. Take of Strychnia three grains, Acetic Ether, Distilled Water, of each, four fluidrachms; mix.—No. 2. Take of Strychnia four and a half grains, Acetic Acid seven drops, Distilled Water four fluidrachms; mix.—Make of these two perfectly transparent solutions, of which three or four drops are to be injected into each Eustachian tube. In employing No. 1, we inject at a sitting, one-thirty-fifth or one-fortieth of a grain of strychnia, or one-eighteenth or one-twentieth of a grain for the two ears. In employing No. 2, we inject one-twelfth or one-fourteenth of a grain of strychnia, or one-sixth or one-seventh of a grain for both ears. This injection is successful about once in ten or twelve times, and occasions no bad results; it may be employed once in every two, three, or four days. It, together with the one following, has also proved useful in deafness from rheumatism, and from partial ankylosis of the ossicles.

Injections of Veratria. No. 1. Take of Veratria one part, Acetic Acid one part, Distilled Water twenty parts; mix. This solution is never employed pure, but always diluted with four, five, or six times its volume of water. It is a very painful topical irritant.—No. 2. Take of Veratria one part, Alcohol twelve parts; mix. When used, this solution must be diluted with from two to twenty-four times its volume of water.

Veratria being an extremely irritating substance, we must commence with very dilute solutions. The weakest dose for an injection is one one-hundred and fiftieth of a grain in two drops of water; the sensation, from this quantity, is hardly perceptible; however, the ear into which it is injected becomes slightly irritated. The strongest dose in which veratria has been used is one-twelfth of a grain in three drops of alcoholized water. The effect was very violent, the pain in the ear torturing. Pure water was immediately injected to mitigate this pain; but after the seventh insufflation of the solution, there was a decided amelioration, sufficient to authorize the continuance of this agent. However, great caution is required in employing these stronger solutions.

2. *Leeches or Cupping.* Local depletions, by leeches or cups, will often be found useful in acute diseases of the auditory apparatus, and especially at the commencement of catarrhal phlegmonous inflammations of the meatus. When a single ear is affected, three or four leeches will be sufficient for children, and six or eight for adults. The number, however, will be variable according to the intensity of the inflammation. They should be applied as near to

the painful part as possible, and be kept in their place, by being, each one, enclosed in a small leech glass, having a bevelled mouth.

In inflammations of the auditory canal and membrana tympani, they should be applied immediately around and within the margin of the meatus, (previously placing a little cotton into the ear, both to prevent the leeches, as well as the blood, from entering into this organ); or, in the fossa behind the tragus, and sometimes in the hollow in front of the tragus formed by dropping the lower jaw. If the inflammation affects the region of the mastoid process, leeches should be applied over its surface at various points. If the inflammation is in the tympanum, they should be applied to the base of the mastoid process, or to the orifice of the corresponding nostril. In labyrinthine inflammations, scarifying and cupping is preferable, applying the cups along the sides of the mastoid region, at the root of the neck, and at the nape of the neck, repeating them as often as may be required. After the leeching, care must be taken not to allow too much blood to flow from the bites.

However, the use of leeches can frequently be dispensed with, as anodyne fomentations, or the vapor arising from infusions of anodynes may be effectually applied to the outer parts of the ear as well as to the external auditory canal; and this will be still more promptly efficacious, if aided by profuse perspiration effected by means of the spirit vapor bath, and a sinapism along the whole extent of the spinal column. Hypodermic injections will also be often of great service in painful and active inflammations of the ear. In the chronic forms of aural diseases, local depletion is seldom, if ever, required.

Scarifications of the mucous membrane of the external auditory canal is recommended by Triquet, in inflammation and tumefaction of this membrane, as a really excellent measure. He says: "A long experience has convinced me that these scarifications are useful, not only when the inflammation is on the decline, but also in the acute stage and especially when the swelling is considerable. One or two deep and longitudinal incisions, made with a small tenotomy scarificator, about one-third or one-sixth of an inch long, will suffice." If possible, a small pledget of cotton should be gently introduced as far as the bottom of the auditory canal, to prevent the blood from coagulating upon, and irritating the drum membrane; and, to promote the flow of blood, the surface of the incisions should be frequently and gently washed with a small piece of soft sponge moistened with warm water,—light pressure upon the tragus will also aid in obtaining this result. Or, the ear may be syringed from

time to time, when the above can not be accomplished, with a small quantity of warm water.

3. *Perforation of the Membrana Tympani.* Abscess of the drum more frequently discharges itself through the drum membrane than by any other route, and, it has been observed, that several persons who had experienced this accident, recovered a certain degree of hearing. In consequence of which, many aurists have perforated the drum membrane in some of their deaf patients, and with varied success. But, the only instance, in which perforation of the membrane is at all serviceable, is in deafness due to the absence of air in the cavities of the middle ear; or, where these are so filled with pus or other fluids as to distend the membrana tympani and render it liable to rupture; and, perhaps, in cases where there is a permanent thickening and opacity of the membrane, which obstinately resists all the measures employed for effecting its thinning by absorption. But, then we should be certain of these conditions, and also of the fact that they can not be remedied by any other means. Indeed, it may be truly said, that the operation is rarely required, and is apt to be followed by the most serious consequences, even death, if not performed in a careful, delicate, judicious, and proper manner. The value of the operation is much diminished by the difficulty in keeping the orifice open after it has been made.

Toynbee performs the operation by means of the sharp triangular end of a probe, for temporary benefit; and where a more permanent opening of the membrane is required, he makes a triangular flap, about a line long, by means of a small scalpel, having the apex of the flap above, so that it can be turned down. He states that the part best adapted for the perforation is that between the handle of the malleus and the posterior margin of the membrane, so that if we are mistaken in our diagnosis, and there is no effusion, etc., in the drum, the chain of ossicles remains intact, the wound soon heals, and the hearing is not compromised. Wilde selects a similar spot, "its inferior, thin, vibrating portion;" he uses what may be termed "Wilde's perforator." He gently introduces its point into the membrane, and drawing it downward and forward, makes a simple incision about a line and a half in length. Occasionally a crucial incision is made. The patient is often unconscious of its performance, until made aware of its completion by the rushing out of the air through the aperture. If left in this condition it would soon heal up; he, therefore, cauterizes the edges of the wound to prevent them from adhering. The operation may be occasionally repeated, whenever the wound shows an inclination to heal.

The operation should be performed through the speculum auris,

and with the membrana tympani well illuminated by the sun's rays, or by a strong artificial light, and the operator must hold the instrument lightly in his hand, so as not to carry it too deeply into the drum; before undertaking it, a last and careful examination of the membrane should be instituted. Triquet prefers a cataract needle, and selects the anterior and inferior part of the tympanic membrane, about one-thirteenth of an inch from its circumference; the instrument should be passed in about one-eighth of an inch at the farthest, and, in withdrawing it, turn the blade on its axis, so as to allow the fluid to flow out. He says, experience has proven that wounds of this membrane, without loss of substance, readily heal, provided the membrane is kept for a few days from the action of sound-vibrations; and for which purpose he keeps a plug of cotton in the ear, after the discharge has ceased.—Perforation of the drum membrane presents serious inconveniences, even dangers; and when the perforation persists, it is constantly followed by a considerable diminution of hearing, and a suppuration of the tympanum difficult of cure.

4. *Perforation of the Mastoid Process.* This operation is stated by writers to be of service in cases of deafness, where the middle ear and mastoid cells are filled with a sanguineous or purulent fluid; it affords an escape for the pus, and restores the hearing. It has not always been successful, and has occasionally terminated fatally. Wilde recommends the operation in acute myringitis, where no relief is had from the other means employed, and where an indistinct sense of fluctuation can be discovered; also in acute otitis, in which, he remarks,—“So soon as it can be determined that matter has formed under the periosteum, or that the structure itself, or the bone of the mastoid process beneath it, is deeply implicated in the inflammation, the surgeon should not hesitate to make a free incision, as I have recommended, etc.—Promptness and decision in this matter will often save a patient's life, even in an advanced stage of the disease.”

Toynbee says,—“Perforation of the mastoid process also suggests itself, and this operation may, doubtless, be performed in those cases where the matter is pent up in the cavity of the ear, and is causing such urgent and serious symptoms, as are likely, if not relieved, to terminate in death. I have never performed this operation, but I should not scruple to do so in a case where the life of the patient was threatened.” Notwithstanding, perforation of the mastoid process is not without danger; and when it is practised, as some have recommended, for renewing the air of the mid-

dle ear, it must necessarily give rise to a painful and disagreeable fistula.

When there is a collection of pus filling the mastoid process, distending the cells; when the walls of this process have become raised or bulged out from the suppuration; when the skin over this region presents bluish, or purplish-red spots, protruding and presenting a manifest fluctuation; when the abscess is observed to be on the point of rupturing; when, in addition, the *membrana tympani* can be observed thrust outwardly, presenting a prominent convexity; and when all the symptoms of fullness and distention of the tympanic cavity are present, we should promptly perforate the mastoid process. Too long a delay is fraught with serious danger.

In performing the operation, place the patient in the recumbent position, with the head slightly raised and resting upon the healthy side, and in a situation well exposed to the light. The diseased region must be properly shaved; and before commencing the operation, the physician should make a final examination of the diseased part. Some cataplasms of Linseed, previously applied over the affected region, will render the examination more easy. After having verified the existence of fluctuation and crepitation, the operator will select the point at which the operation should be performed. This point is variable; however, as a general rule, it should be selected where the tumor is more prominent, the fluctuation more manifest, the skin purplish-red, adherent to the subjacent bone, or, where the abscess would open if left to itself. The incision should be made about three-quarters of an inch from the attachment of the auricle, so as to avoid the posterior auricular artery, and, as nearly as possible, in a line parallel with the auricle.

Grasping a stout scalpel between the fore-finger and thumb, so as to leave only about an inch of it uncovered, an incision is to be made, until the bone is reached; the process may then be perforated with a trocar, or, the scalpel may be carried through the bone, and the pus be allowed to discharge.*

* Dr. Von Trœltzsch, a celebrated German aurist, states that, the cells of the mastoid process are in open communication with the tympanic cavity, are covered with the same mucous membrane, and participate in all the affections of that cavity. Pus accumulates the more readily in these cells, as their communication with each other and with the anterior part of the middle ear, is often very narrow, so that the pus is easily shut in, beside which a large portion of the mastoid process lies deeper than the membrane of the tympanum, and the *meatus auditorius*. We may, therefore, perforate the *membrana tympani*, which will allow the pus in the tympanic cavity to freely escape outward, but not that within the

The subsequent treatment consists in injecting, but with care and without much force, emollient fluids, as infusions of Slippery Elm, Marsh Mallow, Flaxseed, Barley, or Buckhorn Brake Root, etc. At the commencement, the Eustachian tube being still obstructed, we may rupture the membrana tympani if we inject too strongly. Some days later, the tube having resumed its normal calibre, we will observe that the injection will fall into the pharynx, and then we may use it more frequently.

When all the inflammatory symptoms have subsided, we may stop any further discharge and heal up the fistula, by employing irritating injections, as of Iodine, for instance. But we must not be in too much haste to suppress the discharge, nor to make these irritating injections; it is much better to wait until there is no longer any pain, fever, nor any trouble on the part of the brain, as an injection of this kind made prematurely, will prove hazardous. The irritating injections may be aided by revulsives, caustics, setons, etc., and by an antisymphilitic, antiscrofulous, or tonic, etc., treatment according as the otitis has supervened under the influence of syphilis, scrofula, or fever.—If the pus becomes effused, through a fissure in the mastoid process, into the sheath of the sterno-mastoid muscle, and the cellular tissue of the neck, it may become necessary to open all this abscess by Caustic Potassa, or Moxas.

5. *Catheterism of the Eustachian Tube*, already described on page 1235, is practised for the purpose of giving an exit to fluids effused into the middle ear, and to facilitate the entrance of the air into

mastoid process; and if this does not form a spontaneous opening externally behind the ear, there is no choice left, in order to give vent to the pus, but to break through the external layer of the bone. The tissues adjoining the mastoid process, viz.: the dura mater, the internal carotid, the internal jugular vein, and the sinus transversus, are so important, that a morbid process which spreads to them from the middle ear, is fraught with danger to life, independently of the circumstance that the sense of hearing may be weakened or even be entirely annihilated by the presence of pus in the middle ear. He recommends an incision behind the ear and parallel with the concha, about an inch long; it is better to make the incision three or four lines behind the insertion of the concha, as if made further forward, the posterior auricular artery or its branches might be wounded,—and if made further back, there is danger of touching the sinus transversus with the chisel; then a hollow chisel should be inserted in the middle of the incision, at an equal height with the opening of the ear, and ought to be carried horizontally and a little forward, thus avoiding the dura mater and the sinus transversus. The instrument must be used gently, and stopping occasionally to cleanse the wound and probe it, as during trepanning, and also to avoid a sudden piercing of the bone. If the bony layer which has to be perforated is very thin and fragile an ordinary buttoned probe may be used instead of the chisel.

this cavity; and is always to be preferred instead of the two preceding operations when it can be effected.

When this operation is performed as a simple means of dilatation, very fine bougies must be used, gradually increased in size, and leaving them in long enough each time to be of service, say from five minutes to one or two hours. In a normal state, the diameter of the internal orifice of the Eustachian tube does not exceed one-fourth of a line, hence, the bougies will require to be very small, and their increase in diameter to be carefully graduated; beside which, their extremities should not be too pointed, lest they pierce the membrana tympani, or some portion of the tissue through which they are passed. This operation is frequently pursued to free the tube, and prepare it for injections of medicated vapors, etc.

6. *Syringing the External Auditory Canal.* This may be done for the purpose of cleansing this passage, to remove foreign bodies, ceruminous masses, etc., from it, or, to cleanse the passage, in order that we may the more thoroughly examine its condition as well as that of the membrana tympani. As a general rule, syringing with tepid water is quite sufficient to remove all small, or rounded solid bodies which have found an entrance within this canal. But, in order to be successful, the operation must be performed properly; to place the nozzle of a syringe in the meatus and force the fluid into the auditory canal, is not alone all that is required. The following rule must be observed, whenever syringing the ear becomes necessary:

An ear syringe must be procured, which will hold at least three and a half fluidounces; also an ear spout to carry off the water into a basin, as it runs from the ear. The patient must also be placed in a suitable position for the light to fall into the ear.—Grasping the upper part of the auricle with the fingers of the left hand, we draw it slightly upward, outward, and backward, so as to straiten the auditory canal as much as possible; then placing the point of the nozzle of the syringe (which should be about the size of the blunt end of a common probe), against the upper and back part of the orifice of the canal, we steadily inject a stream of tepid water, in such a manner that it passes along the posterior wall of the passage, and flows around and behind the foreign body, bringing it forward and externally, as it (the fluid) rebounds from the membrana tympani. This is the only method by which a foreign body can be removed by injection; and, if it be so large, that it can not be carried out of the ear, it may be thrown outwardly to such a distance, as will bring it the more readily within reach of the ear forceps, or other instrument. This injection may be repeated several times before the foreign body will be dislodged.

Syringing the ear sometimes occasions coughing or sneezing, perhaps syncope, and occasionally sickness at stomach; but these symptoms need occasion no uneasiness, where the practitioner has performed the operation in a proper manner. It should always be resorted to, in preference to any other mode, and not until we are fully satisfied that the foreign body can not be removed by this means, ought we to adopt other measures.

It is important in all cases where foreign bodies are removed by syringing, or where any growth has been removed from the meatus, especially when these bodies or growths have existed for some time, excluding the action of the air from certain sensitive parts of the organ, to see that the ear is well protected from cold and the action of the atmosphere, until the parts have again become accustomed to their influence; the introduction of a pledget of cotton wool into the orifice of the meatus, either dry, or oiled, will generally be sufficient.

7. *Counter-irritation.* Blisters, setons, moxa, caustics, etc., have been advised. But, probably, a very stimulating liniment, or the Compound Tar Plaster, will answer much better purposes; in applying them, means should be used to protect the back part of the auricle from their action. They will rarely be found serviceable in cases of nervous deafness, but may prove of some value in idiopathic purulent otorrhea, as a substitute for the morbid excretion of the external auditory canal, in thickening of the membrana tympani in chronic engorgements and other affections of the middle ear, and in aural disease supervening disease of the throat and air-passages. The best place over which to apply them is, the mastoid region, beneath the mastoid protuberance and immediately behind the lobe of the ear, and along the sides of the neck; they will be of no service whatever, if applied to the nape of the neck. To be of any efficacy, they will require to be persevered in for weeks and even months.

As stimulating applications, the Compound Tincture of Iodine may be used; the Croton Oil Liniment; the Compound Tincture of Camphor, etc. To relieve neuralgic pain, the Aconite and Chloroform Liniment; the Compound Liniment of Stillingia; Compound Belladonna Plaster, etc.

8. *Direct Cauterization* is often indicated, especially in catarrhal deafness accompanied with chronic affection of the throat, and to remove diseases of the mucous tissues of the naso-pharyngeal passages, the morbid conditions of which tissues frequently extend through the Eustachian tube to the middle ear. For this purpose, Solution of Nitrate of Silver, of various strengths, is applied by

means of probangs, or injection tubes, to the superior part of the pharynx, to the nasal passages, etc. It produces a favorable influence upon the diseased mucous tissues of the pharynx, which influence may gradually extend, even into the middle ear.

9. *Gargles*, and *Sternutatories* are often employed in the treatment of deafness, to modify the condition of the pharyngo-laryngeal and pituitary membranes. The first are usually of an astringent nature, as Alum, Geranium, Beth, Witch Hazle, Tannic Acid, etc., or combinations of tonics and astringents. The second are usually composed of special excitants of the pituitary membrane, as powder of Arnica, Asarum, Bayberry, Myrrh, Benzoic Acid, Bloodroot, etc., and which are also occasionally combined with some of those tonics which act more especially upon mucous tissues.

10. *Electricity*, *Electro-magnetism*, etc. I have employed electricity, galvanism, and electro-magnetism in many cases of deafness, and have also witnessed their application in the hands of others for the treatment of similar affections, but can not conscientiously say that they have ever produced any permanent benefit in a single case. I formerly thought they were serviceable in some cases, but am now convinced it was only due to a restoration of the vital action of the mucous membrane of the tympanum and Eustachian tube, and which might possibly have resulted from the influence of the other measures pursued. These agents can not certainly be safely brought to exert any action upon the internal ear, at least by any of the methods at present used; and, as a remedial means in diseases of the ear, I believe their employment can be entirely dispensed with.

DISEASES OF THE AURICLE AND SURROUNDING PARTS.

The diseases or abnormal conditions to which the auricle is subject, are:

1. *Congenital Malformations*. These are various; thus, the auricle may be as if it were stretched at the expense of the several folds and sinuosities which perform so important a part in the forwarding of sound vibrations; or, the helix may be wanting or extended more or less considerably, with effacement of the furrows; or, the tragus may be pressed so as to completely close the meatus, in which case, a small silver tube will have to be constantly worn, or a portion of the tragus be removed; or, there may be a total absence of the auricle.

All these malformations exert an influence in lessening hearing

to a greater or less amount ; and although the sense of hearing may remain, still it must necessarily be imperfect. Those cases reported by writers where, notwithstanding these malformations, the hearing still continued good, were either not closely investigated, or present themselves as exceptions to the general rule. It must be remembered that in most cases of congenital malformation of the auricle, some defective condition of the external auditory canal, or of the middle ear, will be present.

In the way of treatment but little can be done in these cases ; where the malformation is due to defect or arrest of development, the inconvenience may sometimes be palliated by instruments, as, ear trumpets of proper shape, artificial caoutchouc auricle ; where several auricles, or separate parts of an auricle are present, and where there is an excess of development, the interference of surgery will be required to give its proper form to the ear as nearly as possible.

2. *Acquired Malformations*, in which the auricle is flattened and rests upon the part of the head behind it, or on the temple, instead of forming with it a slight angle opening forward ; this condition of the auricle interferes very much with the perception of sounds, and is very difficult to treat, the only chance of benefit being in the employment of small ear trumpets. It is generally produced by the bad habit of parents in covering the heads of their children to excess, imprisoning their ears, interfering with their free growth, and impressing upon them a faulty direction ; likewise, by the habit of tucking the ears under the hat when it is worn.

Wilde, in speaking of malformations of the external ear, states, that " Congenital malformations and abnormal peculiarities of the external meatus and auditory canal are by no means uncommon ; the passage is frequently smaller, and often more tortuous than natural, and it has been found closed with a polypus excrescence at birth. There is great variety in the length, calibre, and curvatures of the sides of the external auditory passage among different persons,—perhaps just as much as there is in the shape of the nose, the auricle, or any other feature of the face. I had no idea how much diversity existed in the auricle until I began to study diseases of the ear ; and latterly I have so frequently observed congenital peculiarities and malformations of the auricle in persons who have applied for advice on account of some aural disease, that I have been forced to the conclusion, either that these peculiarities occur much more frequently than is supposed, or that, in some way which is at

present unaccountable, persons possessing such peculiarities are more subject to aural diseases than the rest of the community."

3. *Deformations of the Auricle.* These are the results of injuries or diseases, the most frequent of which are as follows:

a. *Wounds.* When produced by pointed or pricking instruments, are not, as a general rule, followed by any serious results; but when they are occasioned by a cutting instrument, they may cause a disfiguration of the auricle from faulty cicatrization of the wound. To avoid this result, the practitioner should not hesitate to immediately reunite the parts, even by sutures passed into the cartilage itself, if it be necessary. Instances have occurred in which adhesion took place, even after the part had been completely removed. Lint, spread with white of egg, and applied so as to keep the parts in strict apposition, is stated, by Wilde, to have been used with much advantage.

Occasionally, eczematous eruptions, or erysipelatous inflammation may follow a piercing of the lobe, or other portion of the ear, with a pointed instrument; but, this occurs so seldom as to warrant us in introducing sutures, as above named, in cut wounds of the auricle. The occurrence of these cutaneous affections must be met by the appropriate measures.

Wounds, the result of blows or blunt instruments, are more serious than those effected by cutting instruments. An immediate reunion of the parts is not practicable; the lacerated, torn, or gangrenous margins of the wound must be partly removed before cicatrization will take place. And as the cicatrix is generally extensive, it modifies the form and structure of the auricle sufficiently to interfere with the hearing in many instances.

b. *Bruises* of the auricle are common among prize-fighters, boxers, wrestlers, etc. The results of the blows, pressures, and bruises of the auricle, are, detachment of the skin, separating to a greater or less extent from the cartilage, and forming a sac or pouch filled with blood. A repetition of these bruises eventually determines a hypertrophy of the subcutaneous cellular tissue. And those who engage in these rough exercises, usually have an increased development of their ears; the integuments are redder, thicker, have lost their pliancy, and form a kind of rounded swelling, frequently of such monstrous dimensions, that the auricle falls like that of certain animals.

When these contusions have been repeated, it is by no means rare to have sanguineous cysts (hematocoele) form on the external

surface of the auricle. These cysts are met with among fighting characters, as well as among the insane, due, in the latter instance, to the personal violence which is sometimes used toward them.

These cysts are mostly situated on the external part of the auricle in the cavity of the helix, and may affect both ears, more commonly but one. Obscure fluctuation and sometimes a slight degree of crepitation may be observed, and the skin presents an ecchymosed appearance; the hearing is intact, and the general health good,—though, at times, cases will be met with in which the growth will advance so as to close the external meatus. These growths are more apt to be met with among cachectic, scorbutic, or strumous habits, as well as among those who are disposed to cerebral congestions and paralysis. If not properly treated they ultimately occasion great disfiguration of the ear.

The matter in these cysts is generally of a sero-sanguineous character, which may be allowed to discharge by a puncture or a free incision into the sac; lint is then introduced into the cavity, with Tincture of Iodine, or other stimulant to excite suppuration, granulation, and union of its walls. If the auricle remains thickened, it may be painted over with a liquid composed of Iodine one drachm, Iodide of Ammonium two drachms, Water two ounces and a half. This may be repeated every second or third day. Methodic compression of the parts will sometimes prove a useful auxiliary measure in the treatment. In some obstinate cases, a seton passed longitudinally through the thick and indurated part will be of some efficacy; but this has in several instances occasioned inflammation, followed by abscess.

4. *Tumors of the Auricle* are of two kinds, viz., erectile and fibrous. The erectile tumors exhibit themselves under two forms, arterial and venous. *a.* Arterial erectile tumors occupy a great part, if not the whole of the auricle; this organ presents a reddish tint, more or less violent pulsation, increases in volume, and the dilatation of the arterial branches of the ear extends into the vessels of the neighboring parts. By pressing upon the artery, near its source, the tumor lessens in size, and becomes flaccid, but resumes its volume on removing the pressure. Venous erectile tumors are generally circumscribed, and appear in the form of bluish maculæ, of a livid, repulsive aspect.

In the treatment of the more severe cases, with dilatation of the blood-vessels, ulceration, and hemorrhage, it will be necessary to ligate the auricular arteries, and should this prove insufficient, the

carotid artery will require ligation, in order to save life. But if these tumors are isolated and without complication, they may be treated by cauterization, filiform setons, injections of Perchloride of Iron, or vaccination.

b. Fibrous Tumors of the auricle are usually of slow growth, and may attain a considerable size; they are not apt to be painful. When they become so large as to present a deformity, they may be removed by a surgical operation.

5. *Fracture of the Cartilage* of the auricle may, notwithstanding its ordinary flexibility, occur, more especially when the ear is forcibly, or suddenly and violently doubled up, and which will interfere with hearing in proportion to the character and extent of the injury. An ear trumpet may lessen the deafness.

6. *Burns or Scalds* of the auricle are more common among children, and are apt to be accompanied with an analogous burn or scald, of greater or less extent, of the face. Although not serious as far as life is concerned, it may seriously affect the function of hearing. The inodular tissue of the cicatrix disfigures the affected organ, and thus, mechanically, interferes with the action of the sonorous vibrations.

To prevent the sad consequences of a faulty cicatrix, the aurist will, beside his local applications to the burn, be careful not to permit any obstruction to the external auditory canal; he will also keep the auricle at its proper angle of insertion, as well as protect the various inequalities of its surface.

7. *Cutaneous Affections* of the auricle are frequently met with, and, if not successfully treated, may extend into the external auditory passage, affecting its walls as well as the outer layer of the membrana tympani. The most common affections of this kind, are the following:

a. Chronic Erysipelas of the auricle may be the termination of the acute form of the disease, or it may appear independent of this. It is of a very annoying character, and is often exceedingly intractable to treatment. The auricle becomes thickened and hardened, with the skin of a dark buff color, and the meatus considerably lessened in calibre. Sometimes the ear loses its natural form, and its surface becomes exceedingly tender. It may occur

at any period of life, but more commonly among females who have passed the "turn of life."

Poultices of Elm and Lobelia will be found of service, especially when assisted by other local applications, as, solutions of Sulphate of Iron, Perchloride of Iron, Nitrate of Silver, Sulphate of Zinc, or of Iodine and Iodide of Ammonium, etc. Or, the treatment named below for Eczema, may be successfully pursued in many instances. (*See Erysipelas*, page 1065.)

b. Eczema Aurium. This disease may be confined to the auricle, or it may extend into the external auditory passage; it may also occur in connection with eczematous eruptions on other parts of the body. It is often met with in children, but more frequently in females somewhat advanced in years; it may, however, exist with both sexes, and at all periods of life. The auricle is more or less irritated, smooth, shining, and deep red, and generally speckled with yellow patches of thin branny scales; sometimes there is a discharge of a thin ichorous matter. In some instances, especially among adults, the auricle becomes hypertrophied, loses its natural shape, and becomes hard, thickened, and lumpy.

The disease, when occurring in the auditory passage, is frequently the result of introducing pins, ear-picks, and acrid substances within the meatus. In this case, a fullness in the ear is frequently experienced, but the most troublesome symptom is the itching, to allay which, pins, ear-picks, etc., are frequently introduced so as to scratch the parts; this, however, affords but a momentary relief, while it aggravates the disease. The meatus becomes red, sensitive, and sometimes tumefied; its calibre becomes diminished, in proportion to the amount of infiltration of its walls, and it is sometimes so narrowed as to prevent an ocular inspection of the membrana tympani. A thin, watery or whitish discharge from the meatus is generally present, more or less profuse, and fetid unless the canal is frequently washed out with a syringe. Sometimes, however, the meatus, as well as the external surface of the membrana tympani, will be dry and scaly. The meatus will often be blocked up with large quantities of epithelial scales thrown off from its surface, with more or less cerumen intermingled; though, as a general rule, the ceruminous secretion is arrested in this disease.

Audition may continue unimpaired; but when deafness exists, its degree will depend upon the amount of infiltration of the walls of the canal, upon the quantity of accumulated discharge and epithelial scales in the meatus, as well as upon whether the membrana tympani, and the tympanum are involved or not. In

quite a number of cases, the drum membrane will be found thickened and opaque. An examination of the external meatus is best made in this affection, with Wilde's half speculum or gorget.

Treatment. This disease is often very difficult to cure, both on account of its being frequently associated with some constitutional taint, and the trouble in making local applications to the meatus in a thorough manner. And when the parts affected have undergone a change in form and texture, it requires a long and tedious course of treatment to restore them to their original condition.

The first thing to be done in treating this disease is to keep the parts as clean as possible, for which purpose the affected auricle must be washed two or three times a day with tepid water, and if the meatus is also affected, it must be washed out, at least twice a day, with a good syringe and warm water, both for the purpose of removing accumulated matters, and soothing the irritable membrane. If the meatus be dry and scaly, a little Almond Oil dropped into it, will soften the particles and facilitate their subsequent removal with the syringe. To allay the itching warm poultices of Elm and Lobelia, or of Elm and Hops, may be applied over the auricle, and then covered with oiled-silk to prevent evaporation; or the meatus may be exposed to the action of warm vapors from water alone, or from sedative infusions.

Various agents have been found useful as local remedies, in removing this obstinate complaint. When one of these is to be applied within the meatus, it may be accomplished by means of a small camel-hair brush holding some of the substance within its fibres; the brush, after having been passed within, for about half an inch, should be gently twisted around, so that every part of the walls may be touched by the medicinal substance. At first, this occasions considerable pain, which, however, remains only a short time; but as the disease improves, the pain will lessen more and more. When the action of the remedy is too severe, an injection of warm water, will generally check it at once; warm soap-suds, if an oil or ointment be used. The applications should always be made by the aurist himself, and be repeated as often as indications require.

Among the best agents are, Solution of Caustic Potassa, ten grains to the fluidounce of Water, up to thirty grains, being careful to graduate the strength of the solution according to the severity of the disease, and not to permit the stronger solution to come in contact with the drum membrane. Indeed, three to five grains of the Potassa to the ounce of Water, will be sufficient for this membrane. If the disease improves under this application, the uneasiness in the

ear subsides, the meatus becomes wider, a large quantity of serous fluid exudes, which, however, gradually diminishes in amount. the hearing improves, and the affected parts assume a healthy appearance. After the disease appears to be gone, a weak solution, three grains to the ounce, should be applied every day or two to the parts, in order to prevent its return. A very effectual remedy in erysipelas and many cutaneous affections of the auricle, is a mixture of one part of Carbolic Acid and three or four of Glycerin, which may be applied by means of a brush; if too severe, the quantity of Carbolic Acid may be lessened. Or, the following may be applied; mix together one drachm of pure Carbolic Acid, half a drachm of Liquor Potassa, and four fluidounces of Distilled Water.

Wilde recommends a solution of Gutta Pereha in Chloroform to be painted over the part several times, until a complete coat has been formed; which should be repeated from day to day, as often as it peels off. Solution of Nitrate of Silver; Citrine Ointment; Solution of Sulphuret of Potassa one part to twenty parts of Water; Turbith Mineral one part to twenty parts of Lard or Rape Oil; Zine Ointment; Tincture of Chloride of Iron; Solution of Sugar of Lead, etc.; have all been used with more or less benefit, according to the statements of writers. The same rules as regards diet, exercise, attention to skin and bowels, etc., that are necessary to pursue in other forms of chronic disease, are also required here. If constitutional means are indicated, the Compound Syrup of Yellow Doek, or solution of Iodide of Ammonium may be administered. (*See Eczema*, page 1018).

Other cutaneous affections of these organs require to be similarly treated, according to the character of the disease; and the remedies for which will generally be the same as indicated for these maladies when existing upon other parts.

8. Just above the insertion of the sterno-mastoid muscle, and on a line with the external meatus, will be found a small gland, lying upon the mastoid process, which occasionally swells and becomes irritable and painful. Young females are peculiarly liable to it. It does not readily yield to treatment. Tonics and chalybeates internally, with local applications of Compound Tincture of Iodine, may be employed.

Scrofulous ulcers, tumors, abscesses, etc., occurring upon the auricle or parts around it, require the same treatment as when seated elsewhere. Abscesses are apt to be attended with diseased bone.

Tumor of the mastoid process, caused by accumulations of matter,

in connection with the mastoid cells, and being either the result of acute or chronic inflammation of the middle ear, have already been referred to, as far as treatment is concerned, under the head of *Perforation of the Membrana Tympani*, and *Perforation of the Mastoid Process*, on pages 1252 and 1253. These tumors, if not attended to promptly and in time, prove fatal.

DISEASES OF THE EXTERNAL AUDITORY CANAL.

1. *Malformations of the External Auditory Canal.* The external auditory canal may be absent, or imperforate; a few cases of each of these malformations have been met with.

The *imperforation* may occur in two ways; the skin may pass in the auditory canal and completely close it up. A simple incision will suffice to open it to a normal condition,—but, before attempting the operation, we must make sure that the canal exists behind the obstacle that closes its entrance.

Or, a membrane may be developed either across the entrance of the canal, or at a point more or less distant from it. The treatment will consist in the excision of this membrane. If it is not situated very deeply within the canal, the operation will be very easy; in the contrary case, we must carefully guard against injuring the walls of the canal, and especially the *membrana tympani*. Perhaps instances may be met with where the false membrane can be removed by caustic.

Stricture of the auditory canal is of more frequent occurrence than its obliteration by a false membrane. It may be either congenital or acquired, depending upon an exostosis developed on the walls of the canal, and which, if of syphilitic origin, may yield to some preparation of Iodine, or other antisyphilitic. It may be due to swelling of the soft parts, as is frequently observed among children who have suffered from inflammation of these parts. In this case the treatment will consist in gradual dilatation, by means of prepared sponge, gentian root, etc., and which must be continued for a long time, in order to prevent a relapse. Also, using mild astringent injections in the absence of irritation or inflammation; or, still better, moistening the walls with a solution of Tannic Acid in Glycerin.—If the stricture be due to a congenital lesion of the osseous portion of the tube, nothing can be done.

If the stricture be owing to a union of the opposite walls, from inflammation or ulceration, and if it be located at the entrance of the canal, the adhesions may be destroyed by a blunt probe, a

bistoury, or trocar, and the opening so made, should be dilated by the introduction of prepared sponge, gentian root, etc. But if the absence of the auditory passage be congenital, nothing can be done.

Hardness of hearing is frequently due to an anomaly in the direction of the auditory canal; as this is seated in the osseous part, it is beyond the reach of art.

2. *Foreign Bodies in the External Auditory Canal.* These bodies may be animate or inanimate. Among the first, are divers insects, as, ants, worms, fleas, flies, earwigs, and even maggots, resulting from a hatching of the eggs deposited around the external orifice by large meat-flies. These insects sometimes occasion intolerable pains, depriving the patient of sleep; sometimes, the brain will be sympathetically affected,—there will be delirium, coma, or even lethargy. Epilepsy, and even death have been known to follow the introduction of foreign bodies into the ear, as well as after rude and forcible attempts at removing them. The diagnosis of living bodies in the ear is not more difficult than that of ceruminous obstructions. The patient may have slept upon the ground, and the insect may then have easily entered the passage, since which there has been a suppuration from the ear, constituting a form of *Otorrhea*. An examination with the speculum will at once enable the physician to determine the presence of a foreign body.

The *treatment* is very simple, viz., to remove the insect by an injection of warm water, which, as a general rule, will answer the purpose. (See page 1256.) But, sometimes, from the large size of the insect, or other cause, other means will be required. If the tepid water will not kill and remove them, it will be necessary to introduce some substance into the ear, in order to destroy them, and thereby prevent any irritation from their movements or struggles. In their dying struggles insects are apt to fasten their claws upon some part of the auditory passage, in which case, they are not very easily detached. Almost any simple substance will effect their destruction, as, tepid water, Olive Oil, Oil of Sweet Almonds, Mucilage, Decoction of Wormwood, or of Hops, solution of Tannic Acid twenty grains in Glycerin one ounce, etc. In introducing the fluid into the ear, the patient should incline his head to the opposite side, and retain the fluid in the canal for some time, in order to be certain of the death of the insect; after which, it may be removed by one of the means named presently.

Among the inanimate bodies which may be introduced into the ear, are beads, glass, marbles, peas, cherry-stones, small pebbles,

grains of corn, pins, paper balls, etc.; if allowed to remain they may become a source of inflammation or suppuration (*Otorrhea*); some of these bodies are more hurtful than others, especially the seeds, which swell up after a time, distend the canal, and occasion much suffering.

The *treatment* consists in removing these bodies by syringing; if, after a proper and sufficient syringing, they still remain in the ear, their extraction must be undertaken by a careful employment of Toynbee's lever ring forceps, or, his rectangular forceps, being very cautious not to injure the ear, or the membrana tympani. Thus, it may be necessary to cut or break the foreign body, to employ a curette, etc. In some instances, even these may fail, and such measures must be adopted as the circumstances will suggest. In the American Journal of Medical Sciences, for October, 1858, p. 409, will be found the description of an instrument for removing certain foreign bodies from the ear, made by Mr. J. H. Gemrig, surgical instrument maker, Philadelphia. As it is necessary in these operations to have the patient perfectly quiet, it is better, with children, to administer chloroform, than to run the risk of injuring the ear, by fruitless attempts to use ear forceps or other instruments with a frightened, screaming, and struggling child.—Any inflammation remaining after the extraction of the body, must be treated, according to its severity, by antiphlogistic means, as, warm emollient and anodyne injections, warm anodyne vapors, etc., protecting the canal from the influence of cold air by loosely placing a plug of cotton in the meatus.

3. *Ceruminous Concretions.* The external auditory canal may be obstructed by ceruminous masses, and which is a cause of deafness that should always be present to the mind, so that we may not pronounce a case of deafness incurable, which may be cured by one or two injections of warm water. The cerumen or wax of the ear is an unctuous, amber-yellow secretion, somewhat resembling honey, and which is secreted in the auditory canal by small glands called "ceruminous." This wax may form concretions in the auditory canal, varying in size from that of a grain of hemp, to a size large enough to completely obstruct the canal.

The color of these ceruminous collections varies from an amber-yellow tint to a dark-brown, and even to a black; at first, not having been long exposed to the air, the cerumen is yellow; at a later period, the particles floating in the atmosphere are deposited upon the collection giving to it a darker and darker-brown color, and finally, it

becomes completely black. This black appearance is not owing to any morbid change in the cerumen, but only to its admixture with the small particles of dust which are deposited upon it. The consistence of these collections also varies considerably; at first, they are soft, semi-fluid, but gradually assume a firmer consistence, until they may become so hard as to be taken for calculi.

When an accumulation of cerumen becomes so large as to fill up the auditory canal, the pressure it exerts upon the walls of this canal may occasion an inflammation; the inflammation causes a detachment of the epidermis, and the detached epidermis forming a layer upon the mass, increases its size; new layers of epidermis take the place of the detached ones, these, in turn are set free to unite with the wax, and thus the accumulation proceeds. Added to this, the inflammation is often so intense as to occasion suppuration; and then the pus, softening and detaching the epidermis, forms clots with it, which become detached to the ceruminous concretion. Independent of this last-named cause of increase in the size of the obstruction, we find another in the irritation of the ceruminous glands, the secretion from which is augmented. But, their secretion is generally suspended, when inflammation affects the tissues around them.

These collections also exert an influence upon the membrana tympani, inflaming its epidermic layer, and determining there, the same as upon the walls of the auditory canal, exfoliation and suppuration; and if the suppuration remains for a length of time, perforation of the drum membrane may ultimately ensue.

The *causes* of these ceruminous concretions are more commonly, the carelessness or neglect of patients with regard to personal cleanliness, or cleanliness of the ear. An irritable condition of the ceruminous glands, may render their secretion more abundant, and give rise to accumulations. Pressing the wax inward by means of a finger, or point of a towel; irritation of the parts by the introduction of pins or ear spoons; exposures to cold, and especially, cold with moisture, are among the causes, as well as all circumstances which will establish a superficial inflammation or irritation of the auditory passage. These collections may be met with at any period of life, but more commonly in middle life.

The *symptoms* of a collection of cerumen, are: pain, this is not always present, but when it does exist, is due to distension of the auditory passage by the ceruminous mass; deafness, which is constant, and is more or less complete in proportion to the size of the concretion; tinnitus, in all its varieties. The pressure exerted by the ceruminous concretion will also give rise to various unpleas-

ant symptoms, as, giddiness, fullness in the ear, confusion of ideas, inability to walk, sense of weight and pressure on the head, etc.—Many patients complain of a whistling, rustling, or purring noise, the cause of which has been heretofore explained; and which they describe as being in the head, and fear an attack of apoplexy.—The hearing is usually better in the morning; it is lessened while the jaws are in motion; and, very often, after a crackling sound in the ear, the hearing becomes suddenly re-established.

The *diagnosis* of deafness occasioned by these ceruminous plugs in the ear, is always easy. The patient has not been in the habit of cleansing his ears, or else he has had a discharge from the ear for a longer or shorter period.

Upon an examination with the speculum, which should always be made in all cases where it can be, and where it is not contraindicated by pain, inflammation, etc., we will be able to see the accumulated mass, and an error in the diagnosis will be almost impossible, at least in the greater number of cases. One can hardly mistake a polypus, or a large perforation of the membrana tympani for one of these ceruminous obstructions. We may distinguish polypus by the impossibility of dissolving it in oil or tepid water, as well as by the other characters named hereafter when treating upon this morbid growth.

Perforation of the membrane can hardly be confounded with a ceruminous mass, if we examine with care. At first sight, this perforation will appear at the bottom of the canal as a blackish spot, because we see the tympanum through the aperture, which absorbs all the rays of light without reflecting any; this spot may appear of equal size with that of the auditory canal, and present an aspect resembling that of old ceruminous concretions, but, if we introduce a probe having a soft extremity, we will readily avoid any error in this matter.

As to the *prognosis*, I will remark that the greater number of patients recover their hearing, as soon as the obstruction is removed; as there is no other difficulty or lesion of the ear, the simple removal of the hardened wax is followed by a cure; though the tinnitus may continue for some time after the hearing has been restored.

Some recover their hearing only for a few hours, and the ceruminous obstruction is renewed; because there is with these patients some difficulty beside the obstruction, as, inflammation of the external auditory canal, and of the tympanum. At the same time that the auditory passage has been filled with cerumen, the tympanum is loaded with mucus secretions. Each of these conditions

is a cause of deafness; in removing one of them, the state of the patient is ameliorated, and he may fancy himself cured, but the illusion is not of long duration. To perfect the cure, the mucous matters must be likewise removed from the tympanum, by means of injections through the Eustachian tube.

Others do not hear for several days, or even several weeks after the removal of the concretion. Itard has given a plausible reason for this. He says, "the ear having been for a long time a stranger to the impression of sonorous vibrations, phenomena must occur with it analogous to those which happen when we remove the opaque crystalline lens of a person affected with cataract. At first he is dazzled, and can not distinguish objects; however, nothing prevents the luminous rays from falling on the retina, and he has to newly educate the sense of sight before he can render it of service to him. Similar phenomena occur in the hearing apparatus. A certain time is necessary in order that it may resume its functions, awake from its sleep, its lethargy, and when the sense of hearing has undergone, as it were, a new education in the method of perceiving sounds, when its sensibility has been newly awakened, the patient recovers the faculty of hearing."—Finally, some patients will experience no benefit from the removal of the ceruminous mass, because, in addition, there also exists another lesion of a more serious character, and which may be incurable.

The *treatment* consists in softening these concretions, and then removing them by syringing; examining from time to time, during the operation to ascertain what progress is being made, as, after the last portion has been removed, it is not desirable to continue the syringing. No pain should be produced by any of the operations for removing the hardened mass of ear-wax. Very frequently injections of tepid water, alone, will soften and dislodge the obstructions; or, warm Castile soap-suds may answer. Occasionally, however, they will be found so hard and impacted, and the parts so tender, that other agents will require to be used for softening them, as, the introduction into the ear, one, two, or three times a day, of warm Olive Oil; a Solution of Carbonate of Soda, one drachm to an ounce of Water; or, a mixture of equal parts of Olive Oil and Liquor Potassa, etc. Sometimes a single injection will suffice; at other times, several will be required. Very rarely indeed will an ear curette, or forceps be required. If, after the obstruction has been taken away, the membrana tympani continues vascular, or, whitish and moist, or thickened, it must be treated by the appropriate means hereafter referred to.

A *deficiency* in the secretion of the ceruminous glands is generally

the result of an inflammatory condition in the neighboring structures, more commonly the superficial, though sometimes, the deep seated; more or less deafness accompanies a deficiency of cerumen in the ear, and if the difficulty be of long standing, the external layers of the walls of the meatus, and of the membrana tympani, become thickened. These cases are difficult to cure, requiring time, perseverance and patience; alteratives, diaphoretics, stimulants, and tonics are useful. Iodine may be given internally, and likewise be applied locally to the membrana tympani and walls of the meatus, by means of a camel's-hair brush. Equal parts of Oil of Turpentine and Olive Oil, or, of Oil of Turpentine and Oil of Butternuts, applied to the meatus and drum membrane by means of a probe having its end covered with cotton, has been found very advantageous in many cases of deficient ceruminous secretion, as well as in cases where there was an abnormal secretion of it.

4. *Abscess in the External Auditory Canal*, differs only from those met with elsewhere, by their small size; they are more frequent in females than in males. They may be seated at any point of the meatus, but more generally near or at the external orifice, and either upon its anterior or posterior wall. They vary in size from a pin's head to that of a pea, and upward, and more commonly several of them appear in succession. There is more or less pain, increased by touching the part, or by moving the jaws; an itching or burning heat, throbbing, buzzing, and sometimes a purring sound or tinnitus. After some time, a drop or two of pus, or perhaps a teaspoonful is discharged, and the symptoms gradually pass away.

The *treatment* is similar to that for boils or hordeolum; as, fomentations and poultices;—warm anodyne vapor;—tepid injections; and protecting the meatus from cold air by a tampon of cotton. When the tumor enlarges, or is painful and fluctuating, it may be opened to allow the matter to escape; and, generally, the abscess will then heal up. In some cases, constitutional treatment will be required, as well as remedies to improve the condition of the digestive organs.

5 *Sebaceous Tumors in the External Auditory Canal*. These tumors are due to glandular hypertrophy of the sebaceous glands. Growing in the auditory canal, they frequently become of quite a large size, so as to produce, without any pain being experienced, absorption of the bone, which may proceed so far as to form communica-

tions with the mastoid cells, the tympanic, and even the cerebral or the cerebellar cavities. The symptoms are deafness, fetid discharge from the ear, (*otorrhea*), or, those common to cerebral irritation; the latter being, generally, the forerunners of a fatal termination.

These tumors may be *determined* from bony tumors in the meatus, having the dermis covering them, by slight pressure with a probe; the osseous tumors will be hard and unyielding; the sebaceous, will be softer and yielding.

According to Toynbee, the only permanently successful treatment, is to thoroughly remove the whole tumor, together with its capsule. For this purpose a crucial incision must be made into the tumor, its contents be evacuated, and then seizing the firm wall of the capsule with forceps, withdraw the whole of it. If any portion should remain behind, it must be removed either by the forceps or caustic. Carbolic acid, one to three parts to one hundred parts of water, may be advantageously applied to remove the remaining portions; or, if it be desired to use it still stronger, from one to six parts of Carbolic Acid may be dissolved in six part of Glycerin, and applied.

6. *Molluscous Tumors in the External Auditory Canal* are by no means a rare disease, especially among persons of advanced age; they must not be confounded with the sebaceous tumors. They may be seated in any part of the canal, but more commonly at its superior and posterior part, near to the attachment of the membrana tympani. If their progress be unchecked they are apt to produce serious results.

Molluscous tumors, so called, from their supposed resemblance to the knots on maple bark, or to certain molluscous animals, originate in the skin or dermis, and have a color varying from that of a reddish flesh to that of a mahogany or copperish red, and which has erroneously led to the supposition that they were of syphilitic origin. They are of variable form, being roundish, elongated, flattened, or pedunculated, and have a soft, spongy, slightly-elastic consistence. As a general rule they ulcerate, present a bad appearance, and discharge a more or less acrimonious serous pus, (*otorrhea*); they may be absorbed without ulceration, or, form wart-like excrescences. When ulcerated, fungous vegetations sometimes shoot out. Their contents consist principally of epidermic cells, finely-granulated amorphous matter, some fusiform or ovoid bodies, oil globules, fibro-plastic nuclei, etc.

These tumors in the ear, gradually enlarge, fill up the auditory

canal, cause absorption of the layer of bone separating the meatus from the mastoid cells, and frequently extend into the mastoid cells; or, if the tumor be situated on the floor of the meatus, its lower osseous wall will be absorbed. They may also cause an absorption of the upper portion of the membrana tympani and of the adjacent bone, and, through the opening thus formed the tumor may extend into the tympanic cavity. When irritation of the dermis is produced by the size of the tumor, there will be more or less pain, catarrhal inflammation, and discharge.

The *treatment* consists in removing the contents of the tumor, by forceps or otherwise, and subsequently syringing the canal with tepid water two or three times a day. Stimulating applications applied to the tumor or ulcerated surface will frequently prove serviceable, as dilute Tincture of Iodine, dilute solution of Chloride of Zinc, etc., adapting the degree of dilution to the tolerance of the parts.—As the disease generally occurs in bad states of the body, constitutional measures will also be required, as, Iodide of Ammonium, Bromide of Ammonium, etc., with a well-regulated diet, exercise in the open air, and attention to the skin, kidneys and bowels.

7. *Osseous Tumors* are occasionally met with in the external auditory canal, more commonly at its middle third; though it may be located at any part of the bony meatus. These tumors consist of hard and dense bone, covered by the lining membrane of the meatus, which membrane is often thick, spongy, and deprived of more or less of its sensitiveness. When the irritation caused by their presence produces a chronic inflammation, there will be more or less fetid discharge, (*otorrhea*). When the bone is exposed, it will often appear white, glossy, hard, and insensible. The bony tumor is usually white, hard to the touch of a probe, smooth, with a broad base, and free from moisture.

The symptoms will vary according to the seat of the disease, the size of the tumor, and its complications with other lesions. At first there will be no symptoms heeded by the patient; until he finds that he is gradually becoming deaf, that there is a feeling of fullness, swelling, and weight on the affected side, with giddiness, noises, etc. The membrana tympani, when it can be seen, will usually be dull. The deafness may be continuous, or, especially when first observed, be intermittent. More than one tumor may be present at the same time, in the same meatus.

The *treatment* to be successful should be commenced at as early

a period as possible, giving internal alterative treatment, with an attention to the hygiene of the patient. If the membrane covering the tumor be thickened, it may be, at first, touched every four or five days, with a solution of Nitrate of Silver, (3j to the f3j); and afterward by Tincture of Iodine, or a solution of two drachms of Iodide of Ammonium, and one drachm of Iodine, in two and a half ounces of Water. This same solution, or an ointment made by substituting lard for the water, should also be rubbed daily behind the ear, over the mastoid process, and above the ear. The meatus, and especially that part beyond the tumor, should be kept free from all obstructions, either by means of forceps, or by syringing; and to prevent drops of water from entering the ear when the patient is washing his face, a small pledget of cotton wool should be inserted in the orifice of the meatus.

8. *Chronic Inflammation of the External Auditory Canal.* This inflammation has been divided into the two following forms:

a. *Simple Chronic Inflammation* of the dermoid tissue of the external meatus, *without discharge*, may follow an acute attack, or it may be *caused* by cold, residing in a moist atmosphere, irritating the ear by picking it with a pin, ear-pick, or other body, or irritation from other causes. Sometimes it accompanies certain impaired conditions of health attended with debility of the general system. Ordinarily the symptoms are not very severe; frequently the only symptom present will be a severe itching within the meatus; at other times, the ear will feel as if filled up, or distended, with or without a slight degree of pain accompanying. If an examination be made, the dermis will be found red, more or less denuded of epidermis, more or less swollen, sometimes to such a degree as to lessen the calibre of the canal one-half; and large flakes of epidermis will be thrown off, often in such quantities as not only to obstruct the meatus, but to dilate it, giving rise to acute inflammation, or even to disease of the bone.

The *treatment* consists in first syringing the canal with tepid water, so as to cleanse it from the irritating flakes of epidermis; and which syringing should be continued from time to time during the course of the disease, so long as the epidermis continues to accumulate within the canal. About six or eight ounces of water should be used at each syringing, which should be repeated two or three times a day; and, as this operation is apt to cause great pain where the surface of the meatus is extremely tender and sen-

sitive, it should be performed with care and gentleness. The following may also be rubbed well in behind the ear, and upon the back part of the ear, and will be found of great service: Take of Aconitina two grains, Acid Hydrocyanic, diluted, one drachm, Glycerin half an ounce; mīx. A small portion, only, to be used at a time.—A drop or two of this rubbed over the walls of the external meatus, will also be found useful to relieve severe pain.

After the inflammatory symptoms have subsided, or, in cases where the dermis is congested but without much tenderness, a weak solution of Nitrate of Silver (five or ten grains to one ounce), or, a solution of Chloride of Zinc (two or three grains to one ounce), may be applied upon its affected surface by means of a camel's-hair brush, and be repeated twice a day. Sometimes a solution of Tannic Acid (four or five grains to one ounce), will answer a better purpose than either of the preceding. Should the patient reside in a damp place, it may be necessary for him to remove to a dry one before a permanent cure can be effected.

b. Chronic Catarrhal Inflammation of the dermoid tissue of the external meatus, *with discharge*, frequently follows idiopathic acute catarrhal inflammation of the meatus, as well as when this acute inflammation attends measles, small-pox, catarrh, scarlet fever, typhoid fever, etc. It may also be due to frequent exposures to cold, cold and dampness, to injuries of the part, to teething, to the improper application of stimulants to the ear, etc., and is more common among lymphatic or scrofulous persons, or those suffering from impaired health. Children are especially liable to it. It is a very obstinate and difficult disease to remove, frequently requiring ten or fifteen months of treatment before a cure can be effected, and, in many instances, proving intractable to all remedial measures.—Irritation of the tympanic cavity is frequently attended with catarrhal discharge from the dermis of the external meatus, as well as from the dermis of the membrana tympani, which symptoms cease with the removal of the irritation.

The *symptoms* vary according to the cause. When it follows a previous acute attack there will generally be more or less dullness of hearing, a dull pain in the tragus and its neighborhood, little or no redness of the affected part, but considerable heat and swelling, with tinnitus, and an abundant discharge. Under other circumstances, the first symptom may be a slight itching in the ear, with or without the discharge of a few drops of a watery fluid daily; again, pain may be the first symptom noticed, while, in

other instances, the discharge itself will be the first symptom that will attract the patient's attention. Sometimes, there will be considerable irritation within the canal, with a sanguineous discharge; this latter symptom is very apt to exist when the disease is complicated with polypus. Generally, the dermoid layer of the canal will be found either congested, or hypertrophied. Pressure made upon the tragus, or directly in front of it, will produce pain; and when this pain is present, a small engorged ganglion may be observed underneath the lobe.

In this malady, the principal thing that annoys the patient or his friends is the discharge; this is more or less profuse, varying in color from milky white to dark slate, sometimes bloody, generally, very offensive, and constituting one form of *otorrhea*.* The matter discharged mixes with water forming an opaque fluid; it has no

* *Otorrhea*, or a chronic discharge from the ear, is generally described under a separate head, notwithstanding it is a very common symptom, one of a serious character, and which may be owing to several lesions of the ear.

Triquet makes the following remarks in relation to this symptom, its causes, treatment, etc.: "There is not a practitioner, however little versed in the knowledge of diseases of the ear, who has not been struck with the interminable duration of these discharges, the difficulty of curing them, the dangers attending them, and the fatal results frequently following them. . . . The symptoms of *otorrhea* have a great analogy, whatever may be their seat. . . . The discharge is at first simply mucus, then pus globules become added, gradually it becomes muco-purulent, and by insensible degrees it becomes wholly purulent.

"Idiopathic *otorrhea* is that which recognizes for its cause a primitive disease of the ear, an external or internal otitis, catarrhal, phlegmonous, or periosteal, an inflammation of the membrana tympani, or the presence of a foreign body in the ear; also external periosteal otitis, and granulations of the membrana tympani. Symptomatic *otorrhea* is, on the contrary, a discharge, the origin of which exists outside of the auditory apparatus. For instance, we have a symptomatic *otorrhea* when a collection of pus, formed near the ear, is discharged into the tympanic cavity, or in the auditory canal through the fissures of Santorini; also, when it originates in abscess of the parotids, caries, necrosis of the petrous portion of the temporal bone, or of neighboring bones, exostosis of the tube, etc.; and, as remote causes, the influence of syphilitic and scrofulous diatheses. It may also occur during catarrhal epidemics, characterized by a general affection of the mucous membranes of the eyes, nose, fauces, as well as of the ears. The discharge may also flow through the Eustachian tube.

"The symptoms of *otorrhea* are the symptoms of the diseases giving rise to the aural discharge. Thus, for *otorrhea* following external catarrhal otitis, the patient has been exposed to cold and dampness, there is a painful point immediately in front of the tragus, and a swollen ganglion underneath the lobe.—An *otorrhea* determined by the presence of a foreign body in the auditory canal, will be detected by the commemorative symptoms, and an examination of the canal. We may also ascertain if the *otorrhea* be due to a polypus, by this examination. If nothing be found in the external auditory canal, observe if the membrana tympani be inflamed, or perforated, or if the discharge comes from

collections of mucus in it, except when polypus is present, or when the fibrous layer of the drum membrane is ulcerated.

the tympanum, and should be attributed to an internal otitis; also ascertain whether the internal otitis is catarrhal or phlegmonous.

"After having recognized all the symptoms of the diseases that may occasion the discharge, we will next consider its quality and quantity; it may be mucous, muco-purulent, or purulent. Its quantity will be found to vary, even from one day to another; and we will observe that when the otorrhea diminishes, this diminution will be accompanied by general symptoms, an uncomfortable feeling, vertigo, loss of appetite, vague pains in the limbs, and a feeling of extreme lassitude. When the discharge returns to its original quantity, these symptoms disappear. Add to these symptoms the habitual fetor of the discharge, always considerable, and we have all the characters of otorrhea.

"Persons affected with otorrhea sometimes present a symptom which may give rise to very serious consequences, but which may be easily remedied, I mean obstruction of the auditory canal and the retention of pus. This obstruction may be due to the pus drying and forming crusts which entirely fill the auditory canal, or else to an inflammatory swelling of the soft parts which form the walls of this canal. The consequence of this retention of pus, may be the flow of the pus into the internal ear, into the cranial cavity, or else the formation of mastoid abscesses; and, lastly, the passage of the pus into the cellular tissue of the neck.

"The complications of otorrhea are numerous; as, caries of the mastoid process, paralysis of the facial nerve, flow of pus into the labyrinthine cavities, meningitis, abscess of the neck, and metastatic abscesses. The formation of the mastoid abscess is generally the primitive lesion that eventuates in caries. At other times, the pus does not come from the tympanum, it is secreted within the interior of the mastoid cells themselves. It may be due to an inflammation of the mucous membrane alone, and then, the caries is the result of the abscess; but, in some cases, the caries is the primitive affection causing the suppuration. Whatever may be the origin of this suppuration, it may convert the mastoid process into a single cavity distended by pus, a true burrow.

"After a greater or less period of time, the walls of the process become thin, raised up, and ultimately permeable. The pus is effused into the cellular tissue, and forms what has already been pointed out as abscess of the neck. In passing from the mastoid process, the pus spreads throughout the whole length of the sterno-mastoid muscle, behind it, behind the deep-seated coat of its sheath; it may descend even to the clavicle, but, more commonly, it does not go so far, and the purulent collection is arrested at the middle part of the neck. The deep-seated coat of the sheath of the muscle, becoming inflamed by the contact of the pus, after a time, forms of itself a source of suppuration. At the same time, the deep-seated lymphatic ganglions of the neck become engorged.

"We may also observe at the base of the mastoid process, a fluctuating tumor, manifestly communicating with the purulent collection in the tympanic cavity; and, by palpation, we may feel along the sterno-mastoid muscle a chain of engorged ganglions, which may reach as far as the clavicle. All these small tumors are painful; at first hard, they soon soften and become so many small purulent centers; after having been distinct from each other, they coalesce and form with the original one, a spacious burrow. At the same time that these abscesses form, there will frequently be symptoms of torticollis, contraction of

When the dermoid layer of the membrana tympani becomes affected by the inflammation, it becomes congested, and often

the sterno-mastoid muscles, and sometimes, spasmodic movements of these muscles.

"I have treated a patient with whom there was an effusion of pus behind the sterno-mastoid muscle; there were spasmodic contractions on both sides, movements of inclination of the neck, either to one side or the other, which motions were analogous to those observed in chorea. Added to these symptoms there were encephalic disturbances, indicating a commencing encephalitis, as, for instance, cephalalgia, a tendency to coma, and contractions alternating with convulsive motions of the whole of the right side. Fortunately, the energetic treatment pursued, consisting especially of revulsives, effected a cure. . . .

"*Paralysis of the facial nerve*, sometimes met with, is due to the suppuration (having caused the osseous laminæ forming the walls of the auditory canal, or of the tympanic cavity, to give way), finding its way into the canal of Fallopius and coming in contact with the facial nerve. This nerve, then being irritated, or inflamed, remains without the power of transmitting nervous influence to those muscles it ought to animate. At other times, the suppuration does not reach the facial nerve itself; it stops at a certain distance in the canal of Fallopius; but it produces an ostealgitis in the osseous layers forming the walls of this canal, the consequence of which is, hypertrophy of these layers, diminution of the canal containing the facial nerve, and thence compression of this nerve.

"Or, again, the discharge, limited at first to the external auditory canal, determines an inflammation of the membrana tympani, and then an internal otitis; the suppuration may then reach the deeper parts of the ear,—it may penetrate into the labyrinthine cavities, either through the fenestra ovalis, which becomes opened when the stapes has been dislocated, or, through a loss of substance caused by the ostealgitis and caries of the osseous partitions which separate the internal from the middle ear.—This inflammation of the internal ear is a serious complication. The pain is violent, and we have to fear meningitis or meningo-encephalitis.

"Inflammation of the brain or of its membranes is always a consequence of pus passing into the cranial cavity, whether it passes directly from the tympanum into this cavity, or, reaches it only after having traversed the labyrinthine cavities. . . .

"The *diagnosis* of otorrhea is based upon the symptoms which have preceded it, and upon the diseases which have occasioned it; and which have been, each, studied separately throughout the work.—The *prognosis* of this affection is unfavorable; indeed, we generally have to fear that the discharge will continue for a long time, and that the hearing will never be restored. It becomes still more unfavorable, when any of the above named complications are present. . . .

"The *treatment* must be at the same time general and local. The general treatment must be directed against the presumed general cause of the otorrhea. If the patient is of a strumous diathesis, Cod Liver Oil, ioduretted preparations, tonics, sea-bathings, salted water baths, iodine baths, etc. The physician will employ these different means, alternately, without pursuing any one of them exclusively; he will successively pass from one to the other, satisfied that the system becomes accustomed to only one kind of treatment, and that, if this be too long continued, it will gradually cease to exert a remedial influence upon the system.—Thus he may commence with the ioduretted preparations and salted water baths; if the patient's pecuniary circumstances will allow, advise sea-

hypertrophied; changes its color and form; its external surface becomes flattened; and the processus longus, and, in many instances,

bathings for a season. Then follow with chalybeates, tonics, bitters, generous wines in moderate quantity, roasted meats, toasted bread, etc. When, by these means, long continued, we have materially modified the economy, the time will then have arrived for the commencement of the local treatment.—If a syphilitic taint be present, an antisymphilitic treatment will be required; if a scorbutic diathesis, antiscorbutics will be indicated; if the otorrhea be due to some febrile disease, we must facilitate convalescence by a tonic, analeptic treatment, residence in the country, etc.

“As to local treatment, it will principally consist in revulsives, drastic purgatives, caustics to the temple, and mastoid processes, or even moxas, and a seton to the neck.—We may also shave the head of the patient, and rub it well with the balsam of Fioravanti,* or any other stimulating tincture. The wearing of flannel should be advised, as well as vapor baths, and sudorific infusions, to excite the functions of the skin. At the same time, employing only emollient injections, into the ear, to favor the discharge, or even to increase it, while its acridity and fetor is being diminished.

“Only, after having continued the use of these means for a long time, to modify the entire economy, will it be prudent to attempt measures to diminish and suppress the morbid discharge, by astringent and substitutive injections. . . . Itard prefers a solution of Subcarbonate of Potassa two drachms, dissolved in two pints of water; or, Caustic Potassa one drachm in Rose-water two pints; or, Wine of Lanfrance two drachms in Rose-water four ounces. These are to be warned previous to injecting, and employed twice a day.

“But these means should be employed only with great reserve. If the discharge should suddenly diminish or even cease, and the patient at the same time be seized with serious encephalic symptoms, the astringent injections will have to be wholly suspended, and all possible means be employed to recall the flow. For this purpose, Itard recommends half of a loaf of bread from the oven, as hot as can be borne, to be placed over the diseased ear, and also to make use of irritating injections. . . . At the same time, we must return to the revulsives, purgatives, and sudorifics. The astringent injections should not be resumed again, until after a longer or shorter time, and with great cautiousness. It is only by prudent, judicious, and slow treatment that we will be able to suppress otorrhea without having to fear the serious complications spoken of above. . .

“As to the complications, meningitis must be promptly combated by leeches to the mastoid process, or to the anus; ice to the head; revulsives; seton in the neck; caustics; moxas; and drastics.

“Abscess of the neck must be opened by successive applications of Caustic Potassa. If the opening of the abscess becomes fistulous, irritating injections must be passed into it, as, for instance, of Solution of Iodine. These injections will not only modify the condition of the fistulas and the abscess, but they will penetrate within the mastoid process, and into the tympanum. If there is a perforated drum membrane, they will at the same time, run out through the Eustachian tube, and through the external auditory canal.

* Balsam of Fioravanti is a French remedy, the product of distillation of resinous or aromatic substances, as, turpentine, myrrh, elemi, canella, cloves, ginger, etc., after having macerated them for several days in alcohol. The first alcoholic product obtained by distillation from a sand bath, is the article referred to.

the processus brevis, are completely concealed by it. (*Toynbee*.) Deafness invariably accompanies this complication.

Treatment. The pain and irritation must be overcome by frequently cleansing the canal with a syringe and warm water; as well as by local applications of warm vapors from anodyne infusions, warm fomentations, etc., at the same time attending especially to the condition of the skin, bowels, kidneys, and general hygiene of the patient. In connection with which, such constitutional remedies must be administered as are indicated by the general condition of the system, as, tonics, chalybeates, alteratives, etc.—The syringing with tepid water should be practised daily, during the whole course of the treatment, whatever other measures are employed. And if there be much fetor in the discharge it may be entirely overcome, and a healthy stimulus be imparted to the tissues, by injecting a solution of Carbolic Acid one to three parts in two hundred parts of Water; if necessary, this solution may be made still stronger, or, a dilute solution of Permanganate of Potassa may be used. The application of the aconitina mixture mentioned above, will also be found useful.

As soon as pain and irritation have been removed by these measures, we must, in severe cases, carefully apply to the surface of the meatus, by means of a camel's-hair brush, a solution of Nitrate of Silver (ten to forty grains to the fluid ounce), and which may be repeated every third or fourth day. Or, a solution of Chloride of Zinc (three to six grains to one ounce), or, of Sul-

"These injections will act at the same time upon all the diseased parts, and while they favor cicatrization of the abscess and fistulas of the neck, they will modify the condition of the mucous membrane of the mastoid cells, the tympanum, the Eustachian tube, and the auditory canal, and destroy the causes of the otorrhea.—The treatment should be perseveringly continued, for it will require several months, or even years, to effect a cure."

He treats facial paralysis proceeding from the cause heretofore named, not by blisters, electricity, endermic applications of strychnia, etc., which are useless, but by remedies suitable to the particular diathesis which accompanies or has produced the otorrhea, and which has given rise to the disease of the bone occasioning the paralysis. Every morning Cod Liver Oil in doses of one, two, or three spoonfuls, gradually increased; every evening, Tincture of Iodine, commencing with five drops for a child of seven years old, and gradually increasing to twenty drops; salt baths every other day, prolonged for an hour, the bath containing eight pounds of salt; permanent cauterizations over the mastoid process; dropping into the ear Tincture of Myrrh, or of Iodine, or weak solution of Sulphate of Copper.—From this the reader can obtain an idea of the general treatment to be pursued in these cases. Permanganate of Potassa, in solution, has been found serviceable in many cases of otorrhea, used as an injection into the external meatus.

phate of Zinc (three to six grains to one ounce), may be substituted. In a number of these cases, I have derived much benefit from a daily application of the following preparation: Take of Chloride of Zinc six grains, Chloride of Gold and Soda three grains, Distilled Water one fluidounce. Dissolve. If this causes too much smarting or irritation, it may be diluted to the strength required.

In mild cases, the discharge will frequently disappear by the use of gentle astringent solutions applied to the affected parts, instead of the preceding, as, solution of Acetate of Zinc, (five or six grains to one ounce); solution of Carbolic Acid, one to six parts in six, ten, or even forty parts of Glycerin; solution of Tannin; infusion of Geranium and Golden Seal; infusion of Witch Hazel and Bayberry, etc. If the membrana tympani has become involved in the disease, it must also be touched with the local application employed. It may be proper to state here, that the most serious results have been known to follow the use of powerful astringents applied with a view to stop the discharge; mild preparations only are admissible.

When the discharge has lost its green color, its fetid odor, and has become whitish, Triquet recommends the alternate use of the following preparations: No. 1. Tannin twenty grains, Rose-water eight fluidounces; warm and dissolve. Use three injections per day. No. 2. Sulphate of Alumina and Potassa four drachms, Water four ounces; warm and dissolve. Use two injections per day.

In severe or obstinate cases, counter-irritation over the mastoid process will be indicated, as, Croton Oil Liniment, to produce pustulation; or the Irritating Plaster, which may be applied first over the mastoid process, and then to the nape of the neck, alternately changing it from time to time, first over the process, and again on the nape, and persevering in its use for a long period. Even, if these means do not effect a cure, they may prevent the occurrence of ulceration of the drum membrane, caries of the bones, and extension of the disease to the brain. There is a great tendency in these diseases to extend to the brain, and thus cause death, a result which may be avoided in most cases, by carefully watching for collections of matter as they form, and affording them a free exit externally, as well as by the use of counter-irritants or revulsives to lessen or arrest the amount of discharge internally.

Sometimes, during the treatment, or, when there has been no treatment, the discharge will suddenly cease. Occasionally this is due to an acute inflammatory attack occurring about the time of the cessation, and which will require the usual treatment for such inflammation. But, when the inflammation is due to an irritating

cause that has thus suddenly checked the discharge, and is accompanied with severe cerebral symptoms, we should endeavor to recall the discharge, by hot fomentations to the diseased ear, aided by stimulating injections, as, warm Oil of Rue, etc., and active counter-irritants over the mastoid process and to the nape of the neck, as well as upon the temples, as, Croton Oil, Granville's Lotion, Gondret's Ammoniacal Ointment, etc., or, cauterizations with Vienna Paste, etc.

Chronic catarrhal inflammation of the external meatus may, from neglect or improper treatment, produce ulceration of the dermis, and, ultimately disease of the bone. This will require treatment similar to that pursued for similar ulcerations occurring on other parts of the body.*

It must be borne in mind, that chronic inflammation with discharge from the ears, frequently occurs among children who are troubled with worms; the irritation produced by these entozoa extending along the mucous alimentary canal to the throat, fauces, Eustachian tube, etc. And upon the removal of the worms and the mucous irritation they have produced, the ear affection will speedily cease.

POLYPUS OF THE EAR.

Certain fleshy growths, termed *Polypi*, probably the result of a long-continued irritation of the dermis of the external meatus, are frequently met with, and which differ from all other forms of polypi, from never being developed without having been preceded by a chronic discharge, and also, by being more commonly attached to the dermoid layer of the meatus. They are usually painless, except when they grow very large; when they cause headache, giddiness, and other symptoms of congestion. Their shape is from that of a small

* "A slow disorganization of the bone, dura mater, or substance of the brain may be taking place, and the only symptom indicating the existence of formidable disease be the presence of a discharge from the external auditory canal; consequently, no person suffering from catarrhal inflammation of the dermoid layer of the meatus, the membrana tympani, or of the mucous membrane of the tympanum, can be assured that the disease is not being prolonged to the temporal bone, the brain, and its membranes,—and that any ordinary exciting cause, as an attack of fever or influenza, a blow on the head, etc., may not induce the appearance of acute symptoms, which, as a general rule, are speedily fatal.

"Catarrhal inflammation of the dermoid layer of the external meatus, may last for many years, without pain being present or any other symptom indicative of disorganization of the bone, dura mater, and cerebellum.—Affections of the external meatus and mastoid cells are apt to occasion disease in the lateral sinus, and cerebellum." (*Toynbee*.)

round body to a large lobulated mass, and their color, before extraction, varies from deep red to pink, having, with the exception of the cartilaginous polypus, a great resemblance to the reddish, fleshy masses seen springing from the surface of blisters, and irritable ulcers. The chronic discharge, during which they become developed, is almost always the result of an inflammation of the external ear, more commonly that which occurs during an attack of small-pox, typhoid fever, scarlatina, etc. The discharge preceding or accompanying polypus of the ear, constitutes another form of what is termed *Otorrhea*.

Polypi may be developed in the tympanic cavity; upon the dermis of the external meatus; and upon the membrana tympani; there are several varieties of them, which have been variously described by different writers. Thus, we have

1. Polypi springing from the cavity of the tympanum. These are excrescences of a more or less firm character, but always presenting the color and form of those fleshy vegetations which shoot forth from wounds and carious bones; they all seem to be of a similar nature, that is, of the character of fleshy granulations, cellular, and in the composition of which a great quantity of fibro-plastic elements are found. Wilde says of these fungous vegetations, that when they pass through the aperture of a perforated drum membrane, they expand and form a nail-like or mushroom head, which spreading over the outer surface of this membrane, may be deceptive, and give the appearance of an open tympanic cavity.

2. Polypi which are developed upon the membrana tympani, a kind of fleshy production analogous to pannus of the cornea, and which may be called pannus of the drum membrane.

3. Polypi of a cartilaginous character, which are rather a transformation, a kind of chondroma.

Toyubee divides polypi of the external meatus into three classes, viz.,

1. The *Vascular, or Raspberry Cellular Polypus*, consisting of round heads resembling in appearance the free surface of a raspberry, and which are attached by small filaments to a central stem, which forms the root. It is very soft, breaks up very easily, and bleeds freely. It may be attached to any part of the meatus, more generally to the inner half of the tube, or, close to the membrana tympani; when small it is deep red, but becomes paler as it increases in size. Sometimes, but not always, considerable pain, and discharges of blood are present.

2. The *Fibro-gelatinous Polypus*, next in frequency to the preceding, it resembles the gelatinous polypus of the nose, though differ-

ing from it in structure, being composed of corpuscles and fibrous tissue. Its surface is smooth, having a soft, jelly-like appearance, is usually pediculated, frequently attains a very large size, and sometimes attains to so great a degree of hardness that it is with difficulty cut through by a pair of scissors. It is generally of globular form, consisting of from one to as many as six or eight rounded heads, each having pedicles connecting them with the root.

3. The *Globular Cellular*, or *Vascular Polypus*, consists of a single globular mass, perfectly smooth on the surface, and without any appearance of granulation. It is of a deep-red color, softer than the ordinary cellular polypus, seldom grows larger than the size of a pea, is confined to the inner fourth or sixth of the meatus, being usually developed from its upper part, is attended with an offensive mucous discharge, containing flocculi of mucus composed of thread-like particles, and is common among children and young persons. The discharge from catarrhal inflammation of the mucous membrane of the tympanum, resembles the above, but differs from it in being of a yellow color, and presenting large irregular-shaped masses of floccular mucus. The discharge appears to be confined to the surface of the polypus only.

Wilde describes several forms of polypus of the ear; "fungus, or vascular and granular masses which generally grow either from diseased bone, or after the destruction, in whole or in part, of the membrana tympani, and the attachments of which are to be found principally at the very bottom of the auditory passage in the tympanum; while polypi are, for the most part, confined to the glandular portion of the tube, about midway between the external orifice and the membrana tympani, and are attached by narrower roots than the fungi." "They are generally of a florid-red color, smooth, and polished on the surface while still within the meatus, and generally immersed in the discharge; but as soon as they appear externally, they become pale, cuticular and comparatively insensible. They are more sensitive at the root than toward their free extremity, and vary in size and form, being ovoid, lobulated, or divided by deep sulci into a number of minor bodies." They may vary in consistency, being friable and gelatinous; fibrous; fibrous and firm; or dry, cuticular, tough, and unyielding. They may be attached by narrow pedicles, or by an extensive base. When flabby, livid, and excessively fetid, they are of a malignant character, and may be accompanied after a time with sloughing and hemorrhage.

Symptoms. We may suspect the presence of these morbid

growths in the ear, when, following a discharge from the ear of longer or shorter duration, there are strange noises in the ear (tinnitus); or a sense of fullness from distension of the auditory canal; fetid discharge; pain, but this symptom is not always present; slight discharge of blood, in some cases; heaviness, giddiness, and confusion in the head, which last symptoms are increased when the enlarged polypus is pressed upon. There will always be more or less deafness, according to the size of the polypus, and the amount of obstruction it presents in the auditory canal. The pain may be severe or slight, constant, or occur only at irregular intervals, or, it may be entirely absent. Complete insensibility will sometimes follow a pressure made upon the polypus by means of a probe. This will be more apt to occur when the polypus springs from certain portions of the tympanic walls; and, even when insensibility does not occur, the pressure may occasion acute pain, perhaps vertigo, or lachrymation of the corresponding eye, as a general thing. But slight local pain, if any, will accompany pressure upon a polypus springing from the walls of the external auditory canal, when not too near the membrana tympani.

Diagnosis. In all cases of disease of the ear, and especially when a discharge is present, the practitioner should never forget to thoroughly examine the external auditory canal; and if, from the presence of matter or other substance, he can not satisfactorily see the condition of the canal, he should carefully syringe it with tepid water to remove the obstructions; after which, he may again attempt its inspection. If polypus be present, he will see a fleshy mass covered with a thin pellicle, or, in some cases, presenting a surface that bleeds upon the slightest touch; and, when the mass is a vascular vegetation extending from the membrana tympani to the orifice of the meatus, it is apt to be the seat of a constant bloody discharge, and it is important that we should get the patient rid of it as soon as possible.

When the polypus is seated more deeply within, it will become much more necessary to use an ear-speculum in making the exploration. We should always endeavor to ascertain its place of attachment, which will frequently be a very difficult matter; for which purpose we may attempt to lift it off the membrane, or to circumscribe its base with a very fine blunt probe, when, by following it up to its base, we may ascertain whether it passes into the tympanic cavity. But this operation will often be difficult and painful, and to recognize a polypus springing from the tympanum we will only have the commemorative symptoms.

Other foreign bodies in the ear may be distinguished by their

difference of form and color, a difference readily ascertained if the examination be carefully made, and be preceded by an injection. Another characteristic of many polypi is the discharge of blood determined by examining them with a probe.—Ceruminous concretions may be distinguished from polypi, by their different aspect, and by the facility with which they dissolve under the influence of an injection of warm oil or water.

Triquet, who has made a number of post-mortem examinations of the ears of persons laboring under long-continued and obstinate discharge from them during life, states that he has constantly found the mucous membrane of the tympanum hypertrophied, with small papillary eminences thereon, which, in his opinion, were truly the commencing point of polypus of the ear. He likewise states that in all his observations where a polypus existed, he invariably found the membrana tympani destroyed to a greater or less extent. Probably, he refers to those morbid growths which spring from the tympanum; for it is well known that a polypus of the external meatus may continue for a long time, and the drum membrane remain without being perforated or destroyed.

The *prognosis* of polypi of the ear is by no means favorable; many months may be required for their removal, as they all have a tendency to continue for years, as well as to re-appear after their removal is supposed to have been permanently effected. Hearing is not always restored after the removal of a polypus, especially when its growth commenced in the tympanum; so that on this question we should be very reserved.

Treatment. Various means have been recommended for the removal of these morbid growths. For vascular polypus growing near the membrana tympani, after syringing with warm water, Toynbee recommends the Potassa cum Calce, cast into very thin and small sticks, with a small quantity of Iron added to render it firmer and less deliquescent. Before applying the caustic, the ear should be well dried with cotton wool; the caustic should be allowed to touch no part save the free surface of the polypus, and the practitioner should see to what part the caustic is being applied. A glass tube may be used to shield the meatus. It seldom causes pain, but should it occasion any, it may be arrested by immediately syringing the ear with warm water. In a few minutes after its application, the growth becomes livid, and blood will ooze from it; before leaving the patient, the practitioner should again syringe the ear with warm water. The caustic may be re-applied the next day, or every three, six, eight, or ten days according to circumstances, in the same way. In some cases when the polypus has

been nearly removed in this way, and its fetor has also been destroyed, the ear may be advantageously injected twice a day with a solution of Tannin thirty grains, Water four ounces.

Carbolic Acid, applied by means of a brush or sponge-mop,² will prove effectual in many instances; and if care be taken not to have the brush or sponge too wet with the solution, that a drop may not fall on other parts, the escharotic effect of the acid will be confined to the surface to which it is applied. One part of Carbolic Acid may be dissolved in thirty-four parts of water; or, if it be desirable to have it still stronger, the addition of a small quantity of Ether, or Acetic Acid, will enable the fluid to dissolve a still greater proportion of the carbolic acid.

These growths may also be removed with Toynbee's lever-ring forceps, or Wilde's snare, care being taken not to tear or injure the external layer of the membrana tympani when the polypus is being extracted. Should there be any portion of the polypus remaining subsequently, it may be removed by carefully touching it two or three times a day with a solution of Diacetate of Lead four grains, Water one ounce; with Alum half an ounce, Water two ounces; with diluted Caustic Potassa; a solution of Sulphate of Copper, one part to from thirty to sixty parts of Water; or, with a mixture of equal parts of Compound Tincture of Iodine, and Water,—according to the circumstances attending the case, and the effects produced by the agent used.

The above agents have been likewise recommended for the cure of polypus, without a previous use of the instruments; so also have the following: a solution of Chloride of Zinc ten grains in Water one ounce; a solution of Acetate of Zinc forty grains in Water one ounce; with vesicating paper, Croton Oil, or other counter-irritant over each mastoid process. Finely-powdered Sulphate of Copper blown into the ear upon the polypus has also effected cures.

The treatment I recommend is the *careful* extraction of the polypus, either by ligature, using the snare of Wilde; or by extraction with Toynbee's lever-ring forceps, employing a force combining both traction and torsion; and then touching the part remaining with Nitrate of Silver, or one of the above-named caustics; being very careful to confine the action of the caustic to the granulating or fungous surface only, and not to allow it to come in contact with the healthy parts of the auditory apparatus. During this treatment the ear should be syringed two or three times a day with tepid water, or with some sedative solution.—In cases where the polypus is small and seated near the orifice of the auditory canal,

it may be removed by cauterization alone. When it is satisfactorily ascertained that the polypus arises from the membrana tympani, or very near it, it should be removed by ligature, if small, or by cauterization and the knife, if large.

Cures of large polypi of the ear have been made by cutting into the polypus, and inserting into the puncture a small cylinder of Persulphate of Iron, formed by making a thick paste of the iron and mucilage well rubbed together. Every day or two, after gently syringing out the ear, introduce another cylinder, and so continue until the cure is effected, say, from ten to thirty days. In order to keep the cylinders or small portions of the persulphate in contact with the polypus, bits of cotton may be pressed upon them; and, as the deeper parts of the polypus are reached, the quantity of iron applied may be diminished. There is no danger of injury to the adjacent tissues from the use of this salt. Nitric Acid, and Chromic Acid, very carefully applied have likewise been successfully used; but they must not be permitted to cause much pain or inflammation. Triquet states that he employs the Liquid Chloride of Zinc, the action of which, being under the direct eye of the physician, can be limited at will; in more than sixty cases in which he employed this agent, he has not failed in a single instance.

It will always be well to use constitutional treatment in conjunction with the local, as, tonic, antiscrofulous agents, chalybeates, antisyphilitics, etc., according to the general state of the system and the indications it presents. It must be remembered, however, that the removal of polypus may frequently require a persevering treatment for months, perhaps, years; and that it will often obstinately persist in returning. And, again, although the polypus may be permanently removed, and all discharge dried up, yet, the hearing may never return again.

DISEASES OF THE MEMBRANA TYMPANI.

1. *Injuries of the Membrana Tympani*, are in general produced by penetrating instruments, as, pins, for example; also by foreign bodies introduced into the ear, as, the introduction of ear-picks, improper manœuvres in attempting the extraction of foreign bodies, which may not only be pressed against the membrane so as to rupture it, but may even be thrust through it into the tympanic cavity. Again, the drum membrane is frequently ruptured by bathers who plunge into the water from a great height; the water enters the ear, suddenly and forcibly presses upon the column of air

contained in the auditory canal, causing the membrane to project inwardly, and, in many instances, the pressure is so strong as to effect a rupture. In a similar manner, a blow or box on the ear is very apt to cause a laceration of this membrane; or blowing the nose very strongly; as also, a sudden, sharp, loud noise, as the report of a cannon. Artillery-men, and those exposed to loud noises of this character should place plugs of cotton in their ears, and when the cannon is to be fired off, stand to windward of it, holding their mouths slightly open.—The membrana tympani has also been ruptured by the too forcible introduction of air or water into the Eustachian tube.

The *symptoms* of a rupture of the drum membrane, are, at the time of the accident, a sharp, loud noise, as if something had burst in the ear, sometimes hemorrhage and considerable pain, with more or less deafness. An examination with the speculum will reveal the difficulty.

As to the *treatment*, nothing will be required unless inflammation arises, which must be met by appropriate means. The margins of the ruptured membrane, remaining in contact with each other, soon unite and the membrane becomes again imperforate without much damage to hearing. Perhaps, in order to facilitate union of the edges of the wound, and keep the membrane as immovable as possible, and free from sound vibrations, it would be better to place a small tampon of cotton in the ear.—This treatment will answer where there is no loss of substance, but when a portion of the membrana tympani is lost, the edges can not be made to unite, and a permanent fistulous opening will remain.

In hemorrhage from the ear in hooping-cough the membrana tympani is always ruptured. In these cases, Triquet recommends cups or leeches over the mastoid region; derivatives and antiphlogistics; and plugging the ear with cotton to keep the membrane at rest, and protecting the patient from sounds or noises. A mixture of Tannin a grain and a half with Glycerin two and a half drachms, may be applied to the torn membrane, with a pencil, repeating the application once or twice a day, to favor cicatrization; or, a small piece of gold-beater's skin which has been thoroughly moistened with a drop of collodion, may be applied to the wounded drum membrane.

Spontaneous perforation of the drum membrane from abscess, or pus in the tympanic cavity, is always accompanied with a loss of substance, and the edges will not unite unless the orifice spontaneously made be quite small. In order, therefore, to guard against this difficulty, it will be better in all these cases, where we are fore-

warned of a rupture of this membrane, to puncture it; the wound thus made is without loss of substance, and readily heals. (*See Perforation of the Membrana Tympani*, page 1252.)

2. *Relaxation or Collapse of the Membrana Tympani*.—Relaxation of this membrane may be due to a loss of contractile power of the internal muscle of the malleus, which is the tensor muscle of the drum membrane; it may be occasioned by a hypertrophied condition of the mucous layer, the result of cold, or, by inflammation of the fibrous layers; it may also be due to a complete or partial closure of the Eustachian tube, in which the external atmosphere presses the membrane inward; also, to inflammation of the tympanic cavity, in which adhesive bands have formed between the inner surface of the membrane and the walls of the tympanum. Pus, or other matters enclosed in the tympanic cavity, may distend the membrana tympani, and, should these matters be subsequently discharged through the Eustachian tube, a relaxation of the membrane will occur corresponding in degree to that of its distension.

The *symptoms* of relaxed drum membrane are, more or less severe deafness, with or without tinnitus; in some cases, the hearing will be restored when air is passed into the tympanic cavity through the Eustachian tube, either by swallowing while the nostrils are held firmly closed, or by making a forcible expiration with the nostrils closed,—but as soon as the air escapes through the tube, the inflated membrane again collapses, and the deafness returns as before; if there is any derangement of the ossicles, formation of adhesive bands in the tympanum, or, obstruction in the Eustachian tube, this result will not occur; in some instances, the person will hear best, when in the neighborhood of loud noises, as, when in a mill, a car, a carriage, etc., or when bells are being loudly rung near the patient, or the rattling of a wagon, firing of guns, etc.

Upon an examination with the ear speculum the membrana tympani will be found collapsed or more concave than natural, with the handle of the malleus and the tubercle, apparently standing outward very prominent; or, if the ossicles be deranged, the concavity or pressing inward of the membrane will be more complete, no prominence of the handle being observed; the texture of the membrane may be unaltered, or, it may be thickened, opaque, white, shining, with the bright spot longer than natural; or, it may be congested, red, and dull. If the Eustachian tube be not obstructed, and we have the patient to inflate the cavity of the tympanum, by holding his nostrils, closing his mouth, and then swallowing, the membrana tympani will be seen to expand and resume its natural

form, and which will continue until the patient swallows with the nostrils free, when it will again collapse. If the Eustachian tube be obstructed, or the collapse be due to adhesive bands, this effect will not be observed, or, at least, only to a very small extent.

The *treatment* of this difficulty is not always followed by the success that could be desired; and the longer the collapse has existed the less favorable will be the prognosis. If there be any opacity or thickening of the membrana tympani, this must first be removed; for which purpose, a solution of Nitrate of Silver should be applied to its external surface, of a strength varying from three to thirty grains to the fluidounce of water; and this may be occasionally alternated with a solution of Chloride of Zinc, two to five grains to the fluidounce of water. I have found considerable benefit in cases of thickened membrana tympani, from solutions of Iodide of Ammonium, and of Chloride of Gold and Soda; carefully painting its external surface with one of them. These applications may be made once, twice, or thrice daily, according to their action, and should be persevered in until the abnormal condition of the drum membrane is removed.—In addition to these measures, it will also be proper to make counter-irritation over the mastoid process, and along the sides of the neck.

When the thickening is removed, we may then attempt to overcome the relaxation, if this does not disappear with the removal of the thickening of the membrane, and here the chances of success are small. The external surface of the membrana tympani should be painted over two or three times a day with tonic and astringent solutions, as an aqueous infusion of Rhatany Root; an infusion of equal parts of Geranium and Hydrastis; a solution of Nitrate of Iron, or, Sulphate of Iron, or Sulphate of Zinc; being careful not to have the mineral solutions so strong as to pain or injure the parts with which they come in contact. Tannic Acid dissolved in Glycerin, or, Geraniin dissolved in the same fluid, will sometimes be found of benefit, as a local application to the membrane. So, likewise, will a dilute aqueous solution of Carbolic Acid, say one part to one or two hundred parts of Water, or Glycerin. At the same time, vapors of astringent and tonic solutions should be passed into the middle ear through the Eustachian tube, and even gentle stimulants, as, vapors from water containing small portions of Benzoin, Tolu, Sweet Gum, Oil of Turpentine, Carbolic Acid, Acetic Acid, certain volatile oils, Iodine, Bromine, etc. The ear should be kept closed with cotton in order to protect the membrana tympani from sonorous vibrations, and from much pressure of the external atmosphere.

Constitutional measures must also be pursued, according to indications present, administering tonics, chalybeates, alteratives, antisyphilitics, etc., as may be required; as well as giving a close attention to hygiene. It seems to me that if electro-magnetism can be at all useful in diseases of the ear, it would be in collapse of the membrana tympani, where the ossicles and tensor muscle remain intact.

3. *Chronic Inflammation of the Membrana Tympani. Chronic Myringitis.* (See *Healthy and Unhealthy Appearances of the Membrana Tympani*, pages 1228 and 1230). This is commonly the result of acute inflammation of the membrane, though it may occur as a result of general ill health, and exposure to cold, without a previous acute attack. The *symptoms* will vary according to the character of the inflammation. In the simplest form there will be more or less tumefaction of the dermoid layer of the membrane, varying from a slight swelling to a true hypertrophy, with or without abnormal secretion of epidermis, and with from a scarcely perceptible loss of hearing to a considerable degree of deafness. In some cases no inconvenience is experienced by the patient, while in others, he will complain of noises and unpleasant sensations in the ear, as well as in the head; occasionally there will be a tickling sensation, and a slight pricking, tearing pain in the bottom of the meatus, sometimes extending across the temple to the top of the head. An examination with the ear speculum, will detect the membrane less polished and transparent than natural, with more or less epidermis upon it, or around it, and of a reddish color. When the dermis of the membrana tympani is hypertrophied, the mucous lining membrane of the tympanic cavity, is apt to be thickened.

In the *catarrhal form*, which is by no means uncommon, there will be a more or less profuse discharge, containing epidermic cells, (another form of *otorrhea*), with various degrees of dullness of hearing, irritation in the ear, tinnitus and other unpleasant symptoms, a speculum examination, after the ear has been carefully syringed so as to remove the discharge, will discover the dermis of the drum membrane deprived of epidermis, swollen, opaque, and from a pale red to a deep-red color, or, merely streaked with red; in some instances, the dermis will be either partially or wholly white, or, resembling parchment. If not removed, this affection may result in the formation of granulations, of polypi, or, in ulceration. A similar condition of the meatus may be associated with this disease.*

* Kramer, in his work on Diseases of the Ear, translated by Bennett, in speaking of Chronic Inflammation of the Membrana Tympani, observes: "On examina-

When chronic myringitis assumes a *strumous form*, there may or may not be a discharge; in the latter instance the auditory canal will be dry. If there is a discharge, it soon becomes purulent, giving rise to another form of *otorrhea*. There will be various noises and sensations in the ear, catarrhal symptoms, increased in cold and damp weather, seldom any pain, or, pain may manifest itself at longer or shorter intervals, more or less deafness, which often varies with the dry or moist condition of the atmosphere, and in a great many instances there will be swelling of the glands of the neck, or of the tonsils, and, perhaps some strumous affection of the eyes. A speculum examination may detect different conditions of the membrana tympani in different persons; with some its color will be found varying from a pinkish to a red color, (being dark red when the middle ear is also affected), opaque, and thickened. With others again, the membrane will be thickened and opaque, often resembling wrinkled parchment, and studded with pearly-like spots over its surface, while a few red vessels may be seen running parallel with the manubrium; and, any exciting cause will soon tend to produce a dark-red color of the whole membrane. The thicker and more opaque the membrane, the less will be the amount

tion, the membrana tympani is observed to be reddened, either partially or throughout its whole surface, the color exhibiting every shade of red, from a bright pale to a deep-brown red. Striking alterations in the texture of the membrane are also observed. It appears opaque, thickened, uneven, and swollen, so that generally the long process of the malleus, and even the natural naval-like depression of the membrane can not be seen. On this inflamed reddened surface there may be frequently observed granulations of various sizes, and either of a pale or blood-red color; sometimes very soft, sensitive, and bleeding readily; at other times, of cartilaginous hardness, insensible, and not bleeding; situated sometimes on the center, and sometimes on the circumference of the membrane; at other times, covering its whole surface. More frequently, however, one or more openings are observed, (generally close before or underneath the handle of the malleus, seldom behind it), which vary much in size, from that of a pin's point to a split pea, or are even so large as to have destroyed two-thirds of the membrana tympani; in the latter case, the mucous membrane of the cavity of the tympanum is exposed to view. . . . The secretion (from the meatus) may be copious, and become a real discharge, especially if polypi exist at the same time; or it may be so scanty as to escape the notice of the patient, or of a superficial observer; while at the same time the membrana tympani and the walls of the meatus are covered with foul, greenish-yellow, dry crusts. It may be watery, white, mucous, or greenish-yellow, brownish, mixed with bloody streaks, bland or corrosive, void of smell, or very fetid and of a disagreeable ammoniacal odor. Its quantity is often augmented by a simultaneous affection of the mucous membrane of the cavity of the tympanum. There is a total absence of cerumen as long as the morbid secretion from the membrana tympani and the adjoining parts continues."

of redness, from the fact that an increase of deposit interferes with the circulation.

Sometimes, there will be observed upon the tympanal membrane a thin, whitish layer with minute radiating lines running through it; at other times, there will be seen spots, and reddish thickenings, somewhat of a fleshy resemblance, and very analogous with pannus of the cornea. Or, an opacity of a half-moon shape may be observed upon the inferior and posterior part of the membrane, having a well-defined margin, a somewhat rough surface, and which opacity gradually extends over nearly the whole of the membrane, without appearing to produce a general thickening or opacity, and the membrane itself is less sensible in those parts in which this condition is noticed; it results in permanent deafness.

Chronic Myringitis may also be associated with, or be due to, a *syphilitic*, *rheumatic*, or *gouty* condition of the system; and which will have to be determined by the commemorative history and symptoms, in connection with those present.

All these forms of chronic inflammation of the membrana tympani, if not removed, will give rise to changes in the structure and in the appearance of the membrane, as,—morbid sensibility, or insensibility; “hypertrophy, or thickening and opacity of the membrane from deposits of lymph, which may involve all the layers of the membrane, and which not unfrequently proceeds to so great an extent that the membrane is ten or even twenty times its natural thickness, and it becomes opaque, hard, and dense like a piece of cartilage; ulceration, involving only one of the layers, or extending to the whole of them, partially or completely destroying them and causing perforation; an increase of the external concavity, so that its internal surface is in contact with the promontory, to which it is frequently firmly adherent; an absence of the external concavity, in place of which it is perfectly flat; scrofulous degeneration, in which all the layers lose their natural structure; calcareous degeneration, in which there is often not a vestige of healthy structure in any of the layers; and an increased degree of tenseness, frequently accompanied by the presence of membranous bands, which connect the inner surface of the membrane to the promontory, stapes, or other parts of the inner wall of the tympanum.

“The external or epidermoid layer may alone be hypertrophied or considerably thickened, forming a dense laminated mass which adheres to the outer fibrous layer; or, it may be slightly thicker than natural, with numerous small round masses, studded over its surface, and also forming a firm adhesion to the fibrous layer. Or, the outer, radiating, fibrous layer of the membrane may be thicker,

whiter, and more dense than natural, while the internal, circular, fibrous layer is perfectly healthy. The outer layer may also become thickened, vascular, and covered with deep-red granulations, or giving growth to polypi. In other cases, the internal, circular, fibrous layer will be much thickened, while the outer layer is translucent and healthy. Ulceration may occur in one or both of these layers; sometimes the whole of both these fibrous coats are destroyed by ulceration, and the mucous layer remaining entire falls inward, and covers the surface of the promontory and the inner wall of the tympanum. Sometimes one-half of the membrana tympani will be destroyed, and the border of the remaining half becomes adherent to the inner wall of the tympanum, forming a closed cavity; or, the entire substance of this membrane may be ruptured, more generally that portion between the posterior margin and the handle of the malleus.—The internal mucous lamina of the membrana tympani, which, in its natural state, is so thin that it is frequently difficult to detect its presence, becomes thickened by chronic inflammation, and is sometimes so much hypertrophied that its inner surface is in contact with the promontory.” (*Toynbee.*)

The *prognosis* is always difficult in these cases. The more simple the character of the inflammation, the earlier it be attended to, the less morbid changes produced in the drum membrane, and the slighter the degree of deafness, the more favorable will be the prognosis. But, in those cases of thickening, vascular fleshy growths, ulcerations, etc., of long standing, with almost, if not quite, entire deafness, it will be doubtful; for, though we may remove the morbid changes effected in the drum membrane by the disease, we will not always be able to restore the hearing.

“Thickening of the membrana tympani, with or without collapse, is a frequent result of inflammation; it is very difficult of cure, especially if occurring in a debilitated constitution and of long standing. The deafness is very great, and in collapse of the membrane incurable. If any traces of inflammatory action remain on the membrane, we may hope, by removing the morbid action, to improve the condition of our patient; and the means employed for chronic inflammation of the membrana tympani will be the most suitable. But if the membrane is dry, white, and tense, and the meatus in the same condition, and devoid of cerumen, little hope of improvement remains.”

Chronic inflammation of the membrana tympani may be discriminated from otalgia, or neuralgia of the ear, by the changes in the membrane, the tinnitus, and other symptoms of inflammatory action; while, in otalgia, which alternates without any apparent

cause, and without any change of structure, the membrane remains of about the color of the skin on the back of the hand.

The *treatment* will depend somewhat upon the peculiar characters which the chronic inflammation of the part, may present.—If it be of the simple form, without hypertrophy of the dermis, injections of warm water, or of warm infusions of Golden Seal, Solomon's Seal, or Black Cohosh, repeated once or twice daily, will suffice; but if hypertrophy be present, it will be necessary, after syringing the ear, to apply to the surface of the affected membrane a solution of Nitrate of Silver, (five grains to the ounce), or, a solution of Chloride of Zinc, (one grain to the ounce), or, a weak solution of Bromide of Ammonium; or, a solution of Hyposulphite of Soda and Silver, three to five grains to the ounce of Water. In some obstinate cases, counter-irritation over the mastoid process will aid in facilitating the cure.

In the catarrhal form, it will likewise be necessary to syringe the ear daily, and then apply one of the above solutions to the membrane; or, a solution of Tannin, (three grains to the ounce), may be applied; or, a solution of Chloride of Soda and Tannin. In several instances, I have derived much benefit from the application of the following: Take equal quantities by weight of Sweet Gum and Olive Oil, apply enough heat to dissolve the Gum, strain, and stir till cold. Apply on a camel's-hair pencil. Previous to making this application the membrane must be freed from the fluid injected upon it, and which is best done by taking a small piece of old muslin, removing some ten or twelve strands of thread from one end of it, so that when rolled up and attached to the end of a stick it will form a kind of brush; the loose, brush-like end may be placed upon the membrane without occasioning the least pain, and will rapidly absorb the fluid from its surface.

Thickness and opacity of the membrana tympani does not always admit of a cure, and especially when the membrane presents a pearly-white appearance, with one or two red vessels running along the malleus; and, even in favorable cases, many months will be required before the treatment will result in success. One of the following preparations may be rubbed upon the insensible membrane by means of a piece of cotton wool wound around the end of a probe; a solution of Nitrate of Silver, (ten or twenty grains to the ounce), or, a solution of Chloride of Zinc, (three or five grains to the ounce). As soon as a dark layer is formed by the silver solution, we should not re-apply it until the layer has peeled off. (*See Collapse of the Membrane*, page 1292.) If the membrane becomes red and inflamed from the treatment, we must omit it until these conditions have

passed off. Granulations, as well as redness of the membrane without inflammation, may be similarly treated. It must not be forgotten, that a more or less dilute solution of Carbolic Acid will relieve fetor of the discharge as well as lessen it, will check a tendency to morbid growths, and will, also, frequently tend to diminish the thickening of the drum membrane; it may be applied on a small piece of cotton wool wrapped around a probe or small pine stick. Solution of Permanganate of Potassa has a similar effect. Polypi, or Ulceration, must be treated as recommended under their respective heads.

As in the simple form, it may be frequently required to aid the treatment by auxiliary measures, as, the application of counter-irritants to the mastoid process, to the nape of the neck, and along the sides of the neck. These may consist of powerful rubefacients, vesicants, suppurants, or, cauterants, according to the peculiar features of the disease, and the influence exerted by the agent employed. Sometimes, the following preparation, well rubbed over the mastoid process, and on the back part of the ear, will be found beneficial: Take of Aconitina two grains, Hydrocyanic Acid, *off.* one drachm, Glycerin half an ounce; mix; use a small portion only at a time.

In the strumous form of chronic myringitis, one of the above solutions may be applied to the membrana tympani, always after having syringed the ear, repeating it two or three times daily. A very excellent preparation for syringing the ear when there is a profuse and fetid discharge, is composed of Pyroligneous Acid one part, Water three parts; this mixture may be injected into the ear two or three times a day. Also, a dilute aqueous solution of Carbolic Acid, or of Permanganate of Potassa. Kramer recommends, in chronic inflammation of the drum membrane, a solution of Acetate of Lead, one or two grains to the ounce of Water, to be dropped into the ear two or three times a day. He says: "The Acetate of Lead removes, in a singularly rapid and complete manner, the disagreeable ammoniacal odor of the discharge. There is no reason to imagine that by this remedy the inflammatory state will be suddenly and rashly suppressed, or transferred to the brain. I have even observed obstinate chronic headaches relieved, in proportion as the Acetate of Lead overcame the increased vascular action of the membrana tympani and the surrounding parts." Counter-irritants should also be applied over the mastoid process, and down as far as the angle of the jaw; those which will produce a slight vesicular rash are to be preferred, as, the Croton Oil Liniment, Compound Liniment of Turpentine, etc.

But, whatever, local treatment may be employed it is highly

necessary, that in the strumous form of chronic myringitis, constitutional treatment be administered; the Compound Syrup of Yellow Dock, Iodide of Potassium, Iodide of Ammonium, Iodide of Iron, Bromide of Potassium, Bromide of Ammonium, etc., are the agents from which the greatest benefit is to be derived; and the particular agent prescribed, should be selected in accordance with the indications presented by the system.

If the myringitis be due to, or be associated with, a syphilitic, rheumatic, or gouty condition of the system, constitutional remedies must be given to combat these conditions, in addition to the local measures heretofore advised.

In all the forms of chronic myringitis, it is important to act upon the faucial orifice of the Eustachian tube, and the fauces, once or twice every day, and which may be accomplished by applying the liquids on a small probang, or by injection; the agents used for this purpose may be weak solutions of Nitrate of Silver, Acetate of Zinc, Chloride of Zinc, Chloride of Soda, Tannin, or, Alum, etc.; and, in some of these forms, as, the strumous, and syphilitic, it may become necessary to pass medicated vapors into the Eustachian tube, and especially when the tympanic surface of the drum membrane is involved. The vapors may consist of Water and Hydrochlorate of Ammonia; Water and Iodine; Water and Bromide of Ammonium; Water and Tar; Water and Sweet Gum; dilute Carbolic Acid, etc.; and the vapors from which may be introduced according to the methods heretofore named.

Ioduretted or Bromuretted vapors may be obtained by dissolving Bromide of Potassium two hundred forty grains and Bromine one Troy ounce, in distilled Water four fluidounces; or, Iodide of Potassium two hundred and forty grains, Iodine one Troy ounce, dissolved in Distilled Water four fluidounces. A portion of one of these solutions may be added to water, according to the strength desired, and the vapor arising therefrom when heated, be conveyed into the Eustachian tube by the method heretofore named on page 1246. Or, paper saturated with the desired medicinal agent, may, when dried, be formed into cigarettes, the smoke from which may be passed into the Eustachian tube by the method described on page 1247.

During the treatment of chronic myringitis we must not neglect hygienic measures; the bowels must be kept regular; the functions of the skin be attended to; exercise in the open air, at proper seasons, be ordered; the diet must be properly regulated, etc.; and all these measures must be pursued in accordance with the indications present in each individual case. In adult females the state of the

uterine system must be attended to, and any irregularity, if present, be corrected by the proper means.

4. *Morbid Deposits in the Membrana Tympani.* These deposits are usually calcareous, and form in the fibrous layers of the drum membrane, which may be wholly or only partially involved. They may occur at any period of life, but more commonly during middle age, and especially among females. They may exist independent of any other lesion, or, they may be the result of inflammation. The principal *symptom* is more or less deafness with or without a discharge, troublesome noises in the ear, and rarely pain, and a sense of fullness or stuffing in the ear. A speculum examination will find the deposit more generally in the anterior vibrating portion of the membrane, presenting a yellowish color, a sharp, well-defined edge, and imparting a gritty sensation when scratched with a sharp instrument.

Not much can be expected by *treatment*. If a discharge be present, the ear should be syringed with tepid water as often as may be necessary; every day or two, the following solution may be applied to the diseased surface of the membrane, by means of a camel's-hair pencil: Nitrate of Silver ten grains, Nitric Acid, pure, ten minims, Water one fluidounce; mix. Or, the following may be similarly applied: Acetate of Zinc two grains, Acetic Acid twenty minims, Water one fluidounce; mix. A slight discharge should likewise be kept up from the surface of the mastoid process, constantly, proper attention be bestowed upon the hygiene of the patient, and any taint or diathesis of the system be met with the proper remedies. A cure is doubtful, though a persevering treatment for one or two years may remove distressing symptoms.

5. *Ulceration of the Membrana Tympani.* This affection is generally the result of either acute or chronic inflammation of the membrane; it may be confined to the outer dermoid layer, or may extend into, or originate in, the fibrous layers. When confined to the dermoid layer there will be a discharge from the affected ear, more or less offensive, (*otorrhea*), a loss of hearing, more or less severe pain in the ear, headache, perhaps giddiness, tinnitus, and, not unfrequently a discharge of blood. A speculum examination will find redness and swelling of the membrana tympani, and a depression where the ulceration exists, the bottom of which is formed by the external or radiate fibrous layer of the membrane, and which will sometimes be covered with deep-red granulations;

if the tympanic cavity be distended, the fibrous layers may be seen bulging outwardly through the ulcerated part.

When the fibrous layers are involved in the ulceration, the outer surface of the internal mucous layer of the membrane may be seen (after cleansing the ear by syringing), through the ulcerated part, and, generally, the membrana tympani will be observed fallen in, so as to be nearly in contact with the outer surface of the promontory, thus lessening the size of the tympanic cavity.

The *treatment* will depend upon the extent of the ulceration. If this be confined to the dermoid layer of the membrane, syringing the ears with an attention to hygiene, will be all that is necessary in the milder forms; in the more severe forms, the ear should be syringed with mild astringent solutions, and a discharge be kept up from the surface of the mastoid process.

If the fibrous layers be involved, much care will be required in syringing the ear, especially where the ulceration has extended through them to the inner mucous membrane; as a forcible syringing might rupture this latter membrane. The ear should be gently syringed twice a day, with a tepid infusion of Golden Seal, Solomon's Seal, or Bayberry Bark, and in some instances, infusions of gentle astringents, as, Beth Root, Witch Hazel, etc., may be advantageously employed, not only to remove the discharge but also to exert a tonic and stimulating influence upon the membrane and its ulcerated surfaces. A solution of Nitrate of Silver should likewise be applied to the surface of the membrana tympani every day or two; the solution may have the strength of twenty or thirty grains to the fluidounce of water. The vapor of diluted Carbolic Acid passed directly upon the membrane, through a small glass tube, will also be advantageous; but it should not be employed in conjunction with the nitrate of silver.—A weak solution of Permanganate of Potassa, will also often be of service, used as an injection. Counter-irritation should also be applied to the surface of the mastoid process, and to the nape of the neck; in obstinate cases keeping up a discharge from the former location. In addition to which, constitutional remedies should be employed whenever indicated, and a rigid attention be given to hygienic measures. If the treatment fails in overcoming the difficulty, we may expect that perforation of the ulcerated membrane will sooner or later take place.

6. *Accidental Perforation of the Membrana Tympani.* The causes of accidental perforation are various. "It may exist congenitally," says Mr. Wilde, or, "it may happen by accident, such as a pene-

trating instrument, a foreign body in the meatus, loud sudden noises, sneezing, coughing, or blowing the nose, diving to any great depth, falls and blows upon the head, etc. An ulcer may eat its way through, and leave, from loss of substance, a permanent opening; but the most frequent cause of perforation is, otitis, or inflammation of the membrane in common with the lining of the *cavitas tympani*; when during the suppuration which ensues, the pent-up matter bursts through the inflamed membrane as the nearest external outlet." Among the more common causes of perforation, are the febrile exanthematous diseases, especially scarlet fever. And it is during the presence of these diseases, or, as early as possible during the stage of convalescence, that the efforts of the physician to prevent perforation from occurring, will be crowned with success. And if this be neglected, the lesion will then be presented to us as one of a chronic character.

The *symptoms* accompanying chronic perforation of the membrane, are, a more or less profuse, and offensive discharge, which may be mucous, muco-purulent, purulent, curdy, or bloody; thin, or thick and viscid; and of a whitish or yellowish color. Also diminution of hearing, and sometimes pain will be present.—While the *membrana tympani* protects the tympanic cavity from external deleterious influences, as cold, moisture, vicissitudes of temperature, etc., it also aids in rendering the hearing more delicate; yet, notwithstanding, it can not be considered absolutely as an essential part of the organ of hearing, because, although a perforation through it will render the hearing less distinct, it does not necessarily involve a total loss of hearing. A perforation may impair the hearing, but it is only after the prolonged action of cold, moisture, etc., upon the unprotected tympanum, developing otorrhea, polypi, or other morbid conditions in the middle ear, that entire deafness, or *cophosis*, occurs. In a few cases, there will be no discharge at all. Where the discharge is profuse, the walls of the external meatus will be found red, tender and swollen, or, hard, cartilaginous, and insensible.

If a speculum examination be made, the *membrana tympani* will present different aspects according to its condition; if inflammation be present, the membrane will vary in color from a pale pink to a red color, according to the degree of inflammation; otherwise the membrane will present a redness only at the edges of the rent part, or, it may be mottled, red and white, white and opaque, etc. If there be a thickened and relaxed condition of the remaining portion of the drum membrane, or of the tympanic mucous membrane, the deafness will be greatly increased. The aperture itself may vary in size, from a slit to that of a pin's head, or even to an almost total

destruction of the membrane. Its location may also vary; more commonly it is opposite the internal orifice of the Eustachian tube, though it may be located at any part of the membrane; its position, however, does not interfere with the healing process. If the orifice be large enough to render the walls of the tympanic cavity visible through it, they will be seen either bright red and congested, pale red and more or less moist, rough and white, or red, thickened and granular. In order to determine whether it be the drum membrane or the tympanic walls that we are looking at, we may pass a very fine and delicate probe and percuss the surface under inspection; if it be the membrana tympani, the character of its texture is at once detected, and the patient will complain considerably; but if it be the tympanum, (of which the promontory more commonly presents), the firmness and hardness of the part will be readily detected, and the patient will experience a sensation as of something knocking against the skull, and will also complain less.

If one or more globules of air are observed entangled in the discharge filling the meatus, Mr. Wilde states that we may rest assured that the tympanal cavity is open externally; and, we may bring these globules to the surface so as to be within sight, (if the drum membrane is ruptured), by pressing upon the root of the tragus with the point of the finger. He also observes, and truly, that when the membrana tympani is perforated, an air globule or a mucous bubble existing at the bottom of the meatus, or entangled in the aperture, may frequently be seen to pulsate synchronously with the heart and arteries, by keeping the eye steadily fixed upon it. This occurs more especially when the aperture is rather small, and situated posteriorly.

In syringing the ear to remove the discharge, if there be an aperture the patient will complain that some of the fluid passes into the throat. And if the tympanic cavity be inflated, a loud whistling rale will be heard, or a squealing or gurgling sound.

The *prognosis* in chronic perforation of the drum membrane is not very favorable. If the aperture be small, and treatment be commenced shortly after its occurrence, the chances of success will be much greater than where the aperture is quite large, and where a long time has elapsed since its formation. Perforations occurring in individuals of a strumous diathesis, or following exanthematous diseases, or ulcerations, are less apt to heal. Those resulting from ordinary inflammations caused by colds, etc., are more disposed to heal; while those following punctures, or which are the results of accident, usually heal without any difficulty. The most favorable cases are those in which there is no discharge from the middle ear,

the aperture being small, not to exceed one-fourth of the surface of the membrane, and in which a thickening of the membrane, or of the neighboring tissues, or other morbid conditions, do not exist, or, at all events, are present in only a very limited degree.—If we can not always heal the aperture, yet, by a proper treatment, we may, in many instances, effect such normal changes in the condition of the tympanum, and of the remaining portion of the membrana tympani, as to check all discharge and greatly improve the hearing.

In the *treatment* of perforated membrane, the first indication is, to check the discharge and to allay any active inflammatory symptoms, or to remove any organic changes of the membrana tympani, which may be present. It will be useless to attempt healing an aperture the edges of which are constantly maintained in a morbid condition, by uninterrupted contact with an abnormal discharge, and by an undue amount of inflammatory action or organic change in the membrane itself; beside which, as the discharge issues from the walls of the tympanum, and not from the meatus, it would not only be impossible, but undesirable and unwise to heal the aperture through which the discharge finds an exit, until the condition of the tissues from which it proceeds have been restored to a normal condition, or sufficiently so to prevent any further suppuration.

If undue inflammation be present, it may be relieved and finally overcome, by gentle counter-irritants over the mastoid process and sides of the neck, and by steaming the ear with vapors from infusion of Hops, or Poppies, Lobelia, Catnip, etc., at the same time bathing the surface of the body, and producing gentle diaphoresis. In some obstinate cases, leeches may be applied behind the inferior half of the ear, in front of the tragus, and even around the orifice of the meatus. And while pursuing this treatment, the accumulation of pus in the meatus should be removed, by syringing with warm water as often as may be required. And as long as the redness and congestion of the whole surface of the membrana tympani continues, the above course should be rigidly pursued. As a general thing, as the inflammation subsides, the redness of the membrane will gradually disappear, the discharge become diminished, and the edges of the aperture grow together, the cicatrix, however, remaining red and congested for a considerable time, while a slight opacity of the membrane may continue for a few weeks.

It must be borne in mind, that closure of the perforation is effected by local inflammatory action; and if this action be confined wholly to the edges of the rent, as indicated by the redness being only around them and not diffused over the surface of the

membrane, our efforts to allay this inflammation should then cease, for, if we arrest this local process before the healing of the aperture takes place, we may render the perforation a permanent one.

If, notwithstanding the measures previously recommended to subdue the inflammation, the redness and congestion of the membrane continue, the acute stage having subsided, astringents should be applied upon the surface of the membrane, by means of a camel's-hair pencil, or by syringing. Various agents for this purpose have been recommended, as, solutions of Nitrate of Silver, Acetate of Zinc, Sugar of Lead, Tannin, etc., the strength of which solutions should be in accordance with the peculiar conditions present in each case; being rather weak at the commencement, but gradually augmenting their strength, until they are found to constrict the blood-vessels of the membrane, and to diminish the redness and congestion. I have derived much benefit, in these conditions, by the application, three or four times a day, of an infusion of equal parts of Witch Hazel Bark and Lobelia Leaves. The astringent should be dispensed with as soon as the red and congested appearance of the drum membrane has disappeared, except that portion immediately around the edges of the perforation. If, after this period, the healing process should go on very slowly, or not at all, it may be necessary to stimulate the edges, or even excite an artificial inflammation in them, in order to induce a closure of the aperture. For this purpose we may apply a solution of Nitrate of Silver fifteen or thirty grains to the ounce; or, an infusion of Capsicum; Lugol's solution of Iodine; Oil of Turpentine; infusion of Bloodroot, etc. The agent selected should be carefully and gently applied only to that portion of the membrana tympani situated immediately around the margin of the aperture and should not be pushed through the orifice. The easiest and readiest way of applying it, is to take a small pine stick, and whittle one end of it to a blunt point; around this end carefully wind a strand of cotton-wick,—saturate this with the liquid employed, and apply it to the edge of the hole in the manner just stated.

The application should be repeated according to its effect; if only a small amount of irritation is caused, it may be applied every day; if greater, it may be repeated every two, three, or four days, according to the degree of irritation produced.—Should inflammation be excited by the stimulating application, as, known by a redness of the whole surface of the membrana tympani, its use should be omitted for a time, until the inflammation has subsided of itself, or, been subdued by proper treatment; it should likewise be

discontinued when the orifice instead of diminishing in size, tends to become larger.

The above treatment is more especially indicated at an early period of the perforation, before any great organic changes can have occurred in the drum membrane and neighboring tissues. But when the perforation is truly chronic, having existed for several years, a somewhat different course of treatment will be necessary. Such cases are more unyielding to treatment, and afford the most unsatisfactory results.

In these long-standing cases, the first indication is, to remove any morbid conditions present, as, granulations, polypi, congestion or thickening of the tissues of the meatus, membrane, etc.; also, to keep the ear clean, when a discharge is present, by syringing once or twice daily. And it may be proper to state here, that, even where it is impossible to heal the perforation or restore the hearing, in cases where a discharge is present, syringing the ear will generally prevent the disease from extending to deeper-seated parts and the brain, thereby preventing a serious result.

The same local means may be employed to remove the morbid conditions above referred to, as have been heretofore recommended; aided by the introduction of ioduretted or bromuretted vapors into the tympanum through the Eustachian tube, and by the application of more or less active counter-irritants over the mastoid process and extending as far as the angle of the jaw. And when the parts have been restored to a normal condition and the discharge has ceased, attempts may be made to heal the aperture by the application of a strong solution of Nitrate of Silver, forty or sixty grains to the ounce, upon the part surrounding its edges; being guided by the preceding rules as to the periods of repetition, discontinuance, etc. Triquet recommends that the edges of the perforated membrane be touched two or three times a day, with a small fragment of Sulphate of Copper, or, still better, of Lapis Divinus. A still more useful remedy is a solution introduced upon the morbid membrane composed of Tannin one part, Gum two parts, Water five parts. He considers injections worse than useless unless there be a discharge.

Acoustic oils, drops, washes, and all stimulating preparations, "for removing deafness," should positively be prohibited, as they will be found useless, injurious, and may even give rise to very painful and serious symptoms. And the patient should likewise be very careful to protect his ear from the entrance of cold water while washing his face and neck, or during a river or sea bath, by placing a plug of cotton wool within the ear; the same course may be adopted to protect the ear from the unhealthy influence of cold and

dampness, whenever exposed to draughts of air, cold wintry weather, high winds, and foggy atmosphere. This temporary use of a plug, under the circumstances named, will prove beneficial, but it should never be worn constantly, as this would give rise to mischievous results, by preventing free action of the atmosphere upon the walls of the meatus, and by favoring accumulations of the morbid matters which may be discharged therein.

When the perforated membrane can not be made to heal, or when it is entirely destroyed, several plans have been recommended, whereby the hearing may be restored in a greater or less degree. These plans have but one object in view, the employment of an artificial membrana tympani, as a substitute for the perforated one. Mr. Toynbee has recommended a thin lamina of vulcanized caoutchouc or gutta percha, attached at its center to a small wire stem for the purpose of withdrawing and replacing it; the artificial membrane should be cut as nearly of the size and shape of the natural one as possible, having the cut margins smooth and regular, and after having syringed the ear to remove any discharge present, the membrane, moistened with warm water, must be gradually introduced into the meatus until the natural position of the true membrane has been reached.

Mr. Yearsley recommends the introduction into the ear of a pellet of cotton wool moistened with glycerin or sweet oil; a piece of thread being attached to it by which to remove it whenever required. Occasionally, these appliances will be found to answer the desired object, but by no means so frequently as their originators would lead us to believe. Sometimes, the irritation produced by their presence in the ear renders them infeasible; at other times, it will be extremely difficult to apply them; and, again, in numerous instances when applied no advantage results therefrom. Beside which, Mr. Toynbee's membrane is very liable to displacement.— Since penning the above, an improvement has been made upon Toynbee's artificial tympanum by a German; to the extremity of the fine wire he attaches a coil or spiral arrangement, so that the disc is fastened to it somewhat in the manner of a cork to a cork-screw, and may thus be properly retained in the canal of the meatus with less danger of becoming loosened and causing irritation. And, unless the patient can easily and properly apply them himself, instead of calling upon the aurist every time, but little benefit can be expected from them, for the patient would be placed in the condition of one who would be required to call every day upon an oculist to have his spectacles properly adjusted upon his nose.

Certain conditions appear to be necessary for the success of these

artificial membranes, viz., there should be no granulations, polypus, or other morbid growths present, no undue amount of unhealthy suppuration, and no inflammation of the walls of the meatus or of the tympanic cavity; the Eustachian tube should not be obstructed, the tympanum should be healthy, and the membrana tympani should not be wholly destroyed.

Thomas Westroff, Esq., of Bristol, has also proposed an artificial membrane, though more troublesome in its preparation than either Toynbee's or Yearsley's. An idea of it may be had by his description of it: "Having accurately inspected the meatus into which we desire to insert an artificial membrane, we must make a model of it in some hard timber." (I should suppose wax, or hard shoemaker's wax, would answer equally as well.) "This should be as perfect almost as a cast, though not too tight; its end should be flat, cut obliquely, (to suit the direction of the drum membrane), and the circular edge rounded off. This cast or model, previously oiled, should be dipped six or eight times into a solution of gutta percha in chloroform, or, until a film of sufficient thickness is formed, to peel off in one unbroken piece; each coat or film should be allowed to dry perfectly. A slit with a knife can be made longitudinally, without detriment, to aid its coming freely off, but the cut should not go within a quarter of an inch of the flat end; it is sometimes necessary to touch with some of the gutta percha solution any inequalities of the membrane. The tube should not be too thick, else it will be hard and tough, and irritate the ear; it will take two or three days to finish it.—This tube, if the timber model has been properly made, will be found to fit the meatus comfortably, and when oiled and coated with cerumen, to exclude the external air from the tympanic cavity; it should not be allowed to protrude, but should be cut obliquely, so as to lie entirely within the meatus; when it becomes advisable to clean its surface, it can be easily taken out by the patient with a small pair of tweezers, washed in cold water, oiled, and re-inserted. If found to fit, several should be made and given to the patient, who should be taught their use," and the model should be marked and preserved, in case it should become necessary to prepare more."

Rupture of the membrana tympani is sometimes caused by violent paroxysms of hooping-cough, and is generally attended with a hemorrhage, the blood proceeding from the edges of the wound. These linear ruptures readily heal by adhesion. To favor the cicatrization the following mixture may be applied to the lips of the wound, two or three times a day, by means of a small hair pencil; dissolve Tannin one or two grains, in Glycerin two or three drachms.

The patient should be kept from noises which will agitate the membrane and interfere with prompt reunion of the flaps; and immobility of the membrane should be maintained by pledgets of cotton introduced into the ear and placed in contact with the surface of the ruptured septum, by means of a speculum and blunt probe. Or, a small piece of very thin prepared intestine of a sheep, moistened with a drop of Elastic Collodion, may be carefully placed in contact with the membrane.

DISEASES OF THE EUSTACHIAN TUBE AND MIDDLE EAR.

1. *Obstruction of the Eustachian Tube.* The Eustachian tube is a long, narrow canal, slightly inflected obliquely, passing from above downward, and from behind forward, and forming a tube of communication between the pharynx and the tympanic cavity. Its principal functions are, to discharge the matters secreted in the tympanum as well as in its own cavity, and, to permit the renewal of the air in the cavity of the tympanum; the entrance and exit of this fluid at the moment of vibrations, are two conditions necessary to enable the waves of sound to produce their impression on the sensible parts of the auditory apparatus. Consequently, the tube is almost constantly open,—a disposition resulting from the osseous, cartilaginous, and fibrous structure of its walls. Being continuous with the middle ear, on the one hand, and with the superior portion of the digestive and respiratory passages on the other, it is furnished throughout its whole extent by a mucous membrane, being a continuation of that of the pharynx and which extends into the tympanum.

The peculiar situation of this tube protects it from accidental wounds or injuries; but the nature of its functions, its length, its narrowness, its relations with the pharynx and the middle ear, render it liable to the diseases of these parts, as, inflammation, congestion, ulceration, stricture, and even obliteration.

In order to the healthy exercise of the sense of hearing, it is absolutely necessary that the Eustachian tube should be pervious. If it be obstructed, the result would be, not only an accumulation of secretions giving rise to numerous unpleasant symptoms, but, from the absence of air in the tympanum, there would be a want of the proper equilibrium between the air in the tympanic cavity and the external air required to prevent too great tension of the drum membrane, and, of course, the hearing would become more or less seriously affected.

These obstructions are more commonly caused by collections of mucus; congestion and thickening of the mucous membrane surrounding its faucial orifice, more or less, throughout its whole extent, or at its tympanic orifice; relaxation of the mucous membrane, especially around the faucial aperture; or, stricture of the osseous and cartilaginous portion of the canal. And, occasionally, the orifice of the tube may become obliterated.

The *symptoms* are a more or less complete loss of hearing, depending upon the character and extent of the obstruction, as well as upon the amount of air in the tympanum, and various noises in the ears; sometimes a cracking noise in the ear will be followed by a temporary improvement in hearing, especially when the obstruction exists at the faucial orifice of the tube; and again, the symptoms will be suddenly reproduced upon sneezing, coughing, or blowing the nose, probably, from the mucous matters around the faucial entrance of the tube being driven within the tube by the compression of air in the pharynx during these acts; a feeling of pressure or heaviness in the ears is frequently experienced—sometimes even affecting the head, with dullness of spirits. If the nasal mucous membrane be much thickened, the person is very apt to breathe through the mouth, which, during the hours of sleep, produces loud snoring. And an examination of the mucous membrane of the throat and fauces will find it more or less red or thick, sometimes the mucous membrane of the nose also; and frequently the tonsils will be enlarged. Upon employing the otoscope no air can be heard entering the tympanic cavity upon making either a forced expiration, or a movement of swallowing, with closed mouth and nostrils. A speculum examination will detect the membrana tympani dull, or of a leaden hue, opaque, more concave than natural, and uneven upon its outer surface, as shown by observing, instead of the triangular bright spot, two or three irregular bright spots, or, the triangular spot may be duller than natural, or larger.

Mr. Toynbee observes, that the whole of the mucous membrane of the Eustachian tube, excepting at the two extremities, is so surrounded by muscles and bone, as to be little liable to become the seat of disease; also, that the mucous membrane covering the bone which forms the *tympanic extremity of the tube* is, on the contrary, liable to congestion and hypertrophy, being, like the mucous membrane of the tympanum, exposed to the influence of the cold air entering the meatus externus. Mucous disease of the walls of the tympanic cavity, and of the tympanic orifice of the Eustachian tube, usually exist together. And in these cases, there will be loud

noises in the ears, a great concavity of the membrana tympani, which will generally be white, opaque, and frequently thickened from being involved in the disease of the mucous membrane of the tympanum, and there will likewise be an impervious condition of the Eustachian tube; the fauces not being necessarily implicated with the mucous disease of the tympanic aperture of the tube, may remain in a natural state, though, if found red and thickened, it will have no bearing on the disease at this part of the tube.—It must be recollected that deafness from obstruction of the Eustachian tube usually comes on rapidly, often disappears, and as rapidly returns; while that arising from disease in the mucous membrane, is generally slow and regular in its progress.

Obstruction from *relaxed mucous membrane at the faucial orifice of the tube*, is occasionally met with, and is not so common among children and adults liable to glandular enlargements, as among those of an opposite tendency. It is generally due to a cold, or other debilitating influence, as, overwork, late hours, hot rooms, etc. The mucous membrane gradually becomes relaxed, the lips of the tube close, and the muscles can not open them wide enough to allow the air to enter. The deafness comes on gradually; with it there is a singing, ticking, beating, rumbling, or cracking sound. Upon lying down, or turning the head round so as to look somewhat backward, the hearing becomes slightly improved. Frequently, there will be a sense of weight in the ear, as well as a feeling of confusion in the head. The patient has an appearance of being weak, perhaps, anemic; if we examine his throat, the mucous membrane of the fauces will not be found thicker than natural, but it will be relaxed and red, and striated with large blood-vessels,—the uvula will be paler than natural and relaxed, sometimes so much so as to rest upon the root of the tongue. Upon attempting to inflate the tympanic cavity, the Eustachian tube will be found obstructed. A speculum examination will detect the drum membrane more concave than natural, its surface, glossy and of a dark-leadened hue, with irregular bright spots upon it; and, sometimes, the long process of the incus may be seen through it. (*Toynbee.*)

Where the obstruction is seated at the faucial extremity of the tube, the *prognosis* is always more favorable, than where it is located along the course of the tube, or at its tympanic extremity. It is also more favorable when the obstruction is not complicated with disease of the internal ear, or with a scrofulous, or syphilitic taint of the system. In stricture of the tube, the further the narrowing is situated from the faucial orifice, the less favorable will be the

prognosis. In obstructions from bands or bridles, or in obliteration of the tube, the prognosis is always unfavorable, although cases of this kind, have occasionally been cured, or considerably benefited by treatment.

As to the *treatment*, before entering upon it, it will be proper to impress upon the mind of the practitioner that, in all cases of deafness where the Eustachian tube is obstructed, he must ascertain the true character of the obstruction by a close and careful examination. (See page 1235.)

If the *faucial orifice of the tube* be found thickened, this condition must be removed, before there will be any great improvement in the hearing; and the treatment, in order to be effectual and permanent, will frequently require considerable time. The measures to be pursued, are local, constitutional, and hygienical. The *local* treatment consists in applying stimulating and astringent preparations to the congested and hypertrophied mucous membrane, and stimulating or counter-irritating applications upon the external part of the throat. Nitrate of Silver, in strong solution, or even in the solid form, has been highly recommended as an application to the mucous membrane of the orifice of the tube, of the fauces, and over the surface of the tonsils should these be enlarged, as well as to the congested and thickened mucous membrane of the nostrils, when present; repeating the application according to the effect produced, one, two, or three times per week; and its application is usually followed by success. But, I am convinced, from considerable experience in the treatment of this difficulty, that there are other agents which, in many cases, will answer equally as well; thus, a solution of Tannin one drachm, in one drachm of Glycerin and a half a drachm of Rose-water, will be found a very valuable local application; so will a solution of Carbolic Acid one part in two, four, or ten parts or more of Glycerin; or, Iodide of Zinc five grains to half an ounce each of Glycerin and Water. This last solution may be applied every day, or every other day, increasing its strength to ten, twenty or thirty grains to the ounce of fluid, as the parts become accustomed to its action,—it causes a smarting sensation for an hour or two. Or, take one ounce of Olive Oil, one ounce and a half of Sweet-gum; mix, and apply heat, stirring constantly until the Sweet-gum is dissolved, and strain while hot. These articles may be applied to the diseased parts on a sponge-probang, by means of a camel's-hair pencil, or by injection, etc., repeating their application once, twice, or thrice per day, according to their influence upon the affected membrane. As they do not so permanently stain the skin, nor leave such an unpleasant

taste as the nitrate of silver, preference should be given to them in all cases where they act beneficially.—I will remark here that applications to the mouth of the Eustachian tube may be greatly facilitated by the use of a reflector or a rhinoscope, especially when they are made through the nasal passages.

Gargles composed of stimulants and astringents are likewise indicated; a very excellent one is composed of Dilute Acetic Acid, Water, each, one pint, Salt a tablespoonful. This mixture may be used as a gargle two or three times daily; and to improve the condition of the mucous membrane of the nostrils, a portion of it may at the same time be drawn up through the nose, and passed out by the mouth. Or it may be passed upon the mucous membrane of the nasal cavities by means of injections by hydrostatic pressure, referred to at page 548. Other gargles may be similarly employed, as, an infusion of equal parts of Black Cohosh Root and Geranium Root; an infusion of equal parts of Golden Seal Root, Witch Hazel Leaves, and Bayberry Bark; an infusion of equal parts of Golden Seal Root and Blue Cohosh Root, to every pint of which add half an ounce of Alum; or, Chlorate of Potassa four ounces, Hydrochloric Acid forty minims, Distilled Water one pint; mix.

When there is considerable congestion of the mucous membrane, some rubefacient liniment, as the Compound Capsicum Liniment, Black Liniment, Compound Liniment of Turpentine, or, Compound Tincture of Camphor,* may be applied to the external surface of the throat, over the region of the tonsils more especially, rubbing it in thoroughly, and repeating it two or three times a day. And in very obstinate cases, pustulation over the region of the tonsils, the upper part of the sternum, and over the inferior part of the clavicular region may be produced and kept up for a length of time, by means of Croton Oil Liniment, etc.—Sometimes there may be a discharge from the external meatus; if it be profuse or troublesome, treat it according to the method laid down on page 1281. Usually, if there be no active disease of the tympanum or its membrane, the discharge will cease with the removal of the tubal obstruction.

Enlargement of the tonsils, can not of itself give rise to deafness, but when the engorgement and hypertrophy extends to the adjacent parts and to the orifice of the Eustachian tube, obstructing or closing it by thickening or inflammatory exudation, then more or less deafness may be present; and this has been called “throat deafness.” Ablation of the tonsils is in no case justifiable, unless the

*The preparations referred to in this work, where the formulæ are not given, are those described in my *American Dispensatory*.

hypertrophied organ, being increased to three or four times its original size, gives rise to an irritation or chronic inflammation of the surrounding mucous tissues, which the local applications can not remove; in which case, the removal of the enlarged tonsils, (and with them the source of constant irritation), will render the neighboring mucous membranes more readily amenable to treatment. I have frequently cured cases where there was more or less dullness of hearing at irregular intervals, occasional cracking sounds, ringing, or buzzing, with a sense of fullness and indistinct soreness in the ears, merely by removing the inflamed and thickened condition of the fauces, and faucial orifice of the Eustachian tube, by means of local applications; and, in some instances, this condition had existed for fifteen or twenty years, the hearing very gradually becoming worse, and occurring at shorter intervals.

Catheterism of the Eustachian tube is seldom or never necessary in obstruction of its faucial aperture from the preceding cause; nor, indeed, should it be practised in any case of obstruction of this tube, when the mucous membrane surrounding this orifice is thickened; the congestion and hypertrophy of this tissue must first be removed, or at all events be considerably diminished, before attempting catheterism. If the attempt be made before this is effected, it will be found rather a difficult operation, and of no utility even though air be successfully passed into the tympanic cavity; beside, if frequently repeated, it will augment the abnormal state of the membrane, and, may cause laceration of it, emphysema, and even death. After the thickening has been removed, should any mucous interfere with the passage of air into the tympanic cavity, catheterism may be undertaken and air be blown through the tube into the cavity, if the patient can not effect this by the movement of swallowing with the mouth and nostrils closed. These cases are often very obstinate and unyielding, requiring many months, and even two or three years, before any permanent benefit can be effected.

In all cases of obstruction of the Eustachian tube, from whatever cause, attention must be bestowed upon the external meatus and membrana tympani, treating any abnormal condition of them by the means laid down therefor, under their respective heads.

The *constitutional* treatment will depend entirely upon the anemic, strumous, rheumatic, etc., disposition presented by the patient, using those agents which will strengthen and invigorate the system, and overcome, in a greater or less degree, the peculiar disposition manifested. Thus, Citrate of Iron, Citrate of Iron and Quinia, Iodide of Iron, Iodine, Iodide of Potassium, or of Ammonium, Bromide of Potassium, or of Ammonium, bitter vegetable tonics, scrofulous,

antisiphilitic, or alterative syrups, etc., will all prove serviceable when properly employed according to the indications.

The *hygienic* treatment will be that given in the Introduction to this work; keeping the feet, limbs, and body warm; attending to the functions of the kidneys, bowels, and skin; sponging the throat and neck, the upper part of the chest, and the shoulders, night and morning with cold water, and then rubbing the skin with a rough towel, till it becomes red and hot; very sensitive persons should commence with lukewarm water, and gradually accustom themselves to its employment cold. This course tends to overcome the disposition which many have to contract cold upon the slightest causes. Likewise taking plenty of exercise in the open air; attending to diet; avoiding exposures to cold, moisture, and sudden changes of temperature; avoiding overwork and fatigue in either physical or mental labors; breathing always through the nostrils instead of through the mouth, etc.

When the obstruction is due to a *relaxed condition of the mucous membrane of the faucial extremity of the tube*, the treatment will be somewhat different from that just given, in omitting the employment of nitrate of silver, and in having the local applications of a more stimulating character. The *local* applications will consist of stimulants and astringents, as, Tannin, Oil of Capsicum, and Glycerin; Carbolic Acid and Glycerin; solution of Alum; as well as some of the local preparations just named for thickening of this part. Some of these may also be applied directly upon the parts, used as gargles, and drawn through the nostrils, as previously recommended. A very excellent preparation which may be used in injection, or as a gargle, and drawn through the nostrils, is composed of Geranium, Bayberry, Golden Seal, each two drachms, Capsicum one drachm, Whisky half a pint; mix all together, heat to the boiling point, cover, and when cold, strain. It may be used two or three times a day. In connexion with these measures, counter-irritating applications may be applied along the sides of the neck, and to the upper part of the throat. The *constitutional* and *hygienical* treatment will be similar to that just named above.

When the obstruction is due to a *thickening of the mucous membrane of the tympanic orifice of the tube*, the treatment will be the same as that named for hypertrophy of the mucous membrane of the tympanum.—Obstructions in the tube from *stricture of its osseous or cartilaginous portions*, as well as from *adhesions by means of membranous bands*, very rarely occur, and there is no successful treatment known for them. It is in cases of deafness from these obstructions,

and in obliteration of the tube, that perforation of the membrana tympani has been recommended. (*See* page 1252.)

2. *Chronic Inflammation of the Eustachian tube* is commonly associated with that of the tympanum, so that the treatment will be the same.

3. *Chronic Inflammation of the Mucous Membrane of the Tympanum.* This is generally the result of a previous acute inflammation, which may be the result of cold, or it may occur as a sequel of measles, scarlet fever, whooping-cough, or typhus fever, etc., and which may be ascertained from the previous history of the case. And if the disease be allowed to progress it may extend to the brain, affecting the dura mater.

When the mucus secreted from the affected membrane, accumulates to such an extent within the cavity of the tympanum as to press the membrana tympani outwardly, in a more or less convex form, the layers of this membrane gradually yield to the pressure, becoming thinner and thinner, until finally they rupture, and the mucous discharge finds an exit through the opening thus affected, forming an *otorrhea*. Or, the discharge may not accumulate to a very great extent, being eliminated, as fast as it is secreted, through the Eustachian tube; in which case hypertrophy of the tympanic mucous membrane and of the membrana tympani will ultimately take place.

In the first instance, that is where the drum membrane ruptures, the principal *symptom* is the discharge, which may vary from a thin to a thick and viscid mucous secretion, occasionally offensive; and with which one or several of the following symptoms will sooner or later be associated, viz.: dullness of hearing, attacks of giddiness, more or less pain in the ears and head, heat and a sense of weight in the head, confusion in the head, sensation of swimming in the head, hissing, whizzing, buzzing, humming, rattling, and other sounds, which symptoms are apt to be aggravated by cold, fatigue, or slight excitement. Sometimes there will be paralysis of the muscles of the face, owing to the disease affecting the portio dura nerve. Upon an examination with the speculum, more or less of the membrana tympani will be found destroyed; if any portion of it remains it will be white, thickened, and opaque,—but it must be remembered that this thickening of the walls of the tympanum, and its membrane may occur without symptoms of inflammation hav-

ing at any time been manifest. Sometimes a portion of the drum membrane will be found fallen inwards, perhaps, adhering to the promontory; or membranous bands may extend from one part of the tympanum to the other, etc.

In a healthy condition, the mucous lining membrane of the tympanic cavity is smooth, polished, rather dry, exhaling a very slight quantity of thin mucus, so thin as frequently to require the assistance of the touch as well as of the sight to detect it, and so transparent that the bone beneath gives to it a silvery or grayish-white color; it is furnished with numerous nerves which render it exceedingly sensitive, but less so than the drum membrane. During inflammation, its numerous blood-vessels becoming filled, impart to it a color varying from light pink to red, more or less thickness, and sometimes ulceration.

In the disease under consideration, if the aperture in the membrana tympani be large enough to enable the examiner to see any of the tympanic walls, he will find them deep red and smooth; red, thickened, and villous; velvety; pulpy; or occasionally white. The thickening may vary in degree from a slight hypertrophy to one nearly filling the tympanic cavity; and very frequently the external meatus will also be found lessened in diameter, from congestion and thickening of its walls; in many instances, the promontory may be plainly seen. We should also ascertain by the methods already explained, whether the Eustachian tube is free or obstructed; if partially free, a prolonged squealing, gurgling, crackling, or hissing sound will be heard.

In the second instance, that is where the secreted matters are passed off through the Eustachian tube, the membrana tympani remaining entire, the *symptoms* will be similar to those previously named, but considerably slighter; or, partial deafness alone may be present without any other appreciable symptom. Here, we can not detect the condition of the walls of the tympanum, but we can form an idea of it from the appearance of the membrana tympani, the inner mucous layer of which must participate in the unhealthy action, as well as its other layers ultimately. The speculum will reveal the condition of the drum membrane; it will be found to have lost its polish; to have a rough, irregular surface; to have become thickened and opaque, sometimes so much so that the handle of the malleus can not be seen, while, in some instances, the short process may be readily observed; and to present a grayish-white, whitish or parchment-like color, sometimes mottled red and white, or slightly pinkish. If the Eustachian tube be obstructed, the membrane will be collapsed or unnaturally concave on its exter-

nal side, unless the tympanic cavity be so greatly filled with morbid secretions as to distend it and give to it a convexity. The meatus may be healthy, or, more generally, smooth, white, polished, and, if the disease has existed for a long time, there may also be an absence of cerumen. If the thickening of the tympanal mucous walls is so great as to obstruct the tympanic orifice of the Eustachian tube, the patient will be unable to inflate the cavity of the tympanum.

In the above cases, if, from a small aperture in the drum membrane, or, from this membrane being unruptured, a large amount of secretion is retained within the tympanum, all the symptoms will be aggravated, and the disease, extending to the brain, may occasion death.*

Occasionally the mucous membrane of the tympanum becomes ulcerated, in which case there is apt to be more pain, a fetid odor about the ear, and, sometimes, paralysis of the muscles of the face, or convulsions. A speculum examination will find the mucous membrane destroyed, and, perhaps, thick, tubercular deposit in the cavity.

The *treatment* will depend upon the condition of the parts. If the membrana tympani be not ruptured, and the morbid secretions of the tympanic cavity are not in such an abundance as to distend this cavity and cause a bulging outwardly of the drum membrane, but, instead thereof, a whitish, opaque, thickened, and collapsed condition of this membrane is present,—a solution of Nitrate of Silver (ten or twenty grains to the ounce), may be applied every day or two to the external surface of the membrane for the purpose of

*Toynbee states that "affections of the tympanic cavity are very apt to produce disease in the cerebrum. This circumstance is accounted for, first, by the great liability of the mucous membrane of the tympanum to undergo pathological changes; and, secondly, by the existence of very intimate relations between this membrane and the dura mater. The affection of the tympanum which most frequently produces disease in the cerebrum is chronic catarrhal inflammation of the mucous membrane, an affection thus far known only as an otorrhea. The changes produced by these tympanic affections are:—1. Inflammation of the dura mater, and its separation from the surface of the petrous bone by serum. 2. Ulceration of the dura mater, and its complete detachment from the petrous bone. 3. An abscess in the substance of the cerebrum. 4. Undefined suppuration of the substance of the cerebrum. From a careful examination of cases, it appears that chronic catarrhal inflammation of the mucous membrane of the tympanum may exist as many as twenty or more years, without the production of any disease beyond it, or at least *without the existence of symptoms by means of which the presence of such disease can be diagnosed*; nevertheless, in the great majority of cases, vital structures become sensibly affected in a much shorter period." Triquet states that, from his own investigations upon the subject, he can not admit these statements.

removing its hypertrophied condition. Or, instead of the nitrate of silver, one of the local applications named under the treatment of "Relaxed Membrana Tympani," page 1292, or, under that of "Chronic Inflammation of the Membrana Tympani," page 1297, may be substituted.

At the same time vesication or counter-irritation must be applied behind and under the affected ear, and be maintained more or less constantly. The faucial mucous membrane of the Eustachian tube must not be neglected; if this be congested and thickened, the same treatment must be pursued as recommended in the treatment for "Obstruction of the Eustachian Tube," page 1312, and this treatment must be persisted in until the parts are restored to a normal condition. Then, and not until then, (unless the tube be free and unirritable), we may endeavor to pass into the tympanic cavity vapor of water, or, of infusion of Hops, Catnip, Balm, etc. If these enter the cavity readily without giving rise to pain or other unpleasant symptoms, more active vapors may be introduced for the purpose of overcoming the diseased condition of the walls of this cavity, as, for instance, some of those named on page 1299, under the treatment of "Chronic Myringitis." But, the practitioner can not be too strongly impressed with the fact that catheterism of the Eustachian tube, unless properly and carefully accomplished, will prove worse than useless, and probing it by means of elastic probes introduced through the catheter, is very rarely required, and is more apt to produce injury than benefit.

If there be a slight discharge from the external meatus, this must be treated by the means heretofore recommended on page 1281.

If, however, the tympanic cavity be so distended with morbid secretions as to endanger rupture of the drum membrane, it will be better to perforate this membrane artificially, see page 1252. Toynbee truly observes, "It is of great importance to be able to decide when the membrana tympani should be perforated by artificial means, or when an orifice in it should be enlarged." The greatest difficulty in these cases, will be to keep the punctured orifice from closing in a few days. The balance of the treatment will be the same as just described above.

If the drum membrane be already perforated, the above treatment, together with that named on page 1304, for "Accidental Perforation of the Membrana Tympani," will be proper. When there is an ulcerated condition of the mucous membrane of the tympanum, the treatment will be the same as just named.

In chronic inflammation of the tympanic mucous membrane, and especially when this membrane is ulcerated, or exposed to the action

of external agents from perforated drum membrane, the contact of cold air with the affected parts will give rise to pain and irritation, and augment the chronic inflammation, etc., which we are treating; in such cases the ear should be protected, not by plugging up the orifice of the external meatus, but by placing therein a loose and not very thick layer of cotton wool, or, a handkerchief may be worn so as to cover the ears, whenever the patient is exposed to cold or damp atmosphere.

In chronic myringitis not only must the proper hygienic measures be pursued; but, as the constitution is almost always more or less affected, the same constitutional rules must be adopted, as named on page 1314, under treatment for "Obstruction of the Eustachian Tube." Of course, we can not expect rapid or miraculous cures in these diseases; in many instances, much benefit may be had, but no cure.

4. *Rigidity of the Mucous Membrane of the Tympanum.*—This affection may occur in young persons, but is much more common among elderly persons, being, according to Toynbee, "*the disease which causes deafness in advancing years.*" It is not due to any derangement of the auditory nerves. This disease is almost always caused by repeated attacks of cold, and not unfrequently is associated with rheumatism, as well as chronic inflammation and hypertrophy of the fibrous layers of the membrana tympani. In this rigid condition of the tympanic walls, the ossicles, the membrane of the fenestra rotunda, and the labyrinthine fluid, gradually become involved, and finally become fixed and immovable. The disease may or may not be preceded by pain or inflammation; in advanced years, these *symptoms* rarely occur. More or less deafness is present, and this deafness is of a peculiar kind, being rather a want of adapting power of the auditory organ, occasioned by the fixed condition of the ossicles and muscles. With some persons sounds are heard, but seem to be perverted, as the patient can not describe them correctly; others can distinguish single sounds, however low, but become confused and hear indistinctly when two or more sounds are made; again, a third class may hear a person's voice without distinguishing the words; many can hear only when spoken to slowly; while not a few hear sounds imperfectly, imagining very low ones to be quite loud, or else locate the sound in a direction different from its true one. Before the disease becomes permanent, some persons can hear very well upon making an effort, but as the effort involves fatigue, when continued for a length of time, the deafness returns

as soon as relaxation from the fatigue occurs. This peculiar deafness comes on at first at longer or shorter intervals, but ultimately becomes more permanent. One of the forms of tinnitus may be present, or a sense of weight in the affected ear, but these symptoms do not always exist.

A speculum examination will detect little or no opacity of the membrana tympani, or, it may be dull and opalescent or white, so much so that the handle of the malleus can not be distinguished. Frequently, this membrane will be considerably thickened, and more concave than usual. On attempting to inflate the tympanic cavity, the Eustachian tube will be found pervious; but from the morbid condition of its tympanic orifice and of the walls of the tympanum, instead of the normal crackling sound, the air will be heard to enter the tympanic cavity in short puffs, with a bubbling sound; with an unnaturally loud crackling; or, with a dull flapping noise.

The *treatment* consists in applying to the outer half of the external meatus a solution of Nitrate of Silver, thirty grains to the ounce of distilled water, and repeating this every second or third day; and if the membrana tympani be opaque a solution of the same salt, six grains to the ounce, may be applied to it every day. During the intervals between these applications, five or ten drops of Ether and Chloroform may be instilled into the ears, and repeated two or three times a day; or, a tincture may be made with these articles, of Cinicifuga, Gelseminum, Caulophyllum, Jeffersonia, etc., and be used in the same manner. If the application prove too strong it may be diluted with Glycerin, one-half, or to the strength required.

In addition to this, Tincture of Iodine, vesication, or counter-irritation, should be applied behind and below the ears, either daily, or on alternate days. And it will also be proper to apply stimulating washes to the throat and fauces, as well as to the faucial orifice of the Eustachian tube; being careful, however, to remove any congestion or thickening of the lining membrane of these parts, should it be present, by the treatment heretofore advised, previous to employing the stimulants.

Internally, alteratives should be administered, as, Compound Syrup of Turkey Corn, Compound Syrup of Stillingia, Compound Pills of Poke, Compound Tincture of Black Cohosh, Compound Tincture of Colehicum, Iodide of Ammonium, etc., together with such other measures as the condition of the general system would indicate. The bowels must be kept regular; the whole surface of the body should be bathed with a warm, stimulating and alkaline bath twice every week, and once in every two or three weeks a

Spirit Vapor bath should be taken. Patients should exercise as much as possible in the open air; should not suffer themselves to become too much heated by sitting near a fire nor by remaining in warm rooms, and should likewise attend to other matters of hygiene, as, diet, clothing, etc.

In obstinate cases the introduction of dilute vapors of Iodine, Bromide, etc., into the tympanic cavity, will frequently be found to act beneficially. (*See page 1299.*)

5. The *Ossicles* are liable to diseases the same as bones of other parts, as, absorption, ulceration, disconnection, caries, etc. "These little bones may also be dislocated one from another, or become totally disconnected, and they have been found within the mastoid cells, or even in the vestibule." The muscles and ligaments of the ossicula auditus may also be affected similarly to analogous tissues elsewhere. And, sometimes, false membranes are found in various parts of the tympanic cavity, stretching from one part to another, connecting distant parts, and these membranous bands often become so firm and unyielding as to prevent any movements of the bones to which they may be attached. As there are no positive symptoms by which these various morbid conditions may be detected, the *treatment* for them, has to be based upon general principles, consisting of constitutional measures, the use of vapors and other local means, and attention to hygienic rules; there being no established treatment for them.

6. The ossicles of the ear are united to each other by minute articulations which, notwithstanding their minuteness, possess a synovial membrane and a fibrous capsule, the same as other articulations. They are as already stated, subject to all the diseases of larger articulations, one of the most important of which, is *anchylosis*,—which occurs frequently, not only as a consequence of rheumatic, gouty, and syphilitic affections of the ear, but also as a complication of chronic inflammation of the internal ear.

The *symptoms* are, various kinds of tinnitus, or an entire absence of it, more or less deafness, and, rarely, pain. If, after having illuminated the auditory canal, the membrana tympani be gently struck with a blunt probe upon the point corresponding to the malleus, and the patient experiences a fugitive sensation as of feeble but positive distant sounds, the anchylosis is incomplete, and there is some hope. Upon a speculum examination the external

auditory canal will be found healthy, containing, perhaps, a little blackish and hard cerumen; the membrana tympani will be transparent, or present only nebulous tints; the handle of the malleus will project outwardly at its point of insertion, and, in some instances, this will be so marked, that the extremity of this ossicle will seem to have produced a hernia through the membrane. This membrane will not be thickened, nor present vessels at its surface, nor in its layers. If insufflation of the tube be attempted, the air will penetrate into the tympanic cavity without difficulty, making a dry noise with, perhaps, one or two small cracklings. But if the patient makes a strong expiration, the mouth and nose being closed, one or several loud and harsh sounds will be heard; when this sign is positively verified, there is undoubtedly an incomplete anchylosis. If the anchylosis be complete, neither the douche of air, nor the expiration will cause any crackling sound to be heard; the ossicles are then perfectly stiff and consolidated, and their joints ossified, remaining silent and immovable during the above-named examinations.

In the *diagnosis* we must ascertain the commemorative symptoms; the rheumatic, gouty, catarrhal, or syphilitic tendency of the patient or of his parents, will materially aid in doubtful cases. The character of the disease may be determined from *chronic catarrhal inflammation of the middle ear*, in which the membrana tympani preserves its concave form and loses its transparency, and the noises heard are mucus and not crackling. At a more advanced period of the inflammation the principal symptoms of the catarrh and of the anchylosis, are very difficult to distinguish. *Nervous deafness*, may be determined readily, by the entire absence of cerumen in the auditory canal, by the perfect transparency of the drum membrane, its integrity of form and situation, as well as of the ossicles, and by the absence of mucus, and, especially, crackling sounds. Beside, the erethism and the buzzing tinnitus are considerable, and these last are often synchronous with the arterial pulsations.

The *prognosis* is unfavorable, and the more so when treatment is instituted at a long period after the commencement of the disease, at which early stage the adhesions are still plastic and formed only by the hypertrophied or indurated mucous membrane. The chances for amelioration are greater when the anchylosis is incomplete, or when the adhesions of the articulations are not osseous nor fibro-cartilaginous.

As to the *pathological anatomy*, we will find in incomplete anchylosis a simple hypertrophy or thickening of the mucous membrane of the parts. This membrane serving as a periosteum to the ossicles,

its thickening will impede the motion of these little bones, without wholly suspending it; and hearing will not be completely abolished. More frequently there will be plastic effusions, under the form of induration, and of inflammatory origin.

Complete ankylosis presents four principal anatomical morbid changes, as, 1. A simple expansion of the hypertrophied articular membrane is prolonged over the base of the stapes, or over the head of the malleus, binding it fast to the incus, or over both at the same time. 2. A fibrous expansion over this same base, and strongly attaching the articular surface of the stapes to the petrous bone or the incus to the malleus. 3. An expansion of the articular membrane over the base of the stapes, and the head of the malleus, with scattered calcareous deposits over this base. 4. Osseous deposits embracing the fenestra ovalis and the stapes, consolidating them. These last two are more frequent among the gouty and syphilitic; the former, among rheumatics and those disposed to catarrhal attacks.

The base of the stapes is more frequently ankylosed; the other ossicles are not always exempt from it, but it is then merely a complication of little importance in the prognosis.

In consequence of the consolidation of the ossicles among themselves and to the promontory, certain curious changes occur in the chain of bones, and in the shape of the membrana tympani. In well-marked cases, the chain of ossicles is, so to speak, broken; the handle of the malleus is, as it were, luxated downward, drawing with it the short branch of the incus. The drum membrane follows this movement, and in place of presenting its external concave surface, appears as if divided into two lateral compartments or facets, obliquely directed from the center to the circumference, and forming a double inclined plane. The extremity of the long process of the malleus forms the apex and the edge of it, and the lateral sides or planes are represented by the two facets of the membrane, which is, as it were, cut and divided into two segments by the acute projection of the malleus. This curious pathological disposition, is important to verify, and is one of the most certain signs, not only of ankylosis, but also of adhesions of the drum membrane to the promontory through the intermedium of membranous bands.

The *treatment* must be local and general. Of the local means, those which have succeeded the best, are fumigations with Acetic Acid, or Spirit of Mindererus, at first passed into the external ear, and afterward through the Eustachian tube into the middle ear. In case, the original cause of the ankylosis, inflammation of the tympanum, is not subdued, cupping and counter-irritation to the

mastoid process, cauterization of the pharynx in case of persistent granulations, etc., are the proper means to pursue.

As to the general treatment, gout, rheumatism, syphilis, or catarrhal disease, must be combated by the appropriate remedies; and injections of Strychnia or Veratria be passed into the middle ear through the Eustachian tube, prepared and used as described on page 1249. In some cases, gaseous and fluid sulphurous douches will be of service.

7. Occasionally, *morbid growths and deposits* of various kinds occur in the tympanic cavity, which can not be detected during life, unless the membrana tympani be destroyed. Not only the soft tissues but even the bones may become involved. "In fact, when once disease seizes upon the parietes of the middle ear, it is impossible to say what amount of mischief it may not effect." (*Wilde.*)

8. The *Mastoid Cells* may become diseased by extension of morbid action from the tympanum, and which frequently accompanies or follows measles, scarlatina, small-pox, and scrofula. More generally it is the result of acute inflammation produced by cold, or, by the causes just named. These cells may have their delicate mucous lining membrane livid, red, thickened, and pulpy, similar to the morbid condition of the tympanic mucous membrane; the cells may be filled with purulent or muco-purulent, scrofulous, or tuberculous matters; the bones of the part may become soft, or carious, forming fistulous communications; and, especially in children, exfoliation of a part, or of the whole mastoid process may occur, particularly when the case is neglected. Unless the disease progresses toward the surface, causing a protuberance of the process the diagnosis will be obscure. If the accumulated matter finds a free exit through an aperture in the membrana tympani, or at some other safe location, the disease may not prove fatal; but if the matter be pent up, or be so lodged in the concavity of the process that it can not be discharged, a fatal result will sooner or later take place. Gentle percussion upon the process, an exploration of the tympanic cavity, and the presence of cerebral irritation, as great pain in the head, convulsions, rigors, restlessness, delirium, drowsiness, etc., together with the previous history of the case, as, a tendency to glandular swellings, pains in the ear, in the back of the head, and in the region of the mastoid process, coming on at different times, giddiness from time to time, occasional sharp pains on masticating or

while gaping, etc., will aid in the diagnosis. The walls of the meatus will commonly be red and giving out a discharge, while the membrana tympani will be found entire, but white and thickened. If the disease has not reached the brain or its membranes, there may be a chance for recovery; if it has affected these organs death will certainly ensue, notwithstanding all treatment.

The *treatment* consists in keeping the patient quiet, applying counter-irritation over the mastoid process, as the Compound Tar Plaster, and, after a discharge has been kept up for a length of time, change its location placing it between the shoulders, and so continue alternately from one point to the other, being very careful, however, not to let the discharge at one point wholly dry up, until a discharge has commenced at the other. If there be a bulging outward of the membrana tympani, from distension of the tympanic cavity by matter, it may become necessary to perforate this membrane. (See *Perforation of the Membrana Tympani*, page 1252.) If the mastoid process be more elevated than natural, the skin over it being discolored, with manifest fluctuation, it may become necessary to perforate this process. (See *Perforation of the Mastoid Process*, and *Note*, page 1253-4.)

The various symptoms that may present themselves will have to be treated on general principles, giving antiscrofulous agents to the strumous, tonics to the debilitated, chalybeates to the anemic, etc. The hygienic measures will principally be, regularity of bowels, attention to diet, bathing the body every three or four days, avoidance of fatigue and exposures, and confinement within the house.*

*Toynbee states that if an aural discharge "arises from the dermoid meatus, the membrana tympani being entire, there is, as before stated, most probably irritation in the tympanic cavity or mastoid cells, of which irritation the discharge is the symptom. Unless there were simply some eczematous state of the meatus to account for the discharge, and unless the hearing power were perfect, such a case should be looked upon with suspicion, especially if attended with any symptoms of brain or cerebral irritation. Again, if the discharge issues from the tympanic cavity through a small or valvular opening, and it is requisite to blow the nose forcibly to clear out the tympanum, there probably is, or will be, some affection of the bone, from the accumulation of the discharge. If there is a large orifice in the membrana tympani, or that membrane is absent; if there is no ulceration of the mucous membrane of the tympanum; if there is some power of hearing remaining; and if, by pressing and tapping the region round the ear, no pain is felt; and if there are no other symptoms of disease in the ear or head, I think it may be assumed that there is no disease of the bone; and that by attention to daily syringing, and the other plans alluded to when speaking of the treatment of these affections of the ear, there is a fair prospect of the disease remaining confined to the mucous membrane of the ear. On the other hand, it becomes a duty to state that any negligence on the part of the patient, by which

DISEASES OF THE INTERNAL EAR.

That there may exist diseases of the internal ear, that is to say, of the vestibule, semilunar canals, cochlea, and the nervous expansions enclosed within these cavities, has been satisfactorily demonstrated by post-mortem investigations; yet it is not only difficult, but generally quite impossible to determine the presence or character of such diseases during the life of the patient. This is owing to the concealed situation of the ear, to our imperfect knowledge of these diseases, to a want of more certain modes of investigating them, and to the fact that they are often rendered still more obscure by the accompanying cerebral symptoms. And even, were we able to properly diagnosticate affections of the internal ear, our therapeutical resources would accomplish but little in the way of cure, being principally confined to counter-irritation over the mastoid process and nape of the neck, tonics, and alteratives.—Acute inflammatory affections of these parts, as well as of the external and middle ear, may frequently be promptly subdued by hypodermic injections of solutions of Sulphate or Muriate of Morphia, or other sedative, made at the temple, over the mastoid process, or below the ear just posterior to the ramus or angle of the inferior maxillary bone.

Nervous Deafness. Until recently, all cases of deafness,—in which, after as thorough an examination of the external and middle ear as the circumstances would allow, no appreciable lesion of the external ear, membrana tympani, Eustachian tube or middle ear could be detected,—were set down as cases of nervous deafness. But pathological anatomy has revealed the fact that the greater part of these so-called cases of nervous deafness, were due entirely to abnormal conditions of parts associated with the middle ear; also, that certain morbid changes may occur in the tympanum, with the ossicles and the fenestræ, which it is impossible for us to detect during life, either by catheterism of the Eustachian tube, or by speculum examination; the membrana tympani, in the latter case, being intact and presenting no unhealthy appearances. And, consequently, the cases of true nervous deafness have been very much diminished in number.

the discharge should be allowed to collect so as to fill up the orifice in the membrana tympani—a blow on the ear, an attack of fever, or any severe illness might cause an irritation in the ear, which, if unattended to, might advance to the bone,”—and thence to the brain.

That the nervous apparatus of the organ of hearing may become diseased, does not admit of a doubt; but, unfortunately, we have no positive method of arriving at a correct diagnosis, nor even a reliable curative treatment for the disease, should we be so fortunate as to arrive at a proper diagnosis.

Now there can be no satisfactory reason given, why the soft and minutely ramified and subtilized labyrinthine nerve should not be as liable to derangements from certain causes as other nerves; why there should not be a hyperacusis from excessive sensibility of this nerve; a paraecusis from imperfect nutrition of the nerve, as, for instance, in anemic conditions; or a complete eophosis from concussions, labyrinthine disease, paralysis, etc. And authors have admitted that nervous deafness may be *caused*, by concussion, as, from a fall on the head, a blow on the ear, violent and unexpected sounds, and a severe jar of the whole frame; by congestion; by exposure to cold; by compression of the nerve; by convulsions; by sympathy with gastro-intestinal, menstrual, and other derangements; by certain poisons, as that of scarlatina, measles, small-pox, typhus, gout, rheumatism, intermittent fever, syphilis, jaundice, etc.; by the influence of certain medicines in large doses, as quinia, and belladonna; by mental excitement, hysteria, and by physical debility.

There are no *symptoms* which may be referred to as peculiar to nervous deafness; more or less deafness may be present, with or without tinnitus in one of its many forms; headache; and, perhaps, opaque or nebulous spots on the membrana tympani; which symptoms, especially the deafness and tinnitus, will increase more or less rapidly; and all of which may be met with in almost every form of chronic aural disease.

As to the determination of nervous deafness, much will depend upon the history of the case, aided by a careful examination, and even then the diagnosis can not always be positive. If the patient, previous to the diminution or loss of hearing, had been exposed to one or more of the above-named causes; if, up to that time, the hearing had been normal, without any previous inflammation, pain, or discharge from the ear; if the loss of hearing manifested itself soon after the exposure; and if we can detect no evidence of disease in the external or middle ear, by the several methods of examination now pursued by aurists, we may have reason to consider that the case is one of nervous deafness, although, as above stated, we must remember that there may be actual disease of the middle ear which, from the concealed condition of the part, it is impossible for us to discover; and again, we may have a true nervous deafness associated with a lesion of the external or middle ear.

The *prognosis* of nervous deafness can not be said to be favorable; in the majority of bad cases but little influence can be effected by treatment; and even when certain conditions of the system which have occasioned the deafness, have been wholly removed, the deafness will still continue, because the original disease has so affected the labyrinthine nerve as to place it beyond the power of restoration by the means usually employed.

Treatment should always be attempted in these cases, when we are fully satisfied of their causes, with the hope that the removal of the cause may be followed by an improvement in hearing, or else so influence the auditory nerve as to allow an improvement by properly directed measures. Thus, if the patient be chlorotic or anemic, the usual means for overcoming these conditions should be resorted to; if there exists gastro-intestinal derangement from worms or other causes; if menstrual derangement is present, or jaundice, etc., we must remove these several states by appropriate measures; and so with other abnormal conditions. In cases, where the deafness results from certain poisons or taints received into the system, tonics and alteratives will be required; if it arises from concussion, convulsions, apoplexy, paralysis, etc., in which constitutional treatment will prove useless, revulsives and counter-irritants may be prescribed, as active cathartics, sudorifics, and Compound Tar Plaster to the mastoid process and to the nape of the neck, alternately continuing this counter-irritation for several months, or even longer if a degree of improvement be observed to follow; these measures being, however, modified to suit the strength and other conditions of the patient. The instillation of stimulating drops, oils, etc., into the external meatus must be positively prohibited, unless the practitioner himself prescribes them for actual disease of this part of the ear.—I may say here, that I have not, in my own practice, derived any benefit from electricity or galvanism, in this form of deafness. (*See formulæ for injections* on page 1245-50.)

The proper hygienical measures, adapted and regulated to suit the mental and physical condition of each patient, should also be rigidly pursued, as, exercise in the fresh air; regularity of bowels and kidneys; attention to the skin, clothing, diet, and hours of rest; and relief from all mental excitement, etc.

Persons who use tobacco in any form, as well as habitual drinkers, are subject to an affection of the ears which frequently results in an obstinate and even incurable deafness, and which is due to the morbid state of the constitution produced by the long-continued use

of these deleterious articles. There is no discharge from the ear, no accumulations of mucus in the tubes or middle ear, no thickening of the aural membranes; but there is a kind of numbness or torpor in the ear, with a peculiar sense of coolness in the same organ, but never any pain; a want of cerumen, a normal disposition of the membrana tympani and ossicles, no pathological vascularity of the membranes; an extreme dryness of the pharynx, nasal fossæ, tubes, and middle ear; such are the principal symptoms which characterize this singular affection. Both ears are generally attacked, though the symptoms may be observed at an earlier period in one than in the other, and in this one the deafness will be the greater. Without being very marked at the commencement, the deafness soon becomes annoying, and increases rapidly, with whistling or hissing tinnitus. This affection may be divided into three stages, as follows:

In the first stage the patient usually experiences suddenly and during the night, a whistling in both ears, intermittent, and having a somewhat metallic tinkling. During the day this morbid noise diminishes, increases after a meal, and especially after supper, and continues thus without interruption; at the same time the slightest sounds are painful to the ear. Conversation in a moderate tone is very fatiguing, and the patient closes his ears with his fingers or with cotton, not only in the street, but also at home, or when among his associates. This period lasts from a few days to two or three months, seldom longer.

The second stage now manifests itself; the patient rejoices in an apparent amelioration of his symptoms; the tinnitus diminishes or ceases altogether; the intolerance of loud and sharp sounds has also ceased—indeed, he now seeks loud noises, noisy conversations, and complains that persons speak too low to him. This state lasts but a short time, and sometimes is suddenly followed by the next stage.

In the short space of one night the third stage comes on; and the patient, to the surprise of his friends, becomes suddenly deaf, and which continues, unless timely assistance be procured, during life, obstinately resisting all treatment. The deafness may be complete, or the patient may be able to hear a watch applied upon the ear or between the teeth.

The *diagnosis* is easy, as the affection is invariably the result of a prolonged use of tobacco or alcoholic liquors. The throat and fauces will appear purplish red, and an innumerable quantity of small red, granular points will be seen, giving to the membranes an appearance of shagreen. The nasal fossæ present the same

aspect throughout their whole extent. If the patient, holding his mouth and nostrils closed, forces air into the tympanum, the physician can hear the air enter it, but without any mucous or crackling sounds; but tinnitus will now appear for the first time, or else be increased at the instant, and this increase of the morbid noise will last for several hours, or even days, disappearing only by a timely and appropriate treatment, or by yielding to the third stage of the disease, in which there is a partial or complete paralysis of the auditory nerve.

No obstructions of any kind will be found in the Eustachian tubes, and the membrana tympani will present a normal appearance. Even without this examination, a verification of the symptoms as they occur in the three stages of the disease, occurring as just named, will render it almost impossible to form an erroneous diagnosis.

The *prognosis*, is always unfavorable, as few patients will consent to give up their bad habits.

The *treatment* consists in the first place in prohibiting the use of tobacco and liquor, and unless the patient will renounce their employment, remedial measures will be useless.

The treatment will commence by the application of counter-irritants over the mastoid processes, and for this purpose the Compound Tar Plaster will be found very valuable. In some cases, previous to the application of this plaster, it has been recommended to cup the part, but this is not always necessary. At the same time an active cathartic should be administered, and which may be repeated every three or four days, according to its influence upon the patient, and his strength. The Compound Cathartic Pill will be found very valuable for this purpose, or, the Compound Pills of Podophyllin. In connection with these means, the patient should be placed upon a tonic and alterative treatment, as for instance, the following compound, which will be found very efficient: Take of Quassia, Sassafras Bark, Black Cohosh Root, each, two drachms, Swamp Milkweed three drachms, Prickly-ash Berries one drachm; mix. Pour on this Boiling Water eleven fluidounces, Boiling Vinegar five fluidounces; cover, and set the vessel containing the articles in a hot place to infuse for two hours. When cold, sweeten if desired, and give a tablespoonful for a dose, repeating it every two or three hours.

Local measures will also be required; the throat should be gargled two or three times a day, with a mixture composed of one drachm of common Salt dissolved in Water, Vinegar, of each, four fluidounces. The external and middle ear should also be fumigated,

in the first stage, with dilute Acetic Acid vapors, or vapors from a solution of Acetate of Ammonia, etc. In the second stage, and more especially, when the preceding treatment has effected an improvement in the mucous tissues, as ascertained by the normal appearance of the throat and fauces, if the deafness still continues, we will frequently succeed, even in hopeless cases, by injections with Strychnia, and especially Veratria, as named in the formulæ on page 1249.

CHRONIC DISEASES OF THE EYE.*

NORMAL APPEARANCE OF THE RETINA EXAMINED BY THE OPHTHALMOSCOPE.

When the eye is properly examined by the ophthalmoscope, the physician will at first see a reddish or pink bottom in the form of

*ANATOMY OF THE EYE.

Although it is presumed that the medical man is well acquainted with the anatomy of the eye, yet a brief description of it here may not be considered out of place.

The organs of sight, by which we are enabled to distinguish color, distance, the form and size of bodies around us, etc., are surrounded with other or secondary organs designed to move and to protect them, as well as to facilitate the free exercise of their important functions. These organs of protection and motion are termed *appendages of the eye*, and consist of the orbits, the eyebrows and the eyelids, the lachrymal apparatus, and the motor apparatus.

The ORBITS or *orbital cavities*, are two cavities of a quadrangular pyramidal form, situated, one on each side of the nose between the cranium and the face. Their osseous walls envelop and surround the ocular globes in such a manner that they are protected at all points, excepting at their anterior surface, from contact with external bodies. Their superior walls are the thinnest, and their apices give passage to the optic arteries and nerves, the latter being whitish cords specially designed to transmit to the brain the impressions produced upon the eyes by the objects presented to them.

The EYEBROWS (*supercilia*) are prominent curvilinear appendages, situated immediately above the orbits, and consist partly of bone, and partly of a thick skin, ornamented (according to the race and temperament) with more or less numerous and dark-colored, stiff and thick hairs, and lined with a fatty tissue, beneath which is found some red fleshy fibres which form a muscle, called the *superciliary muscle*, (*corrugator supercilia*), and which serves to contract or wrinkle the brow. This muscle serves materially in giving expression to the physiognomy, and to portray the violent passions of the mind.

The hairs overshadow the eyelids, and contribute to protect the eyes from various particles which might interfere with their functions; they also serve to convey the drops of sweat, which stream from the forehead, toward the sides of

a spot, a little diffused at first, but changing into a brilliant, clearly defined circle, about one-third or one-fourth of an inch in diameter.

the face; they likewise, by their more or less dark tint, absorb the most powerful rays of light, and thus preserve the eye-globes from the too vivid action of the light.

The EYELIDS (*palpebræ*) are the thin, movable veils or curtains spread out in front of the eyes; there are two for each eye, a superior, and an inferior eyelid. The superior lids are the largest and more extensive; both lids are formed—1, by a thin layer of fine and delicate skin; 2, by a cellular tissue beneath the skin with very loose spaces or intervals; 3, by a muscular plane called the *orbicular muscle* (*orbicularis palpebrarum*), which serves to close the eye by bringing the eyelids in contact; 4, and beneath this, by a small layer of a substance analogous to parchment and called *tarsal fibro-cartilage*. This small layer of fibro-cartilaginous tissue, which extends from one angle of the eye to the other in the substance of the margin of the lid, is strengthened by muscular fibres designed to elevate the lid; its function is to keep the lid extended transversally and to favor its gliding over the eyeball; 5, finally, on its internal surface the eyelid is furnished with a delicate red mucous membrane called the *palpebral conjunctiva*, and so termed because it unites or joins the lids to the globe of the eye, spreading over and covering the anterior surface of this organ, and becoming modified in its structure. Its diseases occupy a very important position in ocular pathology. The groove or gutter-like cavities formed between the eyeball and lids, are termed the *oculo-palpebral sinuses*, of which the superior is much deeper than that of the inferior.

Each eyelid presents two margins, called the *tarsal*, the one of which is continuous with the skin, the other is free and cut obliquely from without inward. Each free border is bounded by two lips or edges, the anterior one being furnished with long, slender hairs called *eyelashes*; the posterior one being in direct contact with the surface of the eyeball, and furnished with a row of small pores which are the orifices of small grape-formed glandules called the *Meibomian Glands*.* These glands are situated in the substance of the tarsal cartilages, about thirty or forty belonging to each superior eyelid, and twenty or thirty to each inferior one. They secrete a semitransparent, viscid fluid, which, becoming mixed with the unctuous and yellowish secretion of other glandules placed at the origin of the lashes, the *ciliary glands*, forms the sebaceous humor or gum of the eye which frequently glues the lids together. These little glands are frequently the seat of affections very difficult to eradicate.

The inner angle of each eye is called the *inner canthus*; the outer angle the *outer canthus*. So that with both eyes there are two inner, and two outer canthi.

The eyelids and the lashes with which they are furnished serve to cover and shade the eyeball during sleep, to protect it from contact with external objects, and to keep its surface moistened, by alternate movements of elevation and depression or shutting and opening, with the fluid furnished by the lachrymal apparatus.

The LACHRYMAL APPARATUS is composed of several parts, some intended to secrete the tears and convey them to the surface of the eye, and others, designed to take up this fluid and convey it into the nasal cavity. The first are, the lach-

* The superior lid has from one hundred and four to one hundred and fifty lashes, and the inferior from fifty to seventy-five.

If the sight has fallen upon the entrance of the optic nerve or the papilla, a brilliant white circle will be seen, from the center of which

rymal gland with its excretory ducts; and the second are, the lachrymal puncta and canals, the lachrymal sac, and the nasal duct.

The *lachrymal gland*, which has about the shape and size of an almond, is situated at the outer and superior part of the eyeball, between this organ and the orbit, being lodged in a depression at the outer angle of the orbit. Its excretory ducts are small, slender canals, about seven or eight in number, and open behind the upper eyelid through the upper and outer half of the conjunctiva, near its reflection on to the eyeball; they are designed to convey and discharge the tears, which are constantly forming in the lachrymal gland, upon the globe.—At the inner angle of the eye is a small reddish tubercle, of a pyramidal form called the *caruncula lachrymalis*; a few small hairs grow out of it. This small glandular body secretes a viscid mucous fluid which lubricates the lachrymal puncta, and thus facilitates the absorption of the lachrymal fluid.

The *lachrymal puncta* are the two minute round external openings of two small, narrow and curved tubes, the *lachrymal canals* or *ducts*, which are about a quarter of an inch in length, and are directed toward the inner angle of the eye where they terminate in the lachrymal sac. There are two lachrymal puncta to each eye, one upon the margin of the superior eyelid, the other upon that of the inferior, and toward the inner extremities of the lids; the canals (*canaliculi*) from these puncta converge, the superior one passing upward at first, and then bending at an acute angle and passing inward and downward to the lachrymal sac, and the inferior one at first passing downward, and then abruptly inward in almost a horizontal direction. Both of these canals unite or open at one and the same point in the lachrymal sac. The superior lachrymal canal is somewhat longer and smaller in diameter than the inferior; sometimes, these canals attain a diameter of $\frac{1}{50}$ of an inch. The puncta absorb the tears as soon as they are diffused over the surface of the eye.

The *lachrymal sac* is a small membranous pouch or bag, oval, about the size of a small horse-bean, and is situated in a deep groove formed on the inner side of the anterior orbital opening; it forms the upper extremity of the nasal duct.

The *nasal duct* is a cylindrical membranous canal formed in the bones of the face, passing from the lachrymal sac obliquely downward, backward, and somewhat outward to the inferior nasal meatus, and is designed to establish a direct communication between the lachrymal sac and the nasal fossæ. The length of the nasal duct is ordinarily from four to six lines, its width transversally from one and a half to two lines, and antero-posteriorly about $2\frac{2}{3}$ lines. Its middle part is narrower by about $\frac{1}{25}$ of an inch than at either extremity. The inferior or nasal orifice of this duct opens into the inferior meatus of the nose at a distance of three or four lines from the floor of the nasal fossæ; it is infundibuliform or oval, a disposition which renders the passage of a catheter very difficult.

These anatomical and physiological details may be summed up as follows: The tears are formed in the lachrymal glands and are conveyed to the eyes by the excretory ducts,—they are then diffused over the surface of the eyes by the eyelids; from thence, absorbed by the lachrymal puncta, they are carried by the lachrymal canals into the lachrymal sac and into the nasal canal. From this last, they finally pass into the nasal fossæ. Under the influence of lively emotions, or of severe sufferings, the tears are secreted in abundance; the narrow passages through which they have to pass not being capable of carrying them

two large vessels, an artery and a vein emerge and pass upward, branching upon the retina, and a similar set passing downward in

off, become filled to overflowing and the tears run out over the surface of the cheeks. At the same time, there is an increased quantity of tears conveyed to the nasal fossæ. The use of tears is to facilitate the movements of the eyeballs in their orbits.

The MOTOR APPARATUS consists of six muscles which move the eyeball, four of which are the recti or straight muscles, and the other two the oblique. The straight muscle inserted into the sclerotic coat of the upper part of the eye at about three or four lines from the margin of the cornea, is called the *Rectus Superior (attolens)*; it is the thinnest and narrowest of the recti muscles, and raises the globe of the eye upward. That inserted into the sclerotic coat of the under part of the eye at about two or three lines from the margin of the cornea, is called the *Rectus Inferior (depressor)*, and pulls the eyeball downward.

That which is inserted at the external lateral portion of the eyeball, about two or three lines from the margin of the cornea, is named the *Rectus Externus (abductor)*; it is the longest of the recti muscles, and moves the eyeball outward. That which is inserted at the internal lateral portion of the eyeball, about two or three lines from the margin of the cornea, is called the *Rectus Internus (adductor)*; it is the thickest and shortest of the recti muscles, (a peculiarity which will explain the frequency of convergent strabismus), and moves the eye inwardly toward the nose.

All these muscles, as stated above, are inserted into the sclerotic coat of the eyeball, at a distance from the margin of the cornea of about three or four lines, and the breadth of their tendons at their points of insertion, are about four lines for the internal and external recti, and about three and a half lines for the superior and inferior recti; when acting separately, these muscles direct the eyeball, as already observed, upward, downward, outward, and inward, as expressed by their names; but when any two of them act conjointly, the eye is carried in the diagonal of their directions, as, upward and inward, upward and outward, downward and inward, or, downward and outward.

The oblique muscles are the rotatory muscles of the eyeball. They are, 1. The *Great or Superior Oblique (trochlearis)*, a small round fusiform muscle, situated at the inner and upper part of the orbit; after passing through a cartilaginous pulley in which it readily slides, its tendon become wider, proceeds backward and outward beneath the superior rectus, and is inserted into the sclerotic coat at the outer and posterior part of the eyeball, between the Superior and External Recti muscles, about midway between the margin of the cornea and the entrance of the optic nerve. Its action is to rotate the eye so as to carry the pupil downward and outward.

2. The *Small or Inferior Oblique*, is a flat, thin, narrow muscle situated upon the inferior wall of the orbit, it passes outward and backward beneath the Inferior Rectus, and is inserted into the sclerotic coat of the outer and posterior part of the eyeball below the body of the External Rectus, at about two lines from the entrance of the optic nerve. Its action is to rotate the eye so as to carry the pupil upward and inward. When these two oblique muscles act together they retain the eyeball in front, and which, without their aid, would be drawn backward by the simultaneous contraction of the four recti muscles.

The muscles of the eye are animated by three nerves. The superior, inferior, and internal recti, as well as the inferior oblique, are under the influence of the

like manner. This brilliant white disc, has been compared to that of the full moon on a clear night; if examined in the inverted

common motor oculi or third nerve. The external rectus receives a nervous supply from the external motor oculi or sixth nerve; and the superior oblique receives a special nerve, the pathetic or fourth nerve.

The *EYEBALLS*, or *Visual Organs proper*, are situated in the cavities of the orbits; they are held there by the muscles heretofore referred to, by the optic nerve, by an aponeurotic membrane called *orbito-ocular aponeurosis*, which sheathes the eye and its motor cords, by a mucous membrane, and by blood-vessels, upon which the phenomena of nutrition depend. These globes lie upon a fatty cushion, which gives a soft and elastic resting place to them. Their form is that of a spheroid, surmounted in front with a rounded prominence formed by the transparent cornea, and which gives to the antero-posterior diameter of the eye, called the *axis of the eye*, a predominance of $\frac{1}{2}\frac{1}{5}$ to $\frac{1}{1}\frac{1}{3}$ of an inch over the transverse and vertical diameters; these last two measure about $\frac{1}{2}\frac{0}{0}$ of an inch.

The human eye is about the same size in all persons; the apparent difference being due to the size of the opening between the lids, and the depth at which the eyeball is seated in the cavity of the orbit. When normally situated, the two eyes have their axes parallel.—The essential constituents of each eyeball, are, membranous *coats* of different structure, with divers functions, and transparent humors, each having a special part in the phenomena of vision.

The eyeball is enveloped externally by a dense, compact, hard, and resisting coat, called the *Sclerotica*, or *opaque cornea*, which covers the posterior five-sixths of the eyeball, and presents on the anterior portion a circular aperture, which is occupied by a transparent membrane, called the *cornea* or *transparent cornea*. Upon removing the sclerotica we come to the second coat, termed the *Choroid*, a thin soft, and delicate membrane, remarkable for its dark color; this coat lines the internal surface of the sclerotica, and is prolonged in front behind the transparent cornea, under the form of a movable curtain, called the *Iris*, which is perforated by a circular aperture, susceptible of being enlarged or diminished in its diameter, and termed the *Pupil*.

By carefully removing the choroid membrane, the third coat of the eyeball is exposed, called the *Retina*; it is in contact with the internal surface of the choroid in the whole of the posterior part of the eyeball.—Besides these three superposed membranes, forming as it were the shell of the eyeball, this globe also contains three different humors, viz., in front, the *Aqueous humor*, behind that the *Crystalline lens*, and posterior to this the *Vitreous body*. We will now enter into a further examination of these several parts of the eye.

The *SCLEROTICA* is formed of strong, resisting fibres, running in an antero-posterior direction, and intermixed with other circular fibres of less resistance. It varies in thickness, being thin in front and gradually increasing in thickness as it advances posteriorly, where it acquires its maximum of resistance, being about $\frac{1}{2}\frac{1}{5}$ of an inch in thickness. Ordinarily of a white color, it presents a bluish tint among children, which is due to its thinness at this age, so that the dark color of the subjacent choroid coat may be imperfectly seen through it. The same phenomenon is sometimes observed in the adult, but it is then indicative of a serious affection of the eye. On the anterior portion of its outer or external surface, the sclerotica is covered by a thin membrane, called the *Conjunctiva*, or mucous membrane of the eye, and which is a reflection of the palpebral conjunctiva over the fore part of the sclerotica and cornea; it is loosely attached to

image, its average apparent diameter is about three lines, being frequently, somewhat oval in its vertical diameter. Three concentric

the sclerotica, is transparent, and but slightly vascular in health; by means of a lens it may readily be seen on the normal eye. When the eye is diseased, so that the small blood-vessels of its conjunctiva become engorged, they may then be seen with the naked eye, and the eye is then said to be red. Diseases of the conjunctiva of a vascular character are quite frequent, and sometimes reveal even a deeper seated affection of the visual organ.

The CORNEA or *transparent cornea*, which has been called the window of the organ of vision, is a very dense, exceedingly transparent membrane, deprived of blood-vessels, but furnished with numerous nerves which endow it with a very remarkable vitality, as manifested in the modifications of which it is susceptible under the influence of age, and by the facility with which its wounds heal. It is flatter, and its tissue is harder and more compact in old age than at any previous period of life. Its thickness is estimated at about $\frac{3}{16}$ of an inch at its center, and about $\frac{1}{5}$ of an inch at its circumference; and it forms the anterior sixth of the eyeball. Its longest or transverse diameter is about six lines. It forms the section of a spheroid having a diameter of seven lines and a half. The cornea is apparently a continuation of the sclerotica, but, in reality, it is a distinct organ which may be separated from the sclerotica, into the margin of which it is, as it were, enclashed like a watch-glass in its case, its peripheral margin being overlapped, at the point of union, by the sclerotica more upon its outer or anterior surface, than upon its inner or posterior. The cornea is covered over its outer surface with the conjunctiva, but which is more firmly adherent than it is to the sclerotica, and which is so modified in its texture as to be reduced to an epithelial layer, not interfering with the important functions of the cornea which it defends and protects, and over the surface of which it facilitates the gliding of the eyelids.—The structure of this membrane is still a subject of controversy. Generally, however, it is considered as consisting of five very fine concentric layers, arranged somewhat like the peel of an onion, separated from each other by a diaphanous lymph, and kept apart by a very delicate areolar tissue.

The thin vitreous membrane forming the posterior layer of the cornea, is called the *membrane of Descemet*; it is shining, transparent, and perfectly homogeneous, has a certain stiffness and considerable fragility, and, when the cornea is removed from the eye, it has a great tendency to roll up upon itself; its transparency is not affected by any reagents; it is easily detached from the cornea by submitting this to the action of alkalis, or to prolonged boiling. In old persons, a kind of warty excrescences are often seen upon it.

The CHOROID makes a true camera obscura of the eye, in which those rays of light which do not co-operate with vision are absorbed. It is formed of three layers of different structures; the first or external, being a fine cellular tissue which connects it with the inner surface of the sclerotica; the second or middle, being essentially composed of arterial and venous vessels; the third or internal, is pigmentary, that is, it is covered with a blackish matter contained in a layer of small hexagonal cells, which, however, may be removed from the membrane by maceration in water. This black matter is called *pigmentum nigrum* or *pigmentum fuscum*. This pigment is identical with the coloring matter of the skin, is one of the most perfect absorbents of light, and its use is to prevent the rays of light entering, except through the crystalline lens, as well as to absorb the light after it has impinged on the retina. It is easily washed off from the membrane which

circles will be distinguished at this point, the external one, clear white, the middle one brownish, and the central one brilliant white.

secretes it. The vascular layer of the choroid contains numerous vessels; the veins especially are very numerous, and are arranged in curves or whorls, hence their name *whorling vessels* (*venæ vorticipsæ*). They are very close to the sclerotica. The third or pigmentary layer is connected with the retina. The pigment is abundant among brunettes and Africans; it is thinner and less dark among old persons, and disappears under the influence of certain pathological conditions. Albinos are deprived of it.

With the description of the choroid should be associated that of the iris, of the ciliary circle, and of the ciliary body.

The Iris is a distinct, thin, flat, circular-shaped, and contractile membranous diaphragm, extending across a portion of the cavity of the eye, and designed to regulate the quantity of luminous rays necessary to the normal exercise of vision. It is that part of the eye by which we determine its color. The color being due in part to the vessels, and in part to the amount of pigment present. Its anterior surface, which seems formed of radiating fibres, is tomentose and velvety, and presents in different persons, different colors, and various degrees of brilliancy. Its posterior surface, called *uvea*, from its color being similar to that of a ripe grape, is apparently continuous with the choroid which furnishes it with a large amount of dark pigment. Its external margin or large circumference is set in a groove or plait formed by the ciliary circle. Externally, it corresponds to about the $\frac{1}{25}$ of an inch from the point where the insertion of the cornea and sclerotica appears to terminate. Its inner margin or small circumference forms the pupillary opening, or *Pupil*.

The iris is a membrane consisting of contractile muscular fibres and blood-vessels. Some of these fibres are circular, forming a kind sphincter, by which the pupil is contracted; others are radiating, and effect dilatation of the pupil. These phenomena of motility are under the influence of the nerve of the third pair; while the sympathetic nerve and the fifth pair control the phenomena of nutrition.

The canal of *Schlemm* (circular sinus) is situated at, and a little behind the point of union of the sclerotica and cornea; it is a minute triangular canal, probably vascular or venous, and is sometimes incompletely closed. In sections made perpendicularly it presents an oval, very narrow slit, without any trace of epithelium.

The CILIARY MUSCLE, or LIGAMENT, or *C. Circle*, (*tensor muscle of the choroid*), which has been for a long time considered as a prolongation of the cellular web of the choroid, is a true muscle in the form of a whitish or grayish ring; it is of a pulpy consistence, and is placed around the circumference of the iris, between the choroid, the cornea, and the sclerotica, which parts it serves to connect. It is the part where an infinity of small nervous filaments, called *ciliary nerves* are congregated previously to their distribution, and which are under the influence of the ophthalmic branch of the fifth pair, and of the common ocular motor nerve, from which the iris derives its sensibility and its mobility. This muscle is designed to play an important part in the act of adaptation of the eye to different distances.—This muscle consists of radiating and circular fibres, and its smooth fibres have their origin at the internal wall of the canal of Schlemm. A perpendicular cut of this muscle gives a triangular section of it, the base of which is formed by the ciliary body, and of the two sides one is directed toward the iris,

The retinal vessels appear under the form of bright scarlet or reddish striæ; the veins being of a darker color, (brownish or blue),

and the other toward the sclerotica, while the apex responds to the canal of Schlemm.

The CILIARY BODY, also called the *Zone of Zinn*, is a blackish ring which surrounds the crystalline lens, in the manner of a crown; it is placed behind the iris and the ciliary circle. It bears a resemblance to the disk of a radiated flower, and is formed by the union of the *ciliary processes*, which are longitudinal, triangular, projecting folds of the choroid, placed side by side, being about sixty or eighty in number, arranged in a radiated manner, lodged in the depressions of the anterior face of the vitreous humor, and reaching to the circumference of the lens. These plaited folds are called the ciliary processes; and the whole of this structure, or the membrane thus plaited is called the ciliary body. It is about two lines broad, has a black pigment on the whole of its inner or posterior surface, and is very vascular; its uses are not known.

The third coat of the eye, the RETINA, is a very thin, transparent, soft, pulpy, pinkish-gray membrane, embracing the vitreous humor, and situated between it and the choroid to which it adheres by simple contact, without vascular or other continuity. It is considered as being an expansion of the optic nerve, commencing from its point of penetration through the sclerotica, a little above and within the visual axis. At this point the nerve appears constricted, and forms on the internal face of the retina a slight circular flattened prominence, called the *papilla of the optic nerve* or the *optic disc*. In the normal state, with the ophthalmoscope, this papilla may be seen in the form of a circle $\frac{2}{3}$ of an inch in diameter, glistening white, from the center of which passes several vessels which are directed above and below. These vessels are not seen on the yellow spot; they do not give off any branches at the surface of the papilla,—they divide only beyond this, and their ramifications, in the normal state, are not numerous.

The retina extends from its origin, at the optic nerve, to the commencement of the ciliary processes where it terminates by a finely-jagged or dentated margin, called the *ora serrata*. At this point, its nervous elements disappear, its vascular layer alone being prolonged to the periphery of the crystalline lens.

The *yellow spot*, (*macula lutea*), above referred to, is situated at a point corresponding to the antero-posterior axis of the eye, and $\frac{1}{3}$ of an inch on the external or temporal side of the entrance of the optic nerve. This spot is of a yellowish or saffron-color, which is brightest at the center, is circular or oval, about a line, or rather more, in diameter, and in its center is apparently a round hole equal in diameter to one-fourth of the spot. Generally, there are several small plaits or folds of the retina about this place; and one of these, which is very constant, extends from the optic nerve to this spot, which is seated near its termination. It is not a hole, but merely a depression, *fovea centralis*; also called the *foramen centrale* of Sæmmering, from the retina being thinner at this place. This spot is pale in children and old persons, but is bright during the middle period of life; the color diminishes when there is any obstruction to vision, and disappears altogether when the sight is lost.

The retina, a membrane so sensitive to the action of light, is not so to the impression of instruments, as has been well ascertained in operations in which it has been pricked without causing the least pain or sensation. It is composed of five different elementary layers, which, studying them from without inward, are as follows: 1. The most external or columnar layer, called *Jacob's membrane*,

somewhat larger in diameter than the arteries, and not so sharply defined.

or *stratum bacillosum*; it consists of small, cylindrical, transparent, flexible, highly refractive, wand-like bodies, disposed perpendicularly to the surface of the retina, lying very close to each other, and having a length equal to the thickness of the membrane, from $\frac{1}{500}$ to $\frac{1}{350}$ of an inch. There are two kinds of these bodies, the small staff-like cylinders, having a thickness of from $\frac{1}{1270}$ to $\frac{1}{800}$ of an inch, bending at an acute, obtuse, or right-angle, or, in hook-form, or, forming a protuberance at their choroidal extremities; and the cones, which have the form of small round cells, fusiform or flask-shaped, the spaces between them being occupied by the cylindrical staffs.

2. The second layer is the *middle* or *granular*, (*stratum granulosum*); it is composed of small granular corpuscles, extended throughout an amorphous substance, analagous to the gray cerebral matter. This has been divided into two layers, the external granular layer, and the internal.—3. The third layer is the *cellular*, (*stratum gangliosum*), consisting of nervous cellules or ganglionic corpuscles.—4. The *nervous* layer, (*stratum fibrillosum*), which is very thick and vascular, and consists of the primitive fibrils of the optic nerve spread out in a radiating direction from the entrance of the optic nerve to the sinuous anterior border of the retina. It is wanting, or nearly so, around the yellow spot, and in the fovea centralis.—5. The *amorphous* layer, (*stratum limitans*), which is the only one that passes in front of the retina, and which extends beyond the external or posterior circumference of the ciliary processes to reach the capsule of the crystalline lens, where it terminates circularly. It is the only layer through which the principal vessels of the retina are dispersed, and it, together with the preceding layer, are the only vascular layers of the retina; its anterior surface is applied against the vitreous humor.

The AQUEOUS HUMOR is a colorless, perfectly transparent fluid, placed between the cornea and the iris, (a space called the *Anterior Chamber of the Eye*), as well as between the iris and the crystalline lens, (a space called the *Posterior Chamber*); the iris forming a partition between these two chambers which, however, communicate with each other through the pupil. The posterior chamber is much smaller than the anterior. The depth of the whole aqueous humor from the posterior face of the cornea to the anterior face of the lens, is somewhat more than $\frac{1}{10}$ of an inch; the humor is small in quantity, not more than five or six grains in weight, and is composed of water, albumen, and chloride of sodium, which is quickly renewed after it has escaped from wounds, etc. It is supposed to be secreted by the iris, the posterior surface of the cornea, and the ciliary processes.

The CRYSTALLINE LENS, although termed a humor, is a solid transparent body of a soft, gelatinous substance, which surrounds a more solid and dense nucleus, and is set in a transparent membranous capsule, called the *capsule of the lens*. This capsule adheres to the sclerotica and to the choroid by a kind of ring called the ciliary body. The lens is small, biconvex, about $\frac{7}{80}$ of an inch in diameter, and half as much in thickness at its axes, and consists of concentric layers; its posterior surface is of greater convexity than its anterior. Its use is to concentrate the rays of light, so as to form a distinct image upon the retina. In old age it becomes slightly flattened on both surfaces, slightly opaque, more dense, and yellowish.

The VITREOUS HUMOR OR BODY, is a soft, perfectly transparent, jelly-like mass,

The slightly dark ring surrounding the optic disc is due to an accumulation of choroidal pigment around the optic nerve, and the white ring inside of this is the sclerotica, which reaches a little further than the choroid toward the entrance of the optic nerve.

At the distance of about one-fifth of an inch from the external side of the papilla will be observed an obscurely, nearly circular spot, having a brilliant point at its center; this is the yellow spot, and corresponds to the posterior pole of the eye; and the point is the fovea centralis, formed by a depression of the retina, due to the absence of the nervous layer at this place,—no blood-vessels, retinal nor choroidal, are to be seen in or immediately around the yellow spot.

The vascular layer of the choroid gives a uniform red, or yellowish red field, over which the retinal vessels may be seen branching, being perceptible through the transparent retina. The color will vary according to the complexion of the individual, being brighter or more yellowish, in those who are fair, and darker, or more of a yellowish brown, in those who are dark. Blackish lines and streaks may also be seen at various parts, which are occasioned by the pigment of the choroid when this abounds in the eye of the person under examination.—Close to the inner side or entrance of the optic nerve, the color will be seen darker at one point, and which is supposed to be owing to the shadow of the semilunar fold of the retina.

EXAMINATION OF THE EYES.*

In the treatment of Diseases of the Eye, the same as in that of all other diseases, the first and most important point is to correctly determine the disease, and unless this be done, all treatment will

which occupies the posterior part of the eyeball, from the posterior surface of the iris and crystalline lens to the retina, occupying the whole cavity formed by the retina. Its weight is from seventy-five to eighty-five grains, and it contains water, a little albumen, and some salts. It is secreted and enveloped by a delicate, transparent membrane called the *hyaloid*, which sends from its internal face numerous prolongations dividing the cavity of the vitreous humor into several apartments, like the sectors of an orange, the object of which appears to be to divide the mass of fluid so that concussions caused by walking, racing, jumping, etc., shall not occasion too strong undulations.

*In the selection and preparation of matter furnishing the preliminary remarks, history, description, symptoms, etc., of diseases of the eye, I am under great indebtedness to Donders, Græfe, Mackenzie, Martin, Wecker, Lawrence, etc.

be unavailable. It may therefore be proper to make a few remarks relative to the method to be pursued when examining the eye. In the first place, before touching the parts at all, the physician should carefully observe all the parts which present themselves to his view, the patient being seated near a window, so that the light from that window only may fall obliquely upon his eyes. The eyebrows should be glanced at, then the eyelids, noting their movements, whether slow or quick, equal or unequal, whether they open fully or remain half-closed, the condition of their margins, eyelashes, and their angles; then the globe of the eye, its size, flatness, projection, and movements, the correspondence of its axis with that of its fellow opposite, the general appearance of the white of the eye, as well as of the cornea, the condition of the pupil, and the color of the iris. The expression of countenance and movements of the patient should likewise be noted; whether from an intolerance of light he shades his eyes with his hands or holds his head down, etc. All these points having been noted, the physician may then proceed to a still closer examination. The principal points to be observed in these investigations of the several parts of the eye, may be briefly stated as follows:

1. *Eyebrows.* Recent injuries of the eyebrows, from blows or wounds, may result in amaurosis from concussion of the brain or retina, or injury to the ophthalmic nerve, or first division of the fifth pair. These should be enquired into, as well as the cause of any cicatrices present. Any tumors, eruptions, abscesses, etc., in the region of the eyebrows, should receive a proper investigation; as well as a falling of the hairs, or pediculi among them.

2. *Eyelids.* It should be observed whether they move freely, or whether there is any defective motion from thickening of their tissues, paralysis of their muscles, or partial closure of the lids from photobia. Wounds, tumors, cicatrices, warts, ecchymosis, cutaneous diseases of the lids, etc., require careful attention. Adhesions of the lids, or unnatural positions, as retraction, inversion, etc., may in most cases be readily observed. The tarsal borders may be inflamed, ulcerated, thickened, or may present more or less crusts, from dried matter discharged from ulcers, from diseased Meibomian glands, or from both; there may also be small tumors, or thickening of the borders of the eyelids, etc.

3. *Eyelashes.* These should always receive a close inspection; they may assume a wrong direction, their ends being turned inward so as to keep up constant irritation of the eyeball. A similar irritation may be produced by minute pale hairs, called "false," or vulgarly, "wild hairs," which are very difficult to recognize, unless

aided by a magnifying glass ; they will often be seen growing upon the caruncula lachrymalis, situated at the inner canthus of the eye. Pediculi among the lashes upon the edge of the lids, will, in many cases, increase or keep up an inflammation of the lid or eye. When disease of the lid has destroyed the hair-bulbs, a partial or complete absence of the eyelashes will be the result.

4. *Conjunctival surface of the Eyelids.* In order to examine the inner surface of the lids, it will become necessary to evert them, so that these surfaces may be thoroughly exposed; and, we may then observe the existence of any inflammation, granulations, tumors, or foreign particles. By placing a finger or two upon the external surface of the lower lid, and drawing it downward, while at the same time the patient is requested to look upward, the whole of its inner surface will be brought into view.

For the *upper lid* a different manœuver is required. With the finger and thumb of one hand, grasp the eyelashes growing from the middle of the lid, as well as a minute portion of the tarsal border of the lid, and draw the lid gently downward and away from contact with the eyeball; then, with the other hand, place a probe across the outer surface of the upper lid, about half an inch above its free margin,—request the patient to look downward, and at the same moment raise the edge of the lid upward, and slightly press the probe downward. The lid will suddenly become everted.

The looking downward on the part of the patient, the elevation of the edge of the lid, and the depression of its central part, by the physician, must all be done at the same instant, in order to readily accomplish the eversion. As the whole of the conjunctival surface of the lid is not exposed by this eversion, should a deeper examination of it be desirable, it may be done by the careful employment of a probe. If, however, the lining of the eyelids is known to be in a healthy state, there will be no necessity for everting them.

Small foreign bodies, which have passed beneath the upper lid, will generally be found near its tarsal border; they may be readily removed by a probe, or quill cut tooth-pick fashion.

5. *Angles or Canthi of the Eye.* Abrasions, ulcerations, tumors, etc., are met with at these parts. These may be detected at the outer canthus, by gently separating the lids from each other at this angle. To discover them at the inner canthus, a similar operation is required together with a slight eversion of the lids. And while making this exploration, the physician may also observe the condition of the *lachrymal sac*, *lachrymal papillæ*, *lachrymal puncta*, as well as of the *lachrymal discharge*.

6. *Eyeballs.* These may be unnaturally prominent, from tumors in the orbit, or, infiltration of the orbital cellular tissue; one or both may be misdirected, as in squinting; it may be impossible to turn the ball in every direction, from paralysis of one or more of the oblique or recti muscles, or, there may be irregular movements of the ball. Gentle pressure must also be made upon the eyeballs to determine whether they are of natural consistency, too hard, or too soft.—We will then examine the condition of the parts at the anterior surface of the globe, as, the ocular conjunctiva, the sclerótica, the cornea, iris, pupil, chambers, and the aqueous humor; being careful not to irritate the eyes, by holding the lids apart for more than a few seconds at a time, during the examination.

Natural or artificial light, concentrated by means of a convex lens of three or four inches focus, and directed obliquely into the anterior segment of the eyeball, the patient being in a dark room, will be sufficient to detect abnormal conditions of the cornea, aqueous humor, iris, pupil, and crystalline lens, particularly the anterior surface of this latter body. By moving the lens gradually about, the focus of light may be successfully thrown upon the deeper-seated parts, and their conditions be carefully noted. In this way, the least imperfections of the eye, the most superficial erosions, the slightest disturbance of the aqueous humor, the least morbid alterations of the iris, its changes of color, may readily be observed.

The same method of examination will answer very well to ascertain the condition of the crystalline lens; though it will be better to previously dilate the pupil by dropping into the eye a drop or two of a solution of neutral sulphate of atropine one grain, distilled water three thousand grains. Or, daturine may be substituted for the atropine, in which case the effects will not continue for so long a time. In employing these agents, the patient should always be forewarned of the transient visual disturbance which they will produce. The crystalline lens thus being more fully exposed to view, the finest striæ upon its surface, the least derangement, and the slightest traces of opacity will present themselves with a perfect clearness.

But, in order to examine the condition of the lens, particularly its posterior portion, the vitreous humor, the retina, and the choroid, it will be necessary to employ an ophthalmoscope, because the magnifying lens used, as above recommended, will no longer be of utility.

The *ophthalmoscope*, now so well known to physicians, is the discovery of Helmholtz, a German oculist; since this ingenious instrument was made known by him, there have been various modifications and improvements made upon it, which it is unnecessary to name here. The instrument more generally preferred is that combining the concave reflecting mirror and the biconvex lens; in some cases, where less light is required, a plane reflecting mirror may be substituted for the concave.—The concave reflector, having a focus of ten inches, is perforated with a small hole in its center, and attached to a handle. The biconvex lens has a focus of about two and a half inches, and, although not usually fixed in a handle, it can be more readily and safely managed when it is so fixed. Some instruments have a ring behind the reflector, into which concave glasses may be placed, for the purpose of procuring a magnified upright image of the retina, as, the reflector used with the biconvex lens gives a distinct, but small and reversed image of the retina. If the reflector be employed without any lens, the retina is not seen so distinctly. The numbers more commonly used of these biconcave lenses, are ten and twelve.

To use the ophthalmoscope, the patient, having the pupil of the eye fully dilated by atropine or daturine, if it be not already dilated by disease, is seated sideways near a table, his left side being next the table; the room in which the examination is carried on being darkened. A lamp is placed upon the table near the patient's head, the flame being on a level with his eye, and near the ear; the light making an angle of about twenty degrees with the eye of the examiner; a piece of pasteboard being placed to one side of the lamp, so as to prevent its rays from falling upon the cornea or orbital region of the patient. Everything being thus prepared, the physician will seat himself in front of and facing his patient, and a little higher, so that his eyes will be slightly above those to be examined. Then, with one hand he will carry the reflector to his own eye, so that he can perceive the patient's eye through the central opening; the reflecting surface of the instrument being toward the patient's eye,—the patient looking toward the right ear of the physician, when the right eye is to be examined, and toward the left ear when the left eye is to be explored. The margin of the reflecting mirror should be rested against the eyebrow or superciliary arch all the time of the examination, while the handle may be gently moved in all directions, until the reflected light from the mirror has been thrown on the pupil of the patient.

At first, the examiner will bring the rays of light, passing from the lamp to the reflector, and again reflected from this latter, to a

focus upon the cheek, and as soon as a distinct inverted image of the flame is observed there, he may carefully move the reflector, so that this focus of light will be thrown upon the retina. He will then observe a diffused reddish, orange-red, or yellowish glare, or a disc or patch of white tinged with red—the former being the choroid seen through the transparent tissue of the retina, and the latter, the optic nerve or papilla. In order to obtain a more distinct appearance of the parts now brought into view, the physician, holding the reflector steady in one hand, will request the patient to direct his eye slightly upward and inward, or to one ear, as above stated. Then, with the biconvex lens in the other hand, held between the thumb and index-finger, (if not fixed in a handle), the physician, still looking through the central opening in the reflector, will place this lens in front of the patient's eye, moving it forward or backward, or from side to side, until a clear and distinct view of the bottom of the eye is obtained. I find the flame of a coal-oil lamp with a neutral blue chimney to modify the red and yellow rays, and give a more natural appearance to the parts under examination. Of course, if the crystalline lens be opaque, we can not expect to see the parts posterior to it; and, in some cases, as in adhesions between the capsule of the lens and the iris, only a small portion of the retina can be examined at a time, from the want of dilatability of the pupil. The ophthalmoscopic appearance of the normal retina has already been described on page 1333; the abnormal appearances will be described under their appropriate heads.

The distance at which the fundus of the eye is seen distinctly, depends on the state of refraction and accommodation of both physician and patient; hence, it will be better to hold the convex lens near the eye of the patient, at first, and, as soon as the illuminated retina is seen through the lens, this may be gradually moved away from the patient's eye toward the examiner's. This movement of the lens must be very slow, as soon as a white disk begins to appear on the dark-red or orange-colored fundus.

When the eye is examined without the convex lens, or with the concave lens, it is said to be "*observed in the direct, virtual, or erect image*;" when with the convex lens, it is "*observed in the indirect, actual, or inverted image*." The direct image is formed on the retina, and may be observed by a Zehender's ophthalmoscope; the indirect image is found between the concave reflector and the biconvex lens, and may be seen with a Liebreich's small ophthalmoscope. (I will not name here the various kinds of ophthalmoscopes that have been presented to the profession, but will refer the reader to "Carter's

translation of Zander on the Ophthalmoscope," which gives every necessary information concerning the instrument and its uses.)

Some patience as well as perseverance is required in order to examine the eye successfully and satisfactorily with the ophthalmoscope.—It must always be borne in mind by the oculist, that the mere concentration of powerful light upon the retina, if continued, for more than a few seconds, does, of itself, place the part in an unnatural condition; while, again, there may be eyes so irritable and so intolerant of light, as not to allow of the use of the ophthalmoscope even for a moment. An intense glare of concentrated light thrown upon the retina for more than a few seconds, will be apt to produce irreparable mischief.

For the examination of the *vitreous humor*, we must lessen the brightness of the light, and remove it a little from the patient; the plane reflector is here much better than the convex. We may judge of the perfect transparency of this humor by the more or less brilliant reflection of the pupillary background; and, if we desire to assure ourself that there are no exudations, floating corpuseles, shreds, opaque spots, sparkling scales of cholesterin, or sanguinary clots, we will, after having had the patient to move his eyes rapidly in every direction, request him to suddenly hold them immovable. If any of these bodies are in the vitreous humor, they may be seen moving and slowly falling in the most dependent part of the ocular globe.

In some cases, these explorative methods can not be readily applied, the sensibility of the eye being such that the least light causes painful sensations, or else the central parts are opaque, and illumination of the internal posterior hemisphere of the ball is impossible. In the first instance, we must abstain from a thorough examination until all traces of photobia have disappeared; in the second, we may have recourse to the phosphenic examination, which gives positive information concerning the aptitude of the retina to perceive light.

In the use of the ophthalmoscope, the employment of atropia, daturia, or hyoseyamia, even when in very weak solution, will frequently give rise to considerable congestion of the vessels of the retina, which may be mistaken for a diseased state. And again, the dilatation of the pupil caused by the use of these agents, may continue for several days, much to the annoyance of the patient; and should the sight diminish after its application, this would be attributed wholly to the physician as a result of the examination. On this account, these mydriatic agents should be used as seldom as possible; beside which, if the patient be allowed to remain a

few minutes in the darkened room before commencing the examination; it will be found that the pupils will acquire, in a majority of cases, a sufficient degree of dilatation for examination with a moderate light. The less intense the light used in the examination, the less fatigue will it occasion the patient, and the more satisfactory will be the results of the observation. The plane reflector is suited best for all cases where a feeble light only can be used, or in examinations of the anterior hemisphere of the ball.

In all cases, the proper focus, both of the reflector and of the biconvex lens, will be obtained by gradually moving one or both of them backward and forward. In presbyopic and myopic eyes, great care is required in bringing the retina into focus.

Phosphenic Examination. The retina possesses a peculiar sensibility, in consequence of which the least excitation determines upon it a luminous sensation. Pressure upon the globe of the eye, with the finger, produces a sensation of light. This luminous appearance, in the form of rings, can be readily observed by any one, and has been called *phosphene* by M. Serre, of Uzès. Four principal phosphenes have been recognized, as follows:

1. *Frontal phosphene*, occasioned by pressure upon the eyeball below the eyebrows on the tract of the superior rectus muscle, and which gives rise to a luminous sensation, apparently toward the cheek.

2. *Jugal phosphene*, produced by pressure along the tract of the inferior rectus muscle, and which gives rise to a luminousness toward the orbital arch.

3. *Temporal phosphene*, determined by pressure along the tract of the external rectus, the luminousness of which appears toward the root of the nose.

4. *Nasal phosphene*, determined by pressure along the internal rectus, the luminousness appearing toward the external angle of the orbit, in the temporal region.

These four phosphenes being determined, we may by intermediate pressure give rise to intermediate phosphenes, as, fronto-nasal, fronto-temporal, etc.

The form of these phosphenes is round, when the compressing body is of small diameter; when this is larger, as for instance, the pulp of the finger, it resembles a crescent. The frontal phosphene is the most brilliant, then the temporal, then the nasal, while the jugal has the least luminous intensity.—When a phosphenic examination is considered necessary, the patient must be placed in a dark

room, or with his back to the light, and close his eyes gently, as in sleep; the pressure should then be made as deeply toward the back of the orbit as can be done without inconvenience, the eye at the same time being directed in the contrary direction. The pressure should be slight, and may be made with the end of the forefinger, or any blunt rounded instrument; the various phosphenic regions, and their intermediate spaces should be thus examined. If all the phosphenes appear we may conclude that the excited points of the retina have preserved their sensibility. If one of them does not appear, we may be certain that the corresponding point is the seat of a lesion. The phosphenes may, however, be produced, and yet vision be considerably disturbed; in this case, we may conclude that the central portion of the retina is diseased, or else that the middle parts of the eye are opaque, or, that the case is a disease of accommodation. The means to form a differential diagnosis of these several pathological conditions, will be explained hereafter.

To complete the study of the means for determining the sensibility of the eye, I will refer to an *examination of the extent of the visual field*. The visual field is that space within which it is possible to see, without any change being made in the direction of the optical axis. In the normal state it is limited above by the orbital margin, and inwardly by the nose; below and outwardly its limits are much less restricted.

The extent of the field of vision is variable among persons; we measure it in the following manner;—a leaf of paper having a very visible black point at its center, is placed against a wall at the height of the eye to be tested. The patient, having one eye bandaged, and sitting or standing so that the other eye shall be at a distance of twelve or eighteen inches from the paper, is requested to steadily fix this eye upon the black spot. This done, the physician will move along the paper or wall, and at various distances from the central black spot, a sufficiently voluminous, bright, but not brilliant object, and will successively mark the points at which the patient ceases to distinguish it. In this manner, the whole extent of the visual field is gone over, and its limits noted. In order to corroborate the first results, it will be well to repeat the trial several times, changing the direction of the optical axis and the distance of the objects each time.

As the limits of the visual field vary considerably with persons, we must consider material changes only, as indicative of a pathological condition. Very decided alterations in the distinctness and

extent of vision, ascertained by this method, will furnish valuable information in regard to the condition of the sensibility of the retina at the various points of its surface.

These means of investigation will be rendered still more complete by the knowledge which the touch will impart, in regard to the condition of the eyeball; the consistency and general sensibility of the eye may be detected by light pressure with the pulp of the fingers. And lastly, we must also take into account the constitution of the patient, its morbid tendencies, and his sensations, as, pain, itching, formication, smarting, intolerance of light, and feeble or defective vision, etc.

EXAMINATION OF THE EYE IN CHILDREN.

In very young children it is generally quite difficult to obtain a satisfactory view of the cornea and conjunctiva, from the resistance offered, and which results from a dread of the oculist, as well as from the pain produced by the action of light, etc. In such cases, it is useless to attempt either coaxing or intimidating measures; there is but one course to pursue in order to thoroughly and satisfactorily ascertain the condition of these parts.

The physician sitting in a chair, with a folded towel spread across his knees, has the nurse or an attendant holding the child, to sit opposite to him in such a manner that, as it is lowered backward to lie across the lap, its head will rest upon the towel between the physician's knees, where it is to be held firmly and steadily, as in a vice. The nurse now secures the hands and arms of the child, so that they can not be moved about to interfere with the physician's examination. The physician, having carefully wiped the eyelids dry with a soft linen rag, separates them in the following manner; covering the extremity of the index-finger with a piece of soft rag, it is to be applied to the center of the upper eyelid, upon its border, between the roots of the eyelashes and the eyeball; while at the same time the extremity of the thumb of the other hand, also covered with a rag, is to be applied to the border of the lower lid. This done, the lids are to be separated from each other by carefully sliding them in opposite directions, but without making the least pressure on the globe. By this means, all the anterior surface of the eyeball will be brought into view. Sometimes, however, the eye will be turned upward, so that the cornea can not be seen, but by waiting five or ten seconds, the eye will assume its normal position, or sufficiently so to insure a satisfactory

inspection of it. If it be necessary to evert the eyelids in order to examine the palpebral conjunctiva, this may readily be effected.—When the cornea alone is to be examined, the elevation of the upper lid will suffice, without disturbing the lower one. Prolonged examinations will require a spring speculum, especially adapted to the size of the opening between the lids.

DISEASES OF THE EYEBROWS.

1. *Discoloration of the hair* of the eyebrows occurring among persons in advanced years is not a disease, and can not be arrested; but that which is sometimes met with among young people is a true pathological condition, more commonly caused by excesses of all kinds, late hours, grief, acute mental emotions, etc. Sometimes it may be due to a cutaneous disease of the part. To cure this unsightly affection at an early age, all that is required is to withdraw the patient from those influences that facilitate its development. And, while awaiting the result of a regular course of living and a rigid attention to hygienic measures, which always exert a favorable reaction on the organism, colored cosmetics may be used to disguise the white appearance of the hairs.—If the discoloration be due to cutaneous disease, this must be removed by the proper treatment; but, in such cases, the discoloration of the hair generally remains permanently.

2. *Superciliary Alopecia* or a falling of the hairs of the eyebrows, is almost always a consequence of burns, deep wounds, herpetic diseases, or eruptive fevers, as small-pox, erysipelas, etc. Sometimes it may be caused by an obstinate syphilitic affection. Two conditions may present themselves; where the pileous bulbs have been ulcerated, then destroyed, and placed beyond the resources of art, or, where the bulbs are still existing, in which case we may arouse their torpid vitality by stimulating frictions and aromatic lotions. For this purpose we may employ one of the following preparations: 1. Take of Cologne two fluidounces, Tincture of Cantharides two fluidrachms, Oil of Rosemary, Oil of Lavender, of each, ten drops; mix.—2. Take of strong Alcohol four ounces, strong Aqua Amonia one ounce, Tincture of Arnica one ounce, Rain-water two ounces; mix.—3. Take of Tannin two parts, Quinine one part, Butter of Cacao thirty parts, Olive Oil fifteen parts, Aromatic Alcohol two parts; mix. 4. Take of Lobelia, Sculleap, St. John's Blos-

soms, each, one ounce, Prickly-ash Berries half an ounce, Alcohol half a pint, Castor Oil half a pint; mix.

If frictions with these produce no favorable result, all that can be done, will be to recommend the patient either to have artificial eyebrows, or have the parts properly colored.

3. *Wounds of the Eyebrows*, especially when their internal portion is involved, are frequently followed with a diminution and even loss of sight; the seriousness of a lesion so apparently benign, is due to contusion, pricking, or laceration of the suborbital nerves. The treatment of wounds of this region is similar to that for wounds in general. If the wound is longitudinal and caused by a cutting instrument, the edges may be held together by sutures or adhesive strips; if it be contused, compresses with dilute Tincture of Arnica, or Camphor may be applied, holding the dressings in place by means of a moderately tight bandage around the head. The object in case of wounds, is to heal the wound without any subsequent deformity therefrom. Very severe contusions may require leeches and cold applications. A very excellent preparation for contusions, sprains, etc., and to remove ecchymosis, is prepared by dissolving one ounce of Hydrochlorate of Ammonia in half a pint of Water, and then adding to it, Tincture of Arnica half a pint. Fresh Solomon's Seal Root, grated, and applied, renewing it every thirty or forty minutes, will also be found efficient; the smarting and redness its application gives rise to will disappear after a while.

The sting of wasps, bees, spiders, etc., upon the eyebrows, or eyelids, must be treated by extracting the sting, if possible, and then applying cloths wet with weak Ley-water, with a solution of Hydrochlorate of Ammonia, or, with the same solution, having Tincture of Arnica added, as named above. If there be much pain and suffering, Landanum, Solution of Morphia, or Tincture of Lobelia may be added to the application; and, if the system suffers much, a glass of Wine may be given occasionally, to which five or ten drops of Aqua Ammonia have been added. Any erysipelatous inflammation remaining may be treated by local applications, of Elder-flower Water, Infusion of Lobelia, Solomon's Seal, or Maiden-hair; or, a Solution of one part of Perchloride of Iron in three parts of Distilled Water; apply it every two hours with a camel's-hair pencil.

4. *Cutaneous Diseases of the Eyebrows*, are generally those affections which have a manifest tendency to invade parts of the body

which are covered with hair. (See Integumentary Diseases, *Vesiculæ*, *Pustulæ*, *Parasitici*, etc.) In the superciliary region, the eruption sometimes presents the appearance of pustules of a yellowish color, containing a thick fluid which spreads, coagulates, and forms a hard, dark crust covering the eyebrows either partially or wholly, at other times, the eruption consists of small, agglomerated vesicles, which break and discharge a reddish serosity, which concretes and forms thin scales, less prominent than in the preceding instance. These two varieties of eruption are accompanied with considerable itching, and even a sense of burning and smarting, and may eventually, give rise to serious derangements of the function of vision.

At first, we may attempt the removal of these eruptions by local applications, but when they have existed for some time, it will be proper to add to the local treatment, such constitutional remedies as the character of the disease, the diathesis of the patient, or other circumstances connected with the disease, would indicate.

The first thing will be to remove the crusts, which may be readily accomplished after having softened them by means of emollient cataplasms, glycerin, oily unctions, etc. If the eruption is *pustular*, one of the following compounds may be used: 1. Take of Sulphate of Zinc, in very fine powder, one ounce, Sweet Gum or Styrax two ounces, Lard four ounces; mix together by heat, stirring all the time till cold. Apply it two or three times a day.—2. Take of Sulphate of Zinc three or four grains, Glycerin one ounce; mix. Apply three or four times a day by means of a hair pencil.—3. Take of Iodide of Sulphur two grains, Simple Ocrate half a drachm; mix thoroughly together, and apply two or three times a day.—4. Take of Benzoin in fine powder, four grains, Sublimed Sulphur four grains, Calcined Alum two grains, Lard one drachm; mix all thoroughly together and scent with a few drops of oil of roses. Apply this two or three times a day.

If the eruption is *vesicular* alkaline lotions will be preferable, as, 1. Take of Slaked Lime eight parts, Supercarbonate of Soda two parts, Rousseau's Laudanum two parts, Lard thirty parts; mix.—2. Take of Hydrochlorate of Ammonia, Bicarbonate of Potassa, each, half a drachm, Tincture of Yellow Dock Root, half a pint; mix.—3. Take of Wood Soot thirty parts, Stramonium Ointment one hundred and twenty parts, Oil of Sweet Almonds four parts, Bicarbonate of Potassa one part; mix.

The internal remedies most applicable to these affections are preparations of sulphur, of alkalis, especially the iodides or bromides, as well as vegetable alteratives. (See Treatment of Integumentary Diseases, *Vesiculæ*, *Pustulæ*, *Parasitici*, etc.)

5. *Cysts of the Eyebrows* are small tumors varying in size from that of a pea to that of a pigeon's egg, and popularly called *wens*. Their location is more commonly at the outer angle of the eyebrow; they are, however, almost always situated a little higher or a little lower than the superciliary appendage itself. Sometimes, these cysts are hard to the touch, at other times they are soft and yielding. Some enclose a yellowish, viscid matter, others a white grumous material resembling small lumps of wheat flour. The treatment of these cysts is altogether surgical; but it is better not to remove them, until they have acquired a considerable size, or interfere with the functions of the eyelids. Not unfrequently, after having attained the size of a pea, their further development becomes arrested.

6. *Pediculi. (Phthiriasis.)* When lice exist in the eyebrows, they multiply with astonishing rapidity, and occasion severe itchings and more or less pain. They may be removed by frictions with one of the following preparations:

1. Equal parts of Cologne and Tincture of Larkspur Seed.—2. Take Oil of Sassafras, Oil of Cedar, Tincture of Larkspur Seed, Oil of Sweet Almonds, of each, one fluidrachm; mix.—3. Melt together Beef Marrow thirty parts, Oil of Sweet Almonds four parts, Balsam Peru two parts; stir the mixture thoroughly, remove from the fire and add Oil of Valerian (or Oil of Amber) two parts, Oil of Wormseed one part. Apply one of these preparations two or three times a day. (*See Integumentary Diseases*, page 1094.)

DISEASES OF THE EYELIDS.

1. *Erythema of the Eyelids*, is characterized by a slight superficial redness of the thin layer of skin forming their external surface. It is more generally caused by irritating frictions, strong heat, exposure to a burning sun, flow of tears, etc. Sometimes, it occurs with females at their menstrual period, and, also, precedes or accompanies some cases of pulmonary and gastro-intestinal inflammations, as well as certain cutaneous affections. During dentition, it is often met with among children, and is called "strophulus, red gum, or tooth rash." The disease ordinarily disappears soon, and without treatment. To facilitate its removal, it may be bathed occasionally with a warm infusion of bran, lobelia, bayberry, or elm bark, etc.

2. *Inflammation of the Edges of the Eyelids*, also called, *inflammation of the Meibomian and ciliary glands*, *serofulous blepharitis*, *ophthalmia tarsi*, *tinea ciliaris*, *tinea palpebrarum*, *psorophthalmia*, etc., is almost always a chronic inflammation of the anatomical elements which concur in the structure of the free border of the eyelids,—a pustular eczema, impetigo, or *Eczema Tarsi*. The upper eyelid is more frequently attacked than the lower. It is met with both among children and adults, especially those of a strumous habit of body. When the disease is primary, it appears to be caused by exposure to the changes of the weather, to irritating vapors, impure air, uncleanness, unwholesome food, scanty diet, intemperance, debilitated constitution, etc. Farmers, military men, traveling merchants, coachmen, army teamsters, etc., are more particularly disposed to it. The secondary form of the disease is caused by catarrhal ophthalmia, ophthalmia neonatorum or purulent ophthalmia of new-born children, serofulous conjunctivitis, or it may occur as a sequela of some of the exanthematous febrile diseases.

Symptoms. At first there is a feeling of heat and prickings, or smarting, and nearly all patients complain of a sensation of roughness which they compare to that produced by grains of sand under the free border of the eyelids. Upon a close examination, the oculopalpebral membrane will present a net-work of very fine vessels, filled with blood, which give a uniform, red appearance to the eye, or else small opaline vesicles will be seen scattered irregularly here and there, from the free margin to the oculopalpebral sinus. These local morbid conditions are accompanied either with hypersecretion of a viscid matter more or less consistent and readily concreting, or, with an extreme dryness of the mucous membrane. At this stage of the disease, it will rapidly disappear by simple hygienic attentions; but if neglected, which is more commonly the case, it becomes more extended, invades the Meibomian glands, or the ciliary glands, which swell, and the free border of the lids attains a volume considerably more than normal.

This tumefaction of the palpebral margin, which is indicative of the second stage of the disease, is at first so irregular, that we can readily recognize the swollen glands by the touch, ranged by the side of each other like small beads. At a later period, if the inflammation still extends, these little protuberances disappear, the swelling becomes uniform, invades the substance of the tarsal cartilage, and the border of the eyelid becomes double and triple its natural volume. At the same time, the secretion of the inflamed glands flows more abundantly, and dries in the form of yellowish scales, which so agglutinate the eyelids during sleep, that the

patient can not open his eyes until he has softened the concretion by moistening it. Frequently, but not always, there is photobia, and a flow of tears, from the irritation present.

When the ciliary glands participate in the morbid process, they likewise secrete a thick matter, which mingling with the preceding, equally dries in the form of hard, bluish crusts, so strongly adherent, that they can not be detached without a drop or two of blood following, or without tearing out some of the eyelashes.

Sometimes the ciliary glands only are inflamed, the Meibomian remaining intact; in this case, there is redness of the marginal border of the eyelids, a morbid secretion, such as will presently be described, and an incessant itching which compels the patient to scratch the part. There is no intolerance of light, no weeping, no sensation of sand in the eye. Frequently, there will be an inverted condition of the lashes, which, being turned in upon the ball of the eye, increases the irritation, this is called *trichiasis*; or, slender, dwarfish hairs may be developed, which point directly upon the eyeball, causing considerable pain and irritation, and which are termed *false eyelashes*, *wild hairs*, *pseudo-cilia*. These are often so pale and fine as to escape detection, unless the physician uses a magnifying lens with the aid of oblique light. The itching which accompanies this disease is a pathognomonic symptom; the malady is sometimes called *tinca of the eyelids*. If it be neglected, or be improperly treated, very unpleasant results may occur, as loss of the eyelashes, and ectropium.

The third stage of this disease is characterized by the presence of ulcerations and small pustules or abscesses at the roots of the lashes. These ulcerations, resulting from the irritation produced by the efforts made each day upon the eyelashes to remove the concretion that agglutinates them, and by the constantly secreted acrid and corrosive matter, are sometimes deep, and are always very difficult to cure. They more frequently involve the partial loss of the lashes, which, at a later period, if the affection persists, give rise to a thick, reddish border, more or less large and callous, termed *tylosis*. This condition of the eyelids is often seen among old persons, and has received the name of *lippitudo* or *blear-eyed*; it is accompanied with a continual flow of tears, a more or less intense photobia, and sometimes with conjunctivitis, or corneitis, for the eyeball being no longer sheltered by its protecting curtain, becomes sensible to the least causes of inflammation.

The cure in this affection is usually slow and tedious, not only from the obstinacy of the disease itself, but also from the unwillingness or neglect of the patient in attending to the eyes properly.

When the hair-bulbs have become destroyed, and the Meibomian orifices obliterated, the *prognosis* is always unfavorable. This condition may be known by the skin covering them being smooth and shining, and by pressure upon them not causing any discharge.

The *treatment* in the early stage of the disease is very simple, keeping the eye cleansed by bathing it with tepid water, and, perhaps, employing likewise, emollient or astringent lotions or glyceroles. The eye may be steamed over vapor of Belladonna, Stramonium, or Lobelia; and a lotion of Rose-water may be applied to it, or a Solution of Borax one part in Water, or, still better, pure Glycerin, thirty parts. If there is intolerance of light the eyes may be shaded, or the patient be kept in a darkened room. At the same time, the skin, kidneys, and bowels, must be properly attended to, as well as the diet, and any faulty condition of the system must be promptly remedied by the required means.

It is rarely, however, that the oculist will have the case presented to his notice until the disease has reached its second stage, when it will require much care and patience, on his part, to effect a cure. He must first, satisfactorily ascertain the actual condition of the eyelids, the morbid changes of which they are the seat, and their extent; he will thus learn whether the disease be confined to the Meibomian glands, to the ciliary, or to both combined. He will also enquire at what period the disease first manifested itself, and what were the symptoms, as, smarting, prickings, burnings, itchings, etc.; and, having satisfied himself as to the seat of the disease, its stage, and its essential manifestations, he will then turn his investigation to the constitution of the patient.

In the second stage, when the borders of the eyelids are red and tumefied, and agglutinated together, with severe itchings, etc., the following plan of treatment will be found effectual. In the morning, when the eyelids stick together, no efforts whatever must be made to open them, until the dried matter has been softened, so that no pain nor loss of eyelashes will follow the separation of the lids. For this purpose, a soft piece of linen rag may be well moistened with an Infusion of Walnut Leaves, as hot as can be borne, and be gently and loosely laid upon the closed eyelids, renewing its application every three or four minutes, until the lids open readily. In place of the above infusion, hot water, milk, or, infusion of hops, poppies, etc., may be used.

The eyelids being opened, every particle of concreted matter upon them must be carefully removed, in order that our subsequent applications may come in direct contact with the diseased part; else, they will prove of no service. And which may be effected by softening

them as above, or, with equal parts of Glycerin and hot Water, and removing them with the finger nails, or, still better, with a horn or shell forceps. Should there be any inverted or false eyelashes, or should any of the lashes be found quite loose in their follicles, these must be carefully removed. These matters being accomplished, the patient is now ready for the application of curative agents. Among these agents, the following will be found to answer a better purpose than most of the preparations which have been recommended to the profession; they are not to be applied with a hair pencil, nor to the healthy parts of the lid, but directly upon the seat of the disease, over which they should be rubbed and pressed, so as to enter the orifices of the Meibomian and ciliary glands; and this should be done by the physician himself, or by some trustworthy person, and never be entrusted to the patient, who, as a general rule, will merely rub the preparation on the outside of the lids, and without previously removing the crusts.

1. Take of Laudanum four parts, Glycerin thirty parts; mix.—2. Take of Acetate of Morphia, one grain, Acetic Acid two drops, Glycerin half a drachm; mix.—3. Take of Borax two grains, Glycerin half a drachm; mix.—4. Take of Glycerin two drachms, Hydrocyanic Acid, offic., fifteen minims, Aconitina one grain; mix. These are to be applied when there is considerable tenderness, and irritability; and when this has been lessened, one of the following preparations may be substituted, viz.:

1. Compound Lotion of Golden Seal.—2. Compound Soda Lotion.—3. Compound Lotion of Zinc.—4. Compound Ointment of Oxide of Zinc.—5. To a saturated Solution of Hydrochlorate of Ammonia, half a fluidounce, add half a fluidounce of clear Rain-water, and from one to three fluidrachms of Tincture of Capsicum, according to the degree of smarting it produces. 6. Glycerate of Starch* one drachm, Iodide of Potash, (or of Ammonium), from two to four grains; mix.—7. Glycerin one drachm, Concentrated Nitric Acid two to four drops; mix.

Whichever of these preparations are used, it should be applied two, three, or four times a day, according to the effect produced, and the severity of the disease; always being very careful to

* *Glycerate of Starch*, or *Schacht's Plasma*, is made by placing one drachm of finely-powdered Starch and fifteen drachms of pure Glycerin, in a porcelain capsule, and exposing them to the heat of a spirit-lamp until complete hydration of the starch has occurred, constantly stirring the mixture with a spatula, during the process. This has no fatty odor, keeps without becoming rancid, and instead of developing erythema, as fatty ointments frequently do, it cures it when present.

remove, each time, by the means stated above, every vestige of con-creted matter upon the margins of the lids. In very obstinate cases, it will prove advantageous to wake the patient once or twice during the night, in order to remove the crusts and renew the application. When the patient is old enough, the lids may frequently be prevented from adhering together, by drawing down the lower eyelid, and carefully inserting along its inner surface, a piece of soft tissue-paper which has been moistened with Oil of Sweet Almonds, or Glycerin with which a small portion of Morphia has been combined; then allow the lid to return to its natural position, so as to hold the paper between the lid and the eyeball, the patient at the same time closing the eyes. The paper should be cut of the right size, so as to be long enough to reach from one corner of the eye to the other, and wide enough to have its upper edge lie between the lids when closed. Of course, after this has been applied the patient must keep his lids closed, for opening them will disarrange the paper and give rise to irritation; and, sometimes, from extreme irritability of the lids, it will be improper to use the paper.

In the third stage of the disease, when ulcerations exist, more energetic measures must be pursued. The affected eyes must be exposed to an eye-bath of tepid water, or infusion of Marsh Mallows, or Marsh Mallows and Poppy Leaves, etc.; after which one of the following preparations may be applied, repeating the application once, twice, or three times every day, according to the effect produced:

1. Take of Sulphate of Copper eight grains, Glycerin one drachm and a half; mix.—2. Take of Tincture of Iodine eight grains, Glycerin one drachm and a half; mix.—3. Take of Perchloride of Iron eight grains, Glycerin one drachm and a half; mix. 4. Take of Sulphate of Zinc four grains, Glycerin one drachm and a half; mix.—5. A light cauterization with a crayon of Sulphate of Copper, will be found preferable in most cases.—6. Or, the parts may be touched once every day or two with pure Nitric Acid. Dip the end of a small stick of pine wood in the acid, and then wipe off all superfluous acid with a piece of paper—the wood will absorb enough for use. With this gently touch the diseased part, or only a portion of it at a time, every day or two. The severe pain caused by it soon passes away, without leaving any inflammation. The lids should be kept perfectly clean, and the best wash is a Castile soap-suds, to which an equal quantity of good Brandy has been added; with this, the lids may be bathed three or four times a day.—It has been recommended in cases where the lids are much thickened and indurated, with ulceration of the roots of the eyelashes, to extract

these, previous to applying the caustics, as "those lashes which fall out by ulceration are never replaced, because the bulb which secretes the hair is destroyed; but when they are plucked out they are afterward restored." This will be found beneficial in some cases, but is by no means necessary in all.

When ophthalmia tarsi obstinately resists local treatment, it is almost always owing to some faulty condition of the constitution, and consequently it is always much better to associate with the local measures, an internal alterative and tonic. Various agents may be employed for this purpose, as, Compound Syrup of Yellow Dock with Iodide of Potassium; Compound Syrup of Sarsaparilla: Iodide of Ammonium: Bromide of Ammonium; or, the following: Take of Bromide of Ammonium one ounce, Water thirty fluid-ounces, dissolve, and add Solution of Perchloride of Iron one fluid-ounce; the dose is a teaspoonful three times a day. Another very excellent compound is composed of Fluid Extract of Black Cohosh two fluidounces, Fluid Extract of Cinchona one fluidounce, Fluid Extract of Blue Flag half a fluidounce; mix. Dose, half a drachm to a drachm, three times a day, or enough to fall short of nauseating the stomach, or acting on the bowels.

In addition, hygienical measures should be strictly observed, as, attention to the bowels, skin, and kidneys, a nourishing diet, exercise in the open air, protecting the eyes as much as possible from artificial light, from the glare of sunlight, and from fatigue or irritation by reading, writing, sewing, or any kind of occupation requiring close examination. The eyes should also be protected against the wind, dust, bright light, etc., by the use of neutral tint spectacles, or London smoke, or gridelin. Blue glasses may also be used, but green glasses should be prohibited.

Should the disease become incurable from obliteration of the glands, the only course left will be a palliative one, to remove irritation by fomentations, and some simple glycerate or ointment; the shining redness of the lids, the absence of lashes, and the bleary-eyedness, will remain through life. (*See Eczema Palpebrarum*, page 1018.)

3. *Hordeolum and Furunculus of the Eyelids.* Hordeolum (*stye*) and Furunculus (*boil*) have common characters, and the differences that distinguish them from each other are so slight as not to require special descriptions. Boil may manifest itself on any part whatever of the cutaneous covering of the eyelid; stye, on the contrary, is always developed on its free margin. The first may

attain a considerable size; the second rarely exceeds the size of a grain of barley. They are both inflammatory tumors, occasioning more or less pain, and may equally, if the accompanying inflammation is intense, contribute to impede, or even momentarily suspend the movements of the eyelids. Both terminate by suppuration.

The *treatment* of furunculus is based on that of boils generally, by cataplasms of Elm Bark, Flaxseed or Hops and Lobelia, to hasten suppuration. Frequently, the progress of the tumor may be checked at an early period, by touching it with a saturated solution of Oxalic Acid, or with Oil of Turpentine, being careful not to allow any to enter the eye. A tendency to the formation of boils must be treated as named under their appropriate head. (*See Furunculus*, page 1035.)

Hordeolum or styte is frequent with lymphatic or strumous persons, who have a fine and delicate skin. It is often developed under the influence of a deranged condition of the stomach, and likewise among females shortly previous to the menstrual period, and it is not rare to see several appear successively, one after another, or all at the same time. Its progress is similar to that of furunculus, and more commonly requires no particular treatment. When treatment is necessary in obstinate cases, the same measures may be pursued as recommended for boils; being careful to regulate the stomach and bowels, and to attend to hygienic measures generally. Zeis who believes the disease to be located in the capsules and ciliary glands, advises plucking out the eyelashes at once at the part affected. This arrests or mitigates the disease. There is no objection to this course, as they will soon be reproduced.

4. *Carbuncle of the Eyelids, Anthrax Palpebrarum.* This is a rare disease. It presents itself in the form of a tumor similar to that of boil, but much harder and more voluminous, severe burning pain, and intolerable itching. The swelling is dark red or purple, and at its apex a grayish point may be observed, which is, at a later period, eliminated by the suppuration. We must as early as possible deeply incise the tumor, the same as with carbuncles elsewhere, and then apply emollient poultices, continuing them until the slough separates, and in other respects, both locally and constitutionally pursuing the usual treatment recommended for these tumors generally.—It has also been recommended to apply the vegetable caustic, or caustic potassa to the tumor, freely, until an eschar is fully formed. This will no doubt be found preferable in many cases; as

it is much safer for the patient; and, as a general rule, the cure is thereby effected more rapidly. (*See Carbuncle*, page 1037.)

5. *Malignant Pustule of the Eyelids.* This is a virulent disease of a gangrenous nature, which is frequent in certain countries, and among persons who are almost constantly in contact with animals, their hides, or carcasses, as, butchers, tanners, farriers, hostlers, shepherds, etc. It may also be caused by the bite of a fly, or of a gnat, or mosquito, that has previously been sucking the blood of an animal affected with anthrax, or glanders. It always runs through four distinct stages.

In the first stage the disease commences by a red spot, resembling a flea-bite, then the lid swells, becomes œdematous, with intolerable itchings and violent pains. The next morning, the red spot is replaced by a small brownish vesicle, which ruptures spontaneously, or by the patient's scratching, and beneath which appears a small black spot of the size of a lentil seed.

The second stage is marked by the induration of the parts surrounding this livid spot, by an increase of heat, of smarting, of swelling, and by the appearance of other vesicles, which on rupturing leave a blackish eschar which extends in every direction.

In the third and fourth stages, the tumefaction becomes more and more considerable, invades the neighboring tissues, and the fever increases, with great thirst, small and unequal pulse, and dry tongue. Finally, nausea supervenes, delirium, coma, stupor, and death. These four stages generally succeed each other with great rapidity. In some cases, the disease is spontaneously arrested after having attained the first or second stage, and is followed by a healthy inflammation, which favors the separation of the gangrenous parts, leaving a wound which readily heals; but although cured, it is almost always with a loss of substance of the eyelids, to a greater or less extent.

The *treatment* of this disease can be efficacious only in the first three stages; in the fourth it is rarely of service.

In the first stage, by bathing the parts with the following lotion as well as injecting a drop or two into the diseased tissue, the further progress of the disease may be effectually checked. Take of Perchloride of Iron fifteen parts, Citric Acid two parts, Distilled Water twelve parts; mix.

But the surest plan, is cauterization, either with caustic Potassa, Chloride of Zinc, Sulphate of Zinc, Sulphate of Copper, or the hot

iron. The other treatment, both local and constitutional, being the same as recommended for Carbuncle, which see.

6. *Cutaneous Diseases of the Eyelids.* The remarks under "Cutaneous Diseases of the Eyebrows" equally apply to the diseases now referred to. The most frequent are *impetigo* and *eczema*, and also a variety of *psoriasis* or *lepra*, characterized by small whitish scales which occasion farinaceous exfoliations. The angles of the eyes seem to be the particular seat of this ophthalmic psoriasis, which is chiefly developed among pale strumous persons with a fine white skin.

These affections will require the same treatment as when located in other parts. In several cases of obstinate eczematous disease, which resisted alkaline and other treatment, the following is stated to have been found especially useful: Take of Oil of Tobacco six drops, Sulphate of Zinc fifteen grains, Cucumber Ointment one ounce; mix. I should prefer, however, the following, which I have frequently and successfully used: Take Oil of Tobacco six drops, Ointment of Wood Soot one ounce; mix.

In cases of psoriasis, we may advantageously use lotions of cream, and then sprinkle the following powder upon the affected parts: Take of Camphor one grain, White Oxide of Zinc two grains, fine powder of Rice (rice flour) fifty grains; mix. (*See Integumentary Diseases.*)

Porriago Larvalis, or *Crusta Lactea*, (*milk-scab*), frequently affects the eyelids of infants and young children, to whom it is peculiar. It commences with a pustular eruption which is soon replaced by thin or thick yellowish or greenish scabs or crusts, from beneath which issues a brownish matter; when these fall off, they leave a red and tender surface. In some cases, the conjunctiva becomes inflamed, and which may be followed by destruction of the eye. This disease, when attacking the eyelids, is nearly always an extension of the disease from the forehead and cheek. Its *treatment* is simple; the crusts must be softened by means of emollient or oily applications, and then detached, after which one of the following preparations may be applied, repeating this process three or four times a day:

1. Take of Sweet Gum, Tallow, each, equal parts; melt together and strain.—2. Take of Tallow one ounce, melt, and add to it Oxide of Zinc one drachm; keep stirring until nearly cold, and then add Glycerin one fluidrachm, Tincture of Camphor two fluidrachms; stir till cold.—3. Sometimes, the following paste applied upon the eyelids will be found effectual: Take of fine Wood Soot five

parts, Rice flour five parts, Water a sufficient quantity to form a paste; mix.

As to other means, and general treatment to be pursued, see *Porrigo Larvalis*, page 1026.

7. *Warts on the Eyelids*, (*Verruca*) are small tumors analogous to warts on other parts of the body; they may be attached to a pedicle, or rest upon a large base, and usually do not exceed in size that of a pea. If they do not interfere with the eyelids, nor disfigure the patient, it is best to let them alone. If, however, they become voluminous, or there are several of them, it is better to remove them. This may be done, when they are pediculated, by seizing the tumor with a forceps, and then snipping them off with a single cut of a curved scissors. If they have a large flat base, they may be removed by the ordinary method of excision, by covering them with chalk, in powder, or by the application of some of the agents named under the head of Warts, on page 1095. But, it must be remembered, that, sometimes, the application of acrid vegetable juices, or caustics, inflame and ulcerate the wart, which, ultimately becomes of a malignant or cancerous nature.

8. *Chalazion of the Eyelids*, *Tarsal Tumor*, *Fibrinous Tumor*, somewhat resembles hordeolum, but differs from it in not being situated on the edge, and in not pointing toward the edge; by some, it is viewed as a sty which, having failed to suppurate, has passed into a chronic state. It is generally seated in the substance of the tarsal cartilage, a short distance from the margin of the lid, and more commonly points toward the internal surface. The upper lid is more commonly the seat of this disease, though it may exist in either, or, in both at the same time, and, sometimes, there may be several in the same lid. Upon everting the lid the tumor will project, and the part of the conjunctiva covering it will be of a livid-red color.

The best *treatment*, is, to evert the lid, push a small lancet carefully into the tumor and divide it throughout its whole length; then press out the contents. If they do not readily pass out, introduce the sharp end of a probe and break up the structure of the tumor, and then re-apply firm pressure. Any derangement of the digestive organs should always be properly treated, as the disease frequently appears connected with such derangement.—The application of pure Nitric Acid to these tumors, by means of a

soft piece of wood moistened with it, will frequently be found an effectual remedy. Dip the wood in the acid, wipe off any superfluous acid on the wood with a piece of paper, apply it upon the tumor and hold it there until the patient complains of the smarting, say, from ten to thirty seconds. Repeat this every day or two.

9. *Cysts of the Eyelids, or Encysted Tumors*, are analogous to those met with in the eyebrows. They may be developed in any part throughout the whole extent of the palpebral surface, but more commonly on the ciliary border. They sometimes enclose a yellowish-colored serous fluid, sometimes a thick and brownish fluid, somewhat like blood; they may also contain a matter similar to tallow, or hard grains of wheat flour. These tumors progress slowly, and after having attained a certain size, seldom beyond that of a walnut, they remain stationary. Some are superficial and adhere only to the skin; others develop themselves at the expense of the subcutaneous cellular tissue; and some have their origin in the more deeply-seated parts, are adherent to the tarsus, or to the periosteum of the margin of the orbit, and have not the mobility which characterizes the first two varieties. These cysts are always indolent, and constitute a disagreeable deformity which interferes with the movements of the eyelids and the functions of the eye.

The most certain method of removing them is by dissecting out the entire cyst, if possible, for if any portion of it be allowed to remain the tumor will re-appear, or fungous growths may be developed. The ring-forceps of M. Desmarres, as improved by Wilde, will be found of great service in the extirpation of tumors from the lids. It fixes the lid firmly, and compresses the parts around the tumor, so as to prevent any great amount of hemorrhage. When it can be safely done, the incision should be made through the palpebral conjunctiva; otherwise, through the external integument of the lid.

10. *Nævus Maternus, or Erectile Tumors of the Eyelids* are superficial or deep-seated sanguinary tumors upon the lids, of varied form and size, existing from birth or soon after, or else, but rarely, appearing at an advanced age. Some are arterial, others are venous, and again, others are constituted by a capillary net-work of both arterial and venous formation. The arterial (or active) tumors (aneurism by anastomosis) are of a vermillion red, and pulsate

synchronously with the pulse at the wrist. The venous (or passive) tumors have a livid tint, and a soft consistency. The third variety may be known by its brownish color, and by the resistance of its contents; and one of their distinctive characters is to diminish in size, and even wholly disappear under the influence of prolonged pressure.

These tumors frequently remain stationary; but sometimes they progress rapidly and acquire a large size; the skin then becoming excessively distended, may ulcerate, and if the tumor be arterial, serious hemorrhages may occur.

The various methods of *treatment* recommended for the removal of these tumors have for their object, either their destruction at once, obliteration of their vessels, or their extirpation. These methods are, pressure, vaccination, acupuncture, galvano-puncture, ligation, cauterization, and excision, which I shall not dwell upon here, as they belong to general surgery.

By enclosing the whole substance of the lid in a ring-forceps, having at the same time emptied the tumor of as much of its blood as possible by pressure, and then isolating it completely from its parent vessels by compression of the ring-forceps, we may cut up its tissue subcutaneously with a cataract needle, and carefully inject into it a solution of Tannin, of Perchloride of Iron, or of Iodine and Tannin combined. After a minute or so, relax the pressure of the ring-forceps, and allow the current of blood to return and come in contact with the injected fluid. This plan will frequently succeed. Some oculists recommend a seton of silk to be passed through the tumor, which has been previously saturated with solution of Perchloride of Iron.

11. *Œdema of the Eyelids* may accompany general dropsy, or it may arise from various causes, as, contusions, erysipelas, tumors, osseous disease, polypus, Bright's disease, etc., in which cases, the removal of the original affection will be followed by a disappearance of the œdema. Sometimes, however, it is due to debility or a strumous habit. In which case, tonics and alteratives internally, with gentle stimulants locally, and in obstinate cases, counter-irritation to the back of the neck, or behind the ears, will be found sufficient to remove the swelling.

12. *Cancer of the Eyelids, Cancroid, Epithelial Cancer, or Epithelioma* commences either by a very small elevation or tubercle, more frequently on the lower lid, and toward one of the angles, or else

by a small wound, which soon becomes covered with a scab, inducing the belief that it is cured; soon after, however, the scab is detached or torn off by the patient, renews itself, then cicatrizes again, and so on. At a later period, the indurated tubercle, which at first is not painful, and does not cause discoloration of the skin covering it, except some varicose vessels pervading it,—ulcerates; or, the skin beneath the scab ulcerates. The ulceration enlarges, its surface becomes hard, thick, and smooth; its borders callous, knotty, irregular, and of a pale-red color, and the discharge from the ulcer has in all respects a healthy appearance. With some, there is but little pain, unless, from the ulceration, nerves are exposed; with others, the ulcerative stage is attended with acute lancinating pains. The progress of the ulcerative process is very slow; it may be arrested, and even partly heal, and then commence anew. The surrounding skin is rarely swollen or discolored, and the adjacent lymphatic glands remain unaffected. If allowed to advance, the ulceration affects all the neighboring tissues, so that ultimately the orbit, the eyeball and the nose, form an extensive reddish ulcer, bleeding readily, and discharging an abundance of a sanious matter. At this epoch, the most alarming symptoms manifest themselves, as, emaciation, hectic fever, yellow tinge of the skin and puffiness, or serous infiltrations; and ultimately the patient dies from the effects of the disease upon the organism. This disease is rarely, if at all, met with among children, but almost always during the middle period of life, and often among females who have passed their critical period.

This *treatment* of this disease is divided into external and internal, and although it frequently fails to effect permanent cures, the disease appearing every few years, after having been apparently cured, yet it, at least, aids in prolonging the patient's life for a term of years, by arresting the progress of the ulceration, and preserving the adjacent tissues from its influence for a longer or shorter period.

The *internal treatment* consists of constitutional measures, as the administration of alteratives, preparations of iodine, etc.

The *external treatment* consists in the extirpation of the affected parts with the knife, removing, at the same time, some of the surrounding healthy tissues. But, the better plan, to my mind is the application of caustics, as Sulphate of Zinc, Chloride of Zinc, etc., as advised for Cancer. (See page 490.)

When the disease is past cure, palliative treatment is all that can be pursued; calming pains by anodynes, both internally and locally; mitigating the character of the sanious and purulent secretion by covering the ulcerated surfaces with Geranium in powder, or other

astringents; with a mixture of two parts finely-powdered Golden Seal, and one part of Perchloride of Iron; with powdered Bol Armenia; or, with a mixture of equal parts of powdered Peruvian Bark, Precipitated Carbonate of Iron, and Rosin.—Carbolic Acid half a drachm added to Glycerin one ounce, are stated to have been found a valuable local application in the early stages of this disease.

13. *Entropium*. This is a morbid condition characterized by an *inversion* of the free border of the eyelids, so that their edges are turned inward against the ocular conjunctiva, which is constantly irritated by the friction of the eyelashes upon it. Both eyelids may be affected simultaneously, but, more commonly, it exists in only one. Entropium may be total or partial, according as a part or the whole of the lid is involved. Its more frequent seat is toward the external angle of the eye.

This disease has numerous *causes*. It may be produced by a partial destruction of the palpebral conjunctiva, from whence follows a contraction of this membrane, which results in a more or less complete rolling inward of the free margin of the eyelid; it may, likewise, follow an abscess, long-continued inflammation, improper use of caustics, and injuries to the eyeball or palpebral conjunctiva, by lime, acids, etc. It may also be produced under the influence of a spasmodic condition of the orbicular muscles, or of an obstinate ophthalmia, as, for instance, ophthalmia tarsi, in the upper eyelid especially, when the tarsus becomes relaxed, distorted, and turned inward, drawing the lashes along with it. This variety has been called *tarsal entropium*. That from injuries is termed *traumatic entropium*. *Senile entropium* occurs among old persons, in whom the skin of the eyelid having become relaxed, or extended relatively more considerably than the mucous membrane, this has a tendency to draw the cutaneous surface toward itself and thus occasion an inversion.—A tumor which compresses the ciliary margin of the eyelid, or improper compression upon the eyeball, may also give rise to entropium.

In many instances, the tendency of the lid to invert may be overcome by the application of contractile collodion to the skin of the lid, or by means of a bit of firm wire, so “twisted and bent, as to fit on the back of the head by its middle, and press by its rounded extremities against the orbital portion of the lower eyelid”—(this being the affected one). *T. W. Jones*.

But, it is rarely that anything short of an operation will answer in the chronic form. The operation consists in removing a suitable

portion of the skin of the lid, and then accurately uniting the wound with sutures. Great care being taken to remove enough of the skin, or the disease will still continue to a greater or less extent; and if too much be excised, another difficulty may be produced, viz., Ectropium. An entropium forceps, scissors, and two or three small suture needles are all that is required in the operation.

Dr. Pagenstecher, of Wiesbaden, recommends very highly a compound operation for the cure of severe cases of entropium and trichiasis, consisting of a combination of Gaillard's operation for entropium and the operation of blepharophimosis.

14. *Ectropium*, or *Eversion of the Eyelids*, is exactly the reverse of the preceding affection, the eyelids being turned outwardly instead of inwardly. The lower lid is more frequently affected than the upper, and it may be either total or partial. In the latter case, its seat is usually toward the external angle of the eye; sometimes both eyelids are affected, and this pathological condition has the name of *lagophthalmus*, or *hare's eye*, in which the lids are never perfectly closed during sleep, a portion of the eyeball being always exposed. This is generally considered by authors in a separate chapter, being in several respects somewhat different from ectropium, as it may exist without any eversion whatever, but as its treatment is about the same, I insert it here.

Ectropium presents three different degrees: 1st, the margin of the eyelid may be simply removed from the eyeball; 2nd, extension of the tarsus so as to expose all the internal mucous membrane of the lid to view; and 3rd, complete eversion of the eyelid so as to place the whole of its conjunctival surface externally.

The symptoms which accompany this affection are, a constant flow of tears, irritation of the conjunctiva which, exposed unceasingly to the contact of air and foreign particles, swells, ulcerates, becomes fungous or granulous, hypertrophied, and terminates by assuming the appearance of cartilage; the tarsus is then fixed on the cheek in the form of a crescent. Left to itself, ectropium will ultimately result in a loss of sight, owing to the repeated inflammations which follow each other, and which are owing to the fact that the ocular globe is constantly deprived of the protection of its lids.

The most frequent *causes* of this infirmity are, chronic inflammations of the conjunctiva, purulent ophthalmia, vicious cicatrices, wounds, abscesses, burns, paralysis of the orbicular muscle, and caries and necrosis of the orbital walls.

The *treatment* of ectropium is usually of a surgical nature; and

there are as many methods of operation as there are causes capable of producing the affection. In some instances, a light cauterization will be sufficient; in others, it will be necessary to excise a portion of the mucous membrane; and when the everted eyelid can not be made to cover the eyeball, as a last resource, the whole of the cicatrice is removed, and replaced by a flap of healthy skin borrowed from the neighboring parts, as, from the temple or cheek—this operation is termed *blepharoplasty*. It was first performed by the elder Gräfe, a German oculist, at the commencement of this century; since which, it has been perfected and performed by many surgeons, and in different ways. Most of the cases of ectropium depend upon certain conditions existing within the lid, and may be cured without excision, by using measures to overcome the affection of the lids occasioning the infirmity, and the frequent and long-continued application of astringents, as, Sulphate of Copper, Sulphate of Zinc, Perchloride of Iron, etc.,—which must be carefully applied only to that portion of the palpebral conjunctiva which is not involved in the eversion. Cases, in which the conjunctiva protruded most enormously, have been cured in this way by a patient and persevering treatment.

15. *Anchyloblepharon*, and *Symblepharon*. Following burns, wounds, and ulcerations, the margins of the eyelids may become adherent to each other, the eyeball remaining free; or, there may be adhesions between them and the ball. The first variety of adhesion is called *anchyloblepharon*, and is distinguished into *mediate*, where the adhesion is through the medium of a false membrane, or *immediate*, where the adhesion is direct without any intervening substance. It may also be *total*, involving the whole margin of the lids, except at the inner angle, or it may be *partial*, in which the adhesion is generally toward the outer angle. It may likewise be congenital, and frequently with an imperfect development of the eyeball. The second variety of adhesion is called *symblepharon*, in which the conjunctival surface of one or both eyelids adheres to that of the conjunctiva. Like the preceding it may be *mediate* or *immediate*, *total*, or *partial*. The *treatment* of these two pathological conditions of the eyelids is surgical, and consists in separating the adhesions by the knife, by ligature, or both. The operation requires care, together with subsequent measures to prevent re-adhesions taking place.

16. *Blepharophimosis* is a contraction of the eyelids due to contraction of the orbicular muscles. Patients who are subject to it, appear to have the eye smaller, deeper in the orbit, and present a singular physiognomy, especially when the eyeball can hardly be seen from occlusion of the lids. It is more commonly a congenital affection, and demands the aid of surgery.

17. *Ptoxis*, *Blepharoptosis*, palsy, or falling down of the upper lid, so as to interfere with vision. This disease may be congenital; may arise from an extension and relaxation of the skin of the eyelid; or, may be produced by paralysis, or injury of the levator palpebræ muscle. The paralysis is generally due to pressure upon the nerve of the third pair by tumors, or sanguineous, serous, or other effusion.

The *treatment*, when due to paralysis, will be to remove the cause by proper treatment, aided by the application of stimulants, electricity, solutions of strychnia, etc., to the affected lid, and its vicinity. If these fail, and there are no contra-indications, an attempt at relief may be made by surgical measures.

18. *Epicanthus*, a slight congenital deformity, occasionally seen in children, consisting of a crescentic fold of redundant skin, at the inner corner of each eye, extending from the root of the nose, and partly or wholly concealing the caruncula lachrymalis. Generally, as the bridge of the nose enlarges in after life, this fold of skin disappears. When this deformity is so great as to prevent the eyelids from being separated sufficiently apart to allow vision, it has been proposed to pinch up and remove a vertical fold of skin on the median line between the two eyebrows, and bring the wound accurately together by hare-lip suture.

19. *Trichiasis* and *Distichiasis*. The first is an irregular manner of growing, an inversion of, the eyelashes, in which they are turned against the eyeball. The second is the term applied to a supplementary row of abnormal eyelashes, or *false*, or *wild hairs*, as they are sometimes called, *pseudo-cilia*; more generally, they are the natural lashes, whose bulbs have become displaced. They are sometimes so very pale and fine as to require the aid of a lens to bring them into view, the lid being everted during the examination. These affections give rise to much irritation of the eye,

severe pain, intolerance of light, opacity and ulceration of the cornea. They are frequently present in entropium. Inverted eyelashes are the result of wounds, injuries from caustic substances, tinea ciliaris, chronic conjunctivitis, etc.

The *treatment* consists in carefully extracting the diseased lashes; using a forceps which will hold them firmly without cutting them, and extracting them slowly in a straight direction, so as to remove their roots. If plucked out with a sudden jerk, or in a wrong direction, they will break off, leaving a short end protruding from the margin of the lid, which will give rise to an increased irritation of the eye. Dr. Jas. Hunter states, "The best forceps are those made without teeth; the holding part being merely rough polished, so as not to cut the hairs. When the eyelashes are exquisitely fine, and slip through even the best made forceps, I have found it an infallible plan to damp their points with a saturated solution of shell-lac in alcohol, and to grasp the hairs for a second or two before pulling them." Usually, after this operation has been repeated two or three times, the lashes assume their normal condition.—If the inverted hairs still continue to appear, notwithstanding their repeated extraction, it will then be better to destroy the bulbs, which may be accomplished by a surgical operation, but more commonly, by introducing into the orifice, left immediately after the extraction of a lash, and carrying down to its bottom, a very small splinter of pine or other soft wood, which is moistened with pure Nitric Acid: this will occasion a sense of pain for a few moments only; should it be too severe the part may be bathed with some alkaline solution. If this operation fails, then a resort to surgical means will become necessary.

20. *Nictitation* may become morbidly frequent, and may depend upon an absence of the eyelashes and a state of permanent irritation of the marginal border of the eyelids, or it may be due to a spasmodic affection, producing a visible quivering of the lids, analogous to the twitchings observed in other parts of the body, especially of the mouth and nose. The twitchings are always noticed by other persons, and are quite annoying to the patient. If they be due to foreign particles in the eye, or a single everted eyelash, the removal of these will effect the cure. If occasioned by conjunctivitis, the removal of this inflammation, and protection of the eye from too intense light, by colored spectacles will answer. Sometimes the affection is incurable. At other times it may be removed under the influence of baths, quinia, and counter irritation; or,

by vermifuges, when intestinal irritation from worms is present. All internal stimulants must be avoided, as well as causes of mental excitement. *Twitching* or *Quivering* of the eyelids, also called "Life-blood," and *Blepharospasm*, or spasmodic closure of the lids, are analogous affections, requiring similar treatment. Sometimes tonics and antispasmodics, as Citrate of Iron, Valerianate of Quinia, Alcoholic Extract of Black Cohosh, with counter-irritation to nape of neck or behind the ears, and exposure of the lids to anodyne vapors, will be found useful, when aided by a rigid attention to hygienic measures—as well as by means to remove the cause, when this is ascertained.

21. *Tylosis*, or *Callosity of the Eyelids*. The eyelids frequently become thickened, indurated and knotty, from ophthalmia tarsi, and from excessive use of alcoholic liquors. It is a very difficult affection to cure. When connected with a strumous habit of body, in addition to local applications for the removal of the inflammatory and indurated condition of the eyelids, the appropriate constitutional measures must be pursued. If the affection is brought on by intemperance, *tylosis arthritica*, it is generally incurable; the only chance exists in restoring the biliary and digestive apparatus to a normal condition, and, at the same time, to overcome the morbid inflammatory action in the lids by local applications.

22. *Contusions, Ecchymosis, Burns, Scalds, Poisoned Wounds, Incised and Lacerated Wounds, Erythema, and Syphilitic Ulceration or Eruptions* of the lids, require the same treatment as described under Diseases of the Eyebrows, or, that is applicable to the same affections occurring in other parts of the body; requiring, however, more care in the use of local applications or in operations, on account of the peculiarities of the organ.—*Vitiligo* of the eyelids, yellowish or ochre-colored patches, of irregular shape, slightly elevated, and generally appearing on both sides of the face symmetrically. They are seated in the cutis, and appear chiefly in the loose skin of the lids, often spreading to the sides of the nose and cheeks. The treatment consists in measures directed to correct the faulty condition of the biliary and digestive apparatus, and fomenting the eyelids with vinegar and water. A permanent cure may be effected, without leaving a scar, by carefully excising them. (*See Pityriasis Versicolor*, page 1089.)—*Sycosis*, or a fig-like appearance of the lids from swelling of their ciliary margins and numerous pustules or

tubercles, is a very obstinate and annoying disease. The cure consists in an attention to the biliary and digestive apparatus, with caustics, as, Sulphate of Copper, to the tumor, and warm fomentations if too much irritation be produced. When the tubercles are few I prefer touching them every day or two with a stick of soft wood moistened with pure Nitric Acid. When there are many, or the disease is obstinate, the remedies recommended for Sycosis under Cutaneous Diseases may be used. (See page 1084.)—*Molluscum* or *Albuminous Tumor*, or *Glandiform Tumor*, is usually met with in children, and occasionally occurs among adults. Small, roundish tumors, varying in size from that of a pin head to that of a horse-bean, white, smooth, and shining, imbedded in the skin and subcutaneous cellular tissue of the eyelids, as well as in other parts of the face; sometimes their surface is rough and tuberculated. After a time, a small opening is formed at their apex, from which issues a milky fluid, especially on pressure, and which is of a contagious nature, reproducing the disease in those parts with which it comes in contact. I have cured these tumors by the application to them, every day or two, of a soft piece of wood dampened with Nitric Acid; this, however, will require two or three months to effect a cure. (See *Chalazion*, page 1365). If this fails, the tumor should be split open with a lancet, and its contents be forced out by pressure with the thumb-nails, or otherwise. If the patient be strumous, constitutional treatment should be adhered to for some months.—*Phlyctenulæ* or small watery vesicles of the ciliary margin of the lids, and *Milium*, a small white tumor, about the size of a pin's head, containing a suet-like substance, also situated on the margin of the lids, generally occur in elderly persons. When these become troublesome, they may be removed by opening them with a lancet, or snipping off their prominent part with scissors, and then pressing out their contents. If the internal surface of the cyst, after being emptied, is touched with Nitric Acid, or Nitrate of Silver, it will render them less liable to re-appear.

DISEASES OF THE LACHRYMAL APPARATUS.

The lachrymal apparatus is composed of anatomical elements having various functions, some designed to secrete tears, and others to carry them off. These different parts, the lachrymal gland, the lachrymal puncta and canals, the lachrymal sac, and the nasal duct, frequently become the seat of diseases rather difficult to cure, and which become greatly aggravated by rude, or improper manipulations.

1. *Lachrymal Xeroma*, or *Xerophthalmia*, is a condition in which there is a suppression of the secretion of tears, and may be due to a deficiency of nervous power in the lachrymal gland, or to an injured state of the ducts. It is more common among old persons than young, and is frequently an attendant on amaurosis, in which disease, a return of the secretion is to be considered a favorable indication, as the vision generally commences to improve. When due to want of nervous energy, sternutatories, and gentle stimulants, with internal *treatment* addressed to the nervous system will be proper. As it is more commonly a symptom of some affection, the treatment should be more especially directed to this. The eyeball, when dry, may be frequently moistened with a solution of Albumen one drachm, common Salt thirty-six grains, Water thirteen ounces; this should be applied tepid.

2. *Epiphora*, or an excessive secretion of tears, like the preceding, is usually a symptom instead of a disease, and, likewise, requires a *treatment* directed to the disease of which the overdischarge of tears is merely a symptom. The eye should, at the same time, be properly protected from irritating influences, as cold, dampness, high winds, dust, etc. Epiphora may be due to scrofulous ophthalmia, disordered digestion, intestinal worms, teething, etc.; it is more common among young persons than old, and is often cured, when there is no apparent cause for its presence, by the administration of an emetic or two, attention to the bowels, kidneys, and skin.

3. *Stillicidium Lachrymarum* differs from epiphora in this respect; stillicidium is due to some morbid condition of the organs destined to remove the tears after they have been secreted; epiphora is due to an overaction of the tear glands themselves, secreting this fluid in abnormal profusion. The cause of the difficulty must be detected, and properly treated.

4. *Chronic Inflammation of the Lachrymal Gland*, is generally met with among strumous constitutions. The gland is enlarged, with sometimes an œdematous swelling of the upper eyelid; pain is rarely present, but usually a sense of fullness above the eyeball, which can not be moved with the same freedom as the other; sometimes the globe will be displaced downward and inward. Pressure made between the eyeball and the outer extremity of the superior

margin of the orbit, will occasion a profuse discharge of tears. If the disease be allowed to progress, it may terminate in suppuration. The *treatment* consists in constitutional remedies, nourishing diet, and a proper attention to hygiene, together with mild counter-irritants to the temple, and in front of the ear, aided by local applications, to the gland, of a weak solution of Iodide of Ammonium, say three to six grains to one ounce of Water. If the eye becomes endangered, the gland should be extirpated.

5. *Fistula of the Lachrymal Gland, or True Lachrymal Fistula*, consists in a minute callous opening, located toward the outer extremity of the upper eyelid, through which tears trickle. This may be the result of an abscess of the lachrymal gland, it may also follow an ulceration, a burn, or any traumatic lesion of the upper lid. The disease is rare, and of difficult cure. Unless exceedingly troublesome, it should not be meddled with. Cures have been made in a few days, by passing a red-hot knitting-needle into the fistula, about a quarter of an inch deep, and turning it round on its axis several times. Caustics may also excite a sufficient degree of inflammation to effect a closure of the fistulous opening; a small probe may be coated with Nitrate of Silver or Sulphate of Copper, and passed into the opening at different times, each time with a rotatory motion. Or, Nitric Acid on a probe made of soft wood.

6. *Enlargements of and Tumors in or near the Lachrymal Gland*, as well as *Obstruction of its Excretory Canals* are not common affections, and belong more especially to the department of surgery, which alone can afford relief in these cases. When the obstruction is caused by mucus, this may be removed by the careful introduction of fine probes and injections. When the puncta are obstructed by a displaced hair, a foreign body, or a stony concretion, these may be extracted.

7. *Atony or Relaxation of the Puncta Lachrymalia and Canaliculi*. The lachrymal points and canals although wide open, and free throughout their whole extent, sometimes lose the faculty of absorbing the tears, from which arises a *stillicidium lachrymarum*, and a dryness of the corresponding nostril. This disease may be due to erysipelatous inflammation of the eyelids; to ophthalmia,

the result of exanthema; to the improper or too frequently repeated introduction of probes or injections into these minute canals; and, sometimes, it is associated with certain paralysis of the muscles of the face.

The *treatment* consists in the application of astringents or stimulants to restore tone to the debilitated walls of these organs. One of the following agents may be applied to the relaxed puncta, and also be dropped into the eye at its nasal angle, the patient lying upon his back during the application and for some minutes afterward. 1. Sulphate of Zinc one grain, Plantain Water one fluidounce; mix. 2. Sulphate of Copper one grain, Water one fluidounce; mix. 3. Perchloride of Iron one grain, Water one fluidounce; mix. 4. Tincture of Nux Vomica one drop, Water six to ten drops; mix.

8. *Chronic Inflammation of the Excreting Lachrymal Organs, Lachrymal Tumor, or Chronic Dacryocystitis.* This is a very common affection of the excreting lachrymal organs, and is due to a chronic irritation of the mucous membrane which lines the lachrymal passages. Under the influence of this condition, the membrane thickens and swells, and, as it is surrounded only by resisting osseous walls, the tumefaction tends inward, increases gradually, and ultimately obstructs the nasal canal. The tears, consequently, accumulating in the superior part, that is, the sac, distend it and form a tumor there, which, at a later period, if the mucous membrane is inflamed, becomes an abscess, which opening outwardly produces a fistula. Such is the more common mechanism of the formation of the tumor and of *fistula lachrymalis*, which are only one and the same disease at two different periods.

In some cases, however, the sac only is inflamed, and the mechanism is still more simple; but in others the fistula is more complicated, being associated with fungosities, a polypus, osseous denudations, caries, necrosis, etc., which constitute so many varieties of a great importance as far as choice of treatment is concerned.

The *causes* of this affection are numerous. Sometimes, it is due to an exanthematous disease, as, small-pox, scarlatina, measles, etc. At other times, it is a consequence of obstinate palpebral conjunctivitis, of inflammation of the bones and of the periosteum, of calculous concretions formed in the lachrymal sac, which, the same as a foreign body, irritate the mucous membrane, which swells and obstructs the canal. And again, lachrymal tumors are also de-

veloped by obstruction of the inferior orifice of the nasal canal by a foreign body arrested in the nostril.

This disease is more commonly connected with a strumous or scrofulous constitution; and, not unfrequently with syphilis. Its symptoms are aggravated by exposures to cold and moisture.

At the commencement of the disease, the *symptoms* are rarely observed by the patient; who, for a long time experiences only a slight watering of the eye, which increases and diminishes by intervals, and is more marked in winter than in summer. The action of bright light, wind, or dust increases the intensity of this phenomenon, which soon becomes accompanied with a little dryness of the nostril, corresponding with the side of the disease, more frequently the left, as lachrymal tumor is rarely observed on the right side. After a longer or shorter time, the skin and subjacent tissues become slightly swollen and doughy, and upon compressing them with the pulp of the finger, a transparent or whitish liquid will be seen to regurgitate through the lachrymal puncta, which is the lachrymal fluid changed in its composition by its mixture with the pathological secretion of the mucous membrane lining the sac. At this period the lachrymal tumor is fully formed, and many patients may be met with who have not even at this stage applied for medical aid.

The tumor, once formed, gradually increases in size, until it reaches that of a small bean; upon compressing it, it disappears by discharging, either through the nose or the lachrymal puncta, a fluid which is often ropy like the white of egg. Having reached this stage, the disease may remain stationary for several years, or even during life, becoming thoroughly cured, as may often be observed among young subjects. In the majority of cases, however, it does not subside, or become arrested, but advances in its progress. The secretion becomes purulent, and if it can not be completely evacuated externally, a more or less intense inflammation comes on, the skin reddens, then becomes thinner, and ulcerates, and the tumor spontaneously evacuates its contents through this opening. These inflammatory attacks being repeated several times, at length terminate by establishing one or several fistulous passages, from which a purulent matter constantly escapes, irritating the neighboring parts, rendering the margins of the cutaneous orifice hard and callous, and may even occasion necrosis or caries of the bones which form the walls of the sac and of the nasal canal.

The progress of this disease is essentially chronic. Left to itself, it has but little tendency to become cured; however, it sometimes becomes cured spontaneously by the complete development of the

osseous passage, at the period of puberty, when the nasal canal being enlarged, the tears flow off through their natural channel. Under all other circumstances, the disease persists, and sometimes becomes intractable to the most energetic and rational medication.

Differential Diagnosis. It must be observed that lachrymal tumor consists in a greater or less distension of the sac, accompanied with dryness of the corresponding nostril, watering of the eyes, a change in the character of the tears, as well as in the color of the skin in this region, itchings and obstructions in the inner canthus, and, finally, in the production of a tumor which, under pressure, yields a muco-purulent fluid, which passes either through the lachrymal puncta or through the nasal fossa.

In some cases, pressure will not cause a regurgitation, although the finger experiences the sensation of an accumulated fluid in the sac; the disease is then termed *encysted dropsy of the lachrymal sac*, or *mucocoele*, which must not be confounded with the disease under consideration.

Under some circumstances it may be difficult to determine a lachrymal tumor from a *fistula*; but, it must be remembered that, while in the tumor there is a discharge upon pressure, in fistula there is none whatever. There are fistulas which, at first sight, may be mistaken for a tumor, these are *capillary fistulas*, so named because of the narrowness of their canals; in this case, there is a tumor and fistula at the same time, and the association of these two degrees of the same affection renders the disease very annoying, for the tumor is constantly filling, and the patient is obliged to evacuate its contents, very frequently during the day, by repeated pressure.

Lachrymal tumor may be confounded with the commencement of an *abscess* external to the sac, for inflammation of the surrounding tissues, equally produces swelling, redness, abnormal injection of the eyelids and of the ocular conjunctiva, a more abundant secretion of tears, and dryness of the nostril. In such cases, we inject some warm water through the nasal canal, and if the injected liquid flows through the lachrymal puncta, we may conclude that the sac is free and is not the seat of the disease. We may also compress the sac, and ascertain whether any fluid passes through the puncta. These two tests will clear all doubts, and establish the diagnosis. If we recognize an *external abscess*, it must be punctured as soon as possible, being careful not to carry the puncture too deep lest the lachrymal sac be involved.

Cysts seated in front of the sac have also given rise to errors in diagnosis. To remove all uncertainty, we must refer to the antecedents, and it will be found that these cysts are always formed

without watering of the eyes, a phenomenon which is constant in affections of the lachrymal sac. Beside, cysts are always indolent, while in most cases a slight irritation accompanies lachrymal tumors. Injection through the nasal canal will also show whether the lachrymal passages are free, pressure with the finger will not cause any fluid to regurgitate through the lachrymal puncta, and, neither the characteristic mobility of cysts, nor the variations of size which are constant in diseases of the sac, are met with. The differential characters are summed up in the following table:

LACHRYMAL TUMOR.

It always commences with watering of the eyes, accompanied with dryness of the nostril, and often presents a slight inflammation; pressure gives issue to a fluid; an injection does not penetrate into the lachrymal passages, the tumor is fixed and frequently changes its volume at different times.

CYSTS IN THE REGION OF THE SAC.

There is never any watering of the eyes, any dryness of the nostril, nor inflammation; pressure does not occasion a discharge of fluid; an injection readily passes into the lachrymal passages, and the tumor is often moveable and does not vary in size at different times.

Fibrous tumors, and *exostoses*, may readily be distinguished, when in this region, from lachrymal tumor.

Finally, there are *small fistulas* resulting from an abscess developed at the internal angle of the eye, which have been allowed to rupture spontaneously, and subsequently been neglected. The patients state truly, that, at the commencement there was watering of the eyes, but if we carefully interrogate them, they will acknowledge that this weeping ceased as soon as the abscess ruptured. The weeping, in these cases, is due to the extension of the inflammation to the lining mucous membrane of the lachrymal puncta and canals, and when this has disappeared, the organs resume their functions and the weeping ceases. It is useful to probe the fistulous passage, and if the probe enters deeply, we may conclude that the sac is intact; and to be more certain, we may inject into the part.

Many medical men, in the *treatment* of this affection, commence at once by operative measures; each one employing the method which is the most familiar to him. This practice rarely effects happy results, and should be condemned and abandoned to its just value. I am fully convinced that the local affection can only be made to disappear by energetically combating the cause, and that constitutional medication has a larger share in the cure than the numberless surgical operations which encumber the most scientific treatises. Consequently, when we have diagnosed a lachrymal tumor or fistula, we should observe the temperament and constitution of the patient, and ascertain the relations which exist between

the local affection and any vicious diathesis with which his system may be tainted.

The treatment will be medical or surgical, according to the period of the disease; the medical being local and general. The *local medication* consists in frictions over the region of the sac and the side of the nose with resolvent ointments, such as, Ointment of Iodide of Ammonium (five parts to thirty parts of Lard); or, of Iodide of Cadmium (same proportions); Compound Ointment of Iodine, etc. Before applying these ointments, the sac should always be carefully emptied. Another very fine local application is composed of Hydrochlorate of Ammonia three grains, Chloride of Gold and Soda two grains, Water one fluidounce; mix. This may be applied to the nasal angle of the eye by a camel's-hair pencil, or, it may be poured in, the patient lying upon his back. If the lachrymal lacus be kept filled with this fluid for a few minutes each time it is used, the lachrymal sac having been previously emptied, some of it will be taken up by the puncta and carried into the sac, and thus be brought into direct contact with the diseased mucous membrane. Of course, previous to these applications, any active inflammation present, must first be lessened by appropriate measures. In connection with these applications, fumigations should be directed into the nasal fossa of the diseased side, and renewed several times a day; they act directly on the mucous membrane, diminish its inflammatory condition, render the accumulated fluids less consistent, and facilitate the passage of the tears. For this purpose I would recommend infusion of St. John's Wort, Marigold Flowers, Arnica Leaves, Lobelia, Sage, Rosemary, Figwort, etc. The infusion may be made in a large vessel having a very small funnel-shaped, open extremity, which may be passed into the nostril of the side corresponding to the tumor, and the part be fumigated for ten or fifteen minutes, after which the patient is to blow his nose. In place of carrying the small extremity of the vessel into the nostril, a very small elastic tube may have one end fitted upon the open extremity of the vessel, while the other is placed within the nostril. The fumigation being finished, the patient should snuff up into his nostril a small quantity of the fluid from the herbs, or else, a decoction of Walnut Leaves, Figwort Leaves, Pine Buds, or, a very dilute Solution of Chlorinated Soda.

Fomentations should also be applied to the eye, every night; and some one of the lotions applied to it two or three times a day, that are recommended in the treatment of Chronic Conjunctivitis. Ointments of solutions of lead, nitrate of silver, mercurials, etc., are of no value, and should be banished from our practice. The

same may be said of injections into the lachrymal puncta by means of Anel's syringe, they will be found useless, often injurious, aggravating the mischief by its mechanical irritation. Dixon states that the "remedy he has found most servicable is a little oval blister, about half an inch long, placed directly over the sac or tumor. This may be repeated every fortnight or so, according to the state of the skin, and the plan, to be efficacious, must be persevered in for several months." He also recommends astringent solutions to be dropped into the puncta, as, for instance, of Tannic Acid. An infusion of equal parts of Golden Seal and Geranium, will be found valuable.

The *general or constitutional medication* consists in the administration of those agents which are adapted to the particular taint present, as scrofulous, syphilitic, etc. Thus, the various preparations of Iodine or Bromine, as, Iodide of Potassium, Iodide of Ammonium, Bromide of Ammonium, Alterative or Scrofulous Syrups, etc., as advised under the heads of Scrofula, Syphilis, etc. Anemia will require chalybeates, as Iodide of Iron, Bromide of Iron, etc. Hygiene must be rigidly enforced, good nourishing diet, but to a moderate extent, exercise in open air, regularity of bowels, neutralizing acidity of stomach, and especial attentions to the skin, etc.

If the above treatment fails to effect the desired cure, after a persevering trial of it for ten or twelve months, it will then be proper by surgical measures to endeavor to restore the obstructed lachrymal passages to their normal condition. As there are many plans advised for this purpose, the reader is referred to treatises upon the surgical treatment of the eye, which is not within the scope of the present work.*

* Relative to these affections of the lachrymal organs, Dr. Jas. Dixon, of London, in his late work on Diseases of the Eye, makes the following remarks:

"When a patient applies to us, complaining of habitual watering of the eyes, we must first notice whether there is any displacement of the puncta. In the healthy state, these little apertures face toward the globe, and are in contact with its conjunctival surface, so that to bring them into view it is necessary to draw the margin of the tarsus slightly away from the eyeball. If, in consequence of *Chronic Ophthalmia*, the conjunctival lining of the lids has become considerably thickened, the edge of the tarsus will be sufficiently everted to cause the openings of the puncta to face upward, or even forward; and in that case they can no longer act as capillary tubes in taking up the tears, which, in consequence, trickle over the edge of the lower tarsus. Or the puncta still retaining their natural position, may have become so completely obliterated, in consequence of long-continued inflammation, that we may be unable to trace their original position.

"If, however, the puncta appear to be free, and in their natural situation, and yet no tears can be made to regurgitate through their openings, when the finger is pressed upon the sac, just below the tendon of the orbicularis muscle, we may

9. *Mucocele*, or *Dropsy of the Lachrymal Sac*, is characterized by a swelling of the lachrymal sac, of variable size, sometimes livid,

suspect some obstruction to exist in the canals themselves. To test this, a fine probe (punctum probe) must be passed along them. This is a manipulation in which the greatest care and gentleness are required, on account of the delicacy of their lining membrane, any rupture or abrasion of which would be followed by stricture, or, if the membrane were extensively torn, complete closure of the canal might ensue. The student must bear in mind the abrupt turn which the canal makes at a short distance from the punctum. In passing a probe into the lower one, for instance, *the instrument should be allowed to pass almost vertically downward for about half a line, and then turned inward toward the nose, in which direction it will pass—provided it meets with no obstruction—until it strikes against the inner wall of the lachrymal sac.* In practiced hands, a fine probe without a bulb may be used with advantage when the canal is very narrow, but the beginner should never trust himself to employ any but a bulbous-ended instrument; and even this, as I have said, must be carried forward in the most guarded and delicate manner. It was formerly recommended to carry on the probe through the lachrymal sac and nasal duct into the nose, so as to dilate any stricture that may exist in those parts; but the instrument employed is, of necessity, so slender, that it can not be guided with any certainty or precision through so long a passage; and injury to the lining membrane of the sac is almost certain to follow such fruitless attempts. If the obstruction in the sac or nasal duct be complete, and the canals and puncta be free, firm pressure of the finger just below the tendon of the orbicularis muscle, will cause the contents of the sac to escape at the puncta; but if the passage into the nose, although narrowed, be pervious, steady pressure in a direction downward, and a little backward, will commonly overcome the resistance of the stricture; the firm swelling caused by the distended sac then suddenly yields, and the fluid passes into the nostril.

"In the same way that chronic thickening of the conjunctiva will induce constriction of the punctum, just so will a similar condition of the lining membrane of the nostril cause obstruction or closure of the *outlet* of the nasal duct. Various attempts have, therefore, been made to dilate, from below, strictures of the duct and sac, by introducing sounds from the nostril; and tubes have been passed in through the same channel with the object of injecting astringent or stimulating fluids into the cavity of the distended and inflamed sac; but these attempts have ended in disappointment.

"I have already partly described the appearance of that distension of the sac which is attended with chronic inflammation of its lining membrane. The fluid which escapes from the puncta, when the sac is pressed, may assume the various appearances of tears, thickened with clear mucus, tears mixed with little curdy flakes of a yellowish or creamy color, or a fluid which seems to consist almost wholly of pus.

"If care be taken by the patient frequently to empty the sac into the nostril by pressure, the disease may remain for years almost stationary; under some catarrhal attack, however, or from some other cause, it may happen that this chronic affection of the sac suddenly changes its character; pain is felt in the part; the lids become red and puff;—sometimes to such an extent as to assume an erysipelatous appearance, and wholly to prevent the patient from separating the tarsi. In this state the swollen sac feels hard and unyielding, and even slight pressure over it causes extreme pain.

also hard or soft, but more generally elastic, not painful at first, though it may ultimately become very sensitive to the touch. When

"If allowed to run on, this inflammation ends in suppuration within the sac; the abscess discharges its contents by bursting just below the tendon of the orbicularis muscle, and the opening in the skin sometimes remains fistulous, allowing the tears which may pass through the puncta into the sac to escape on to the surface of the cheek, thus constituting a true *fistula lachrymalis*. When all inflammation has passed away, and the redness and swelling which attended the bursting of the abscess have disappeared, the fistula narrows to such a small aperture that, were it not for the tears which slowly distil from it, the opening would hardly be perceptible. It is about the size of a pin-hole, and except that it does not project above the surface of the skin, almost resembles one of the puncta themselves.

"The *Treatment of Distension of the Lachrymal Sac*, from chronic thickening of its lining membrane or stricture of the nasal duct, is very tedious. Injections of various fluids, either through the puncta or through the nasal duct, were formerly highly recommended, but have now fallen into disuse. The introduction of a *style*, to be permanently worn in the canal, is a step which should never be resorted to so long as any probability remains of restoring the passage by milder measures. . . . (See *Blister, etc., above, in text.*)

"When Acute Inflammation of the Sac comes on in the manner I have described, the best application is warm water dressing. Poultices are apt to irritate the skin of the lids, especially in children. Continued warmth and moisture are sometimes so effectual that, within twenty-four hours, not only do the redness and swelling of the lids wholly disappear, but the swollen membrane of the sac is so much relieved, that gentle pressure suffices to empty its contents into the nose, and the case returns to its chronic condition. If the swelling continues unchanged, it must then be freely opened, and treated like a common abscess.

"Endless varieties of surgical treatment have been devised for curing the chronic distension of the sac, or the stricture of its duct; pads, adjusted by means of springs or screws; catgut, introduced into the nasal duct through an incision in the anterior wall of the sac, strings of greater thickness being used as the canal would admit of their passage; metal tubes, which were intended to be healed in and quietly to occupy the sac and duct, but which Nature, with her dislike to foreign bodies, always rebelled against, and dislodged either upward or downward; styles, which should allow of the tears passing along them and so reaching the nostril;—all these contrivances have been tried, and with the exception of the last, pretty generally abandoned. The chief objection to the style (apart from its unsightly appearance) is that it requires management and care such as very few patients indeed can, or will, bestow upon it. They neglect to remove and cleanse it regularly, and when it sets up some irritation, as it occasionally will do, they probably remove it altogether, and are unable to replace it. These and other reasons had induced me many years ago to abandon its use.

"Mr. Bowman (*Med. Chir. Trans.* 1851, p. 338), has devised a very simple and useful operation, which, in many instances, suffices to cure troublesome Epiphora, while, at the same time, it affords a new and ready access to any obstruction that may exist in the course of the lachrymal canal. If, in consequence of chronic ophthalmia, or from any other cause, the lower *punctum lachrymale* has become displaced, so that instead of facing toward the globe, it is directed up-

pressed upon, no discharge of fluid occurs. This disease may continue for years without occasioning much inconvenience. The *treatment* consists in opening the tumor, thoroughly emptying it of its contents; and then, having examined the part and ascertained the cause of the mucocele, to treat it accordingly.

10. *Eversion of the Puncta Lachrymalis*, in which the puncta are displaced outwardly, so that they can no longer absorb the tears, may be present with ectropium, or other causes that will give rise to a thickening of the conjunctiva, or to its relaxation. A continuance of this affection may ultimately lead to a closure of these little

ward or forward, the tears will run over the edge of the tarsus. In such cases a small probe is to be passed along the whole course of the *canaliculus*, and held steady there, while a fine, sharp-pointed knife is run along the upper surface of the probe as far as the caruncle, so as completely to lay open the *canaliculus*, and thus, as it were, carry its orifice backward to the point where the tears accumulate. This little operation requires much care and nicety, and is facilitated by using a probe grooved to within a short distance of the end, so as to prevent the point of the knife slipping to one side. (A small, narrow-bladed knife should be used.) For several days after the incision has been made, a probe must be passed along its track, to prevent the lips of the wound growing together.

"If a stricture exists in the lachrymo-nasal canal, it may be reached through the now enlarged orifice of the *canaliculus*, through which a probe of suitable size is to be passed till its point is felt to strike against the inner wall of the sac. The probe is then raised into a nearly vertical position, and its point is very carefully carried forward until it meets with the stricture, through which it is to be passed until its point reaches the floor of the nostril. The frequency with which the probe is to be used depends upon the nature of the stricture.

"I would especially warn those who, from this slight sketch of the operation, may imagine that it is easy of performance, and that the subsequent cure of stricture in the lachrymo-nasal duct is to follow almost as a matter of course, to be very careful how they attempt either one or the other manipulation. The passage of an instrument through a stricture in the lachrymo-nasal duct demands even more care and skill than the passage of an instrument through a stricture in the urethra; and those who have seen much practice will bear me out in saying that by far the greater part of obstinate and dangerous cases of the latter kind are due to bad surgery, rather than to original disease. The student must bear in mind that the walls of the lachrymal sac and nasal canal are composed of extremely brittle and fragile bones, and that the rough introduction of a probe may either break some of these, or tear away the delicate and vascular membrane which covers them. Beside, as the canal is a bony tube, all thickening of its lining membrane must take place concentrically; and therefore any undue violence, by setting up inflammation, is sure to increase, instead of lessening, the cause of the stricture. Even when all possible care and skill have been employed, cases of stricture of the lachrymal passages are often extremely tedious; for they may be complicated with great dilatation of the sac; caries of the surrounding bones; or false passages, resulting from former errors of treatment."

orifices. The puncta may be kept open by the introduction of fine probes, until the disease occasioning the eversion has been overcome by proper treatment. If this should fail, prompt relief may be given, by the operation of Mr. Bowman, referred to in the Note on page 1385.

DISEASE OF THE NERVES OF THE EYE; MUSCLES.

1. *Strabismus* or *Squinting*,* is the existence of a want of harmony between the two visual axes, and more generally occasioned

* "Most persons are disposed to search for the essential or most common causes of strabismus, in the external influences; my opinion is wholly of an opposite character,—external causes have but a slight influence, the true cause is internal. In most cases, strabismus is only a symptom, and is associated as a consequence, with an anomaly of refraction. Among these anomalies, hypermetropia should be placed in the first rank.

"The first scientific ideas relative to hypermetropia are found in the work of M. Ruete. It has been recognised since, especially in its higher degrees of development, by MM. Stellwag Von Carion, and Græfe; as to the weak degrees, being concealed by the accommodation, they pass unperceived. We know that hypermetropia is that state of refraction in which the rays of light, parallel previous to their entering the eye, form a focus behind the retina. Among persons affected with it, the antero-posterior diameter of the eye is too short relatively to the focal length of its dioptric apparatus. With young persons, the accommodation annuls the latent hypermetropia either wholly or in part. If it is only in part, the entire inferiority of the absolute refractive power is composed of two parts, the one apparent, the other latent. Latent hypermetropia is concealed by the accommodation, even when a convex glass renders the accommodative effort, in a trial of distant vision, useless; we then determine it by atropine placed in the eye, which paralyses the accommodative faculty.

"In thus studying the state of refraction with different persons, and in a clinical point of view, we recognize that this disease is extremely frequent. Our statistics show that it is much more common than myopia. But this same clinical investigation, has revealed to us, as effects resulting from it, several symptoms much more worthy of attention, and which show that it is the productive cause of two maladies not yet fully understood, viz., asthenopia and convergent strabismus.

"Ordinary asthenopia, *hebetudo visus*, depends, in fact, upon hypermetropia; in extreme and exceptional cases, we encounter, beside, muscular asthenopia. Now, according to our statistic researches, among twenty cases of asthenopia, nineteen were hypermetropic. It is, therefore, difficult, not to observe in hypermetropia the material, anatomical condition, the cause of the functional disorder, asthenopia.

"From considerations which will be presently made known, we have been led to think that convergent strabismus was also associated, more or less directly, with these nineteen cases. We have analysed two hundred and eighty cases, in which the anatomical, optical, and mechanical conditions were determined as fully as possible; the extent and the limits of the movements of each eye were measured and separately specified; the latitude of accommodation and the

by certain abnormal conditions of refraction. When the affected eye is turned outwardly, it is termed *strabismus divergens*, and is

acuteness of vision were also ascertained; the age, and the period of commencement, the conditions presented by the subject, the complications, the preceding treatment, and the hereditary characters were carefully noted. We have thus found that among a hundred cases of convergent strabismus, seventy-seven had hypermetropia. And in the same manner have we been enabled to ascertain that in divergent strabismus, myopia occurs twice in every three cases.

"The comparison of these results certainly authorizes us to believe that anomalies of refraction are the original and more positive causes of convergent or divergent strabismus. As to the other causes, we must attribute them at first to the paralyses and the other primitive lesions of innervation. However, paralysis having existed a certain time, a muscle may be kept in the state of elongation or of relative relaxation, and this state may, consequently, be preserved, after the paralysis is cured.

"Specks on the cornea are also said to have determined strabismus; this being a material condition which provokes a change in the axis of vision. We do not share in this opinion. In rare cases, we see the consequences of an inflammation of the cornea extend by contiguity even to the muscles. But in the greater part of cases, specks on the cornea have been conditions favoring the origin of strabismus in cases of hypermetropia.

"We may now ask what mechanical relation is there between hypermetropia and its consecutive effect, strabismus. This truly requires an explanation. When an emmetropic eye looks at a distance, the axis of the cornea which we have been accustomed to consider, in this instance, as parallel, are not so at all; they very manifestly present a *divergence* of nearly ten degrees. Thus, in ordinary cases, the visual line, or the line which joins the optic center or the second nodal point to the center of the yellow spot, makes, with the axis of the cornea, an angle of five degrees, this last outwardly. This is a fact which has been found in an undoubted manner by MM. Senff, Helmholtz, and Knapp, and which has been established by myself in many cases. Such is the physiological condition. But it is not thus with myopes and hypermetropes.

"With the myopic subject this angle is much smaller. In some cases, there is a coincidence of the visual line and the axis of the cornea; in the higher degrees of myopia, the axis of the cornea is inside. We readily ascertain the cause of this in the distension which the deep-seated membranes undergo, a distension known by the name of 'posterior staphyloma.' The displacement of the optic nerve and of the yellow spot having occurred from without inward, the visual line may consequently be brought to coincide with the axis of the cornea, and may even pass beyond it. It follows from thence that, while looking at distant objects, the myope must present the appearance of convergent strabismus. In consequence of inverse conditions the hypermetrope, on the contrary, will present the appearance of divergent strabismus.—Now, we have just stated that hypermetropia was the cause of convergent strabismus; here is an apparent contradiction, which it is necessary to remove.

"In looking indifferently at distant objects, when no effort is made, the hypermetrope presents, to a close observer, a state of apparently divergent strabismus. But if the accommodative faculty is called into action in order to see them more distinctly, as the accommodation is confined within certain limits to the convergence, this condition of divergent strabismus must diminish in like propor-

almost always due to myopia; when it turns inwardly, it is called *strabismus convergens*, and is mostly due to hypermetropia. This

tion. We do not wish to state that the accommodation is measured exactly by the convergence, or this by the accommodation; but there nevertheless exists between them a connection and a certain degree of dependency. We may form an idea of it, by conceiving that, for the slight degrees of convergence, the accommodation will call into action about a half or one-third, for instance, of its whole power. The hypermetrope, with whom the accommodative power is more or less deficient, may have this defect relieved by means of the convergence. According to that, all hypermetropic persons would be inclined to converge, which is not the case.

"And why does it not occur more often? Because there is still a cause which must be taken into account, and of which we have not yet spoken. Convergence, by changing the direction of the visual lines, gives rise to double images, and we all have a horror of double images. The question then, is placed thus: there is a struggle between the accommodative force, the need of having distinct images, and the no less imperious necessity of having them simple. More commonly the accommodation is sacrificed; sometimes, however, simple binocular vision is sacrificed. This is what occurs, especially when there exists a notable difference in the two eyes, either in the degree of the anomaly of refraction, or in that of the acuteness of vision. In these cases, the least distinct image is unhesitatingly sacrificed. Then the convergence is fearlessly called to the assistance of the deficient accommodation, and a convergent strabismus is the consequence. This difference of acuteness or this amblyopia is often observed as an effect of astigmatism, or of weakness of the retina. Then the strabismus is developed while the deviating eye becomes more and more obscured.

"Although convergent strabismus must recognize hypermetropia as its principal cause, one apparently very singular fact should be referred to here; and which is, that in the higher degrees of this anomaly, strabismus is not met with. It is, however, easy to explain this apparent paradox;—thus, in these cases, the convergence itself is powerless to correct the anomaly, and to bring a sufficient degree of accommodation. The degrees of one-fifteenth to one-tenth of hypermetropia are those which give rise to most instances of strabismus. Then, indeed, the strabismus takes place to overcome the hypermetropia. We will also observe that, when strabismus is developed somewhat late, the hypermetropia is not very considerable.

"Such then is the more general circumstance to which we must attribute the production of convergent strabismus. Aside from the other etiological circumstances that have been named heretofore, we will not meet with more than two auxiliary conditions which, in some cases of hypermetropia, contribute to produce this affection. The first, is a certain inordinately natural facility to converge, a disposition which is connected with the insufficiency of action of the external rectus muscle. The second, belongs to external causes, the most frequent of which is a too great habitual lateral convergence, like that to which infants are subjected when the brilliancy of the light is all the time on the same side. Binocular vision does not exist in these cases, and one of the eyes may be turned inward without producing double images. But still, these causes, as has been remarked, do not produce strabismus, unless there is hypermetropia.

"Generally, strabismus is not hereditary, but hypermetropia is. But we must not forget that this does not inevitably involve strabismus,—strabismus is the

latter variety of squinting is by far the more common, and its frequency may be explained by the facility with which the eye can be

exception. In families where hypermetropia is very common, we will not fail to meet some cases of strabismus; they will be met with among those in whom one or several of the auxiliary conditions mentioned exist.

"Convergent strabismus due to hypermetropia assumes a particular form. It is ordinarily developed about the fifth or eighth year, when the eye commences to observe and to examine with more care; it is at first connected with fixation or looking steadily, and becomes constant at a further advanced period; double images, undoubtedly, are not complained of, because at the commencement it is only by looking steadily at an object that the deviation is developed, and that the second retinal image of the same object is considerably removed from the yellow spot. More frequently strabismus is simple and concomitant; however, in the healthy eye, the inward movement also goes too far, which is explained by the habit of holding the object looked at on the side of the deviating eye. By covering the properly-directed eye, the deviating eye, at first, still looks at the object, although the acuteness of its vision may already be diminished. At a later period, this eye is no longer fixed upon the object, but receives images on the remaining normal internal part of the retina; while, by the mental suppression of images on the yellow spot and on the external part of the retina, these parts have lost, in a great measure, their sensibility; and then the sensibility is not re-established. In this respect, an operation has no effect; however, the retina, when examined by the ophthalmoscope shows no change, and the cornea has not changed its form.

"When convergent strabismus is developed in any other manner, or presents different symptoms, we have a right to suppose that such cases are due to causes not connected with hypermetropia, as spasms, and especially paralyses, and inflammations,—but, as already stated, these cases are relatively very rare.

"*Treatment.* If, as statistics have demonstrated, hypermetropia is the most frequent cause of strabismus, our attention should first be directed to the prevention of strabismus by neutralizing the hypermetropia. For this purpose we must commence at an early period, and not permit the muscle to undergo the effects of a prolonged nutrition while it remains in a state of contraction. But if we are called upon when the affection has become chronic and the muscle contracted, the indication is, to operate. After which, neutralization of the hypermetropia by the employment of suitable convex glasses ought to immediately follow, in order to prevent a renewal of the strabismus. Very often, after a well-performed operation, we observe that the direction of the eye is perfect, while the accommodation is in a state of rest. But as soon as the person looks with attention at a near object, endeavoring to see it distinctly, the eye which sees the least clearly will deviate more or less inwardly. There is then still an effort of convergence associating itself with the effort of accommodation. This effort sometimes exists to as great an extent as it was before the operation. But the principal deviation, existing constantly, will no longer permit an extended movement, and certainly will not permit us to readily ascertain it. Now it is this effort which has saved the properly-directed eye from asthenopia.

"*Divergent Strabismus.* In cases of divergent strabismus our statistics show a proportion of two-thirds which may be charged to myopia. This proportion, like that relative to hypermetropia, clearly shows that, in its general etiology, strabismus must be attributed, as a consequence, to an anomaly of refraction. Persons

turned inwardly rather than outwardly, and by the size and power of the internal rectus muscle. Beside external or divergent, and internal or convergent strabismus, there are also several other varieties, as, *frontal*, or *sursumvergens*, in which the eye is turned directly upward, *jugal*, or *deorsumvergens*, in which it is turned directly downward; and *mixed* or *oblique*, in which the deviation occurs upwardly and inwardly, upwardly and outwardly, downward and inward, or downward and outward. Some persons have

having myopia in a high degree do not easily move their eyes. We will readily comprehend the reason of this, if we will remember the two following circumstances: 1st. A high degree of myopia is anatomically characterized by an absolute and considerable elongation of the antero-posterior axis of the globe, which we have sometimes known to attain even three times the demi-length of the normal eye. 2d. The center of motion of the globe (being on the optical axis, with both the myope and hypermetrope, at a point where, according to the researches of Donders and Doyer, the part situated in front is to the part situated behind the center of motion, as 15 is to 11) is at a distance from the posterior pole. This change of relative position of the center readily explains why myopes can not cause their eyeballs to execute any considerable movements; they can not, as a general rule, make them converge, and some can not turn them outwardly at all; their mobility in both directions is then very limited.

"Let us now look at these considerations laid down in the above remarks: That in the emmetropic eye, the macula lutea is generally found outside of the axis of the cornea, but that, on the contrary, with the myopic eye, in consequence of the distension of the deep-seated membranes, the macula is found removed either nearer the axis of the cornea, on this axis, or inside of it. It follows from this, that, for short distances, a double inconvenience interferes with the vision of the myope. On one side, he finds himself, for these short distances, in a state of considerable relative divergence, and in an equally abnormal difficulty to make this divergence cease. This relative divergent strabismus, very common among myopes, becomes, in some cases, an absolute strabismus; the two visual lines then no longer bear at the same time upon distant objects. The more obtuse eye, obedient to the natural tendency of the muscles, is turned outwardly, leaving the field of vision free to the other, and aiding, moreover, by that means, the relaxation of its accommodation. The double images incommode but very little; from the first, images of distant objects are not distinct in the myopic eye, and, beside, the *relative* divergent strabismus, having been in existence for a long time, has habituated the eye, as it were, to suppress the perception of double images. This physiological mechanism is especially observed in those circumstances where two very unequally myopic eyes are met with, or else an emmetropic eye associated with a considerably myopic one. In such cases, and for vision at great distances, a single eye serves; the binocular association giving rise to the tendency to divergent strabismus from the state of parallelism or of convergence, will by that means increase the accommodation and render vision so much more imperfect. Relative divergent strabismus then instinctively extends to the absolute form, in order to escape this inconvenience.—These developments very evidently show that, considered in its more general point of view, strabismus is not a primitive condition, but only a symptom. In three-fourths of the cases met with, it is the effect of an abnormal condition of refraction." (*Donders.*)

what is called an *intermittent* strabismus, which occurs when they bring small objects rather close to their eyes. These latter varieties are rare.

All the above forms of strabismus are simple; but there are also cases of *double strabismus* met with. Simple strabismus is a deviation of one eye only; double strabismus is one in which both eyes are affected.

Double strabismus is very readily recognized, when the deviation of both eyes is of equal degree, but, when one eye is more distorted than its congener, the diagnosis frequently becomes embarrassing. In such a case, we must carefully examine the extent of the movements of each eye, separately, the other eye being kept closed in the meanwhile; the patient should also be requested to look at us while we observe the relation of the optical axis with that of the orbital. In this position, these two axes make equal angles in the healthy state, and unequal angles when there is a deviation. The vision of an eye that squints is always weaker than that of the normal eye, especially when the strabismus has existed for many years. And, in double strabismus convergens, it is not uncommon for the eyes to be myopic, or even amaurotic.

There are cases in which the strabismus sometimes affects one eye, and then the other, the patient using the eye remaining in the normal position; this is termed *alternating strabismus*, but the most common cases are those in which the squinting is *non-alternating*, being constantly confined to the same eye; and in either case, being generally due to hypermetropia.

"We are readily able to detect non-alternating, as well as alternating strabismus, by desiring the patient to look steadily, with either of his eyes, at any object straight before him, while with our hand we hide the object from his other eye, but keep the hand sufficiently raised toward the temple to allow us to watch the movements of the eye which is thus shaded. Whether the strabismus is alternating or non-alternating, the shaded eye is distorted. If, in a such case, we close both eyes, and then suddenly raise the upper eyelid of either while the other remains closed, the one which is opened is seen to be distorted. If both eyes are suddenly opened, the pupil of the worse eye is discovered to be more distorted than that of the better eye. If, on trying these experiments, the eye which is shaded, or either of them on being opened suddenly, showed no obliquity, we would pronounce that eye to be sound, and assure the patient that the distortion of its fellow might be cured without operation, simply by exercising the squinting eye, with the other bandaged." (*Mackenzie*.)

The *causes* of strabismus are very numerous. The affection is seldom congenital, but is more frequently developed in infancy, a period of life in which the movements of the eyes being uncertain, they readily contract vicious directions. Indeed, infants sometimes become affected with strabismus after having been for some time in the care of a nurse who squints. The disease is frequently perpetuated in whole families for several successive generations, being the result of imitation. Hence, infants should not be allowed the society of persons or children who squint. Convulsions, which are so common among children from the influence of dentition, or of intestinal worms, may also determine strabismus; also cerebral affections, as, meningitis, encephalitis, tubercles, effusions, etc., all of which are capable of abnormally affecting the relative power of the motor organs of the eye, either in augmenting it by contraction, or in destroying it by paralysis. Ulcerations of the cornea, opacities of the lens, injuries, cataract, and certain forms of artificial pupil, are frequent causes of strabismus, as they require the patient to make prolonged efforts in order to observe objects around him, and force him to deviate his eyes so that the rays of light may penetrate through the still transparent parts. A suppurative inflammation of the orbit giving rise to adhesion, or compression of a tumor seated within the orbital cavity, may also occasion an abnormal direction of the eye. But the most common causes occasioning strabismus, are a hypermetropic or myopic condition of the eyes. (See Note on page 1387.)

There are different degrees of this affection. In true strabismus, the inner portion of the cornea is carried a little too much inwardly, yet a considerable portion of the white of the eye, between the caruncula lachrymalis and the cornea may be seen. This slight deviation of the eye is sometimes difficult to detect, but we may readily recognize it, by having the patient to look first at a near object, then at a distant one. Then, while he is attentively looking as directed, place an opaque body, as the hand, before one of his eyes; if the uncovered eye is the affected one, it will be seen to oscillate and execute some movements for the purpose of perceiving the object he is looking at. In what has been called *paralytic strabismus*, the white of the eye almost wholly disappears in the direction of the deviation. In what has been termed *optical strabismus*, the cornea wholly disappears under the eyelids.

Between these three degrees, however, there exist intermediary degrees, which give to the physiognomy a particular expression more or less painful. In all cases, certain symptoms accompany strabismus; thus, at first, patients frequently experience *diplopia* or

double sight, an annoying symptom which eventually disappears, the affected eye becoming weak and wholly inactive in the exercise of vision. At the same time, the healthy eye, compelled to supply the place of its fellow, soon becomes fatigued, and only able to sustain a slightly prolonged exercise. In some cases, vision is indistinct or hazy with the deviated eye, and which may be due to compression of the eyeball by the contracted muscle, to lack of exercise of the retina of the deviating eye, etc. This may be determined from myopia by means of a concave glass. If the patient is myopic, the glass will improve his sight, if, on the contrary, there is a commencing insensibility of the retina, the glass will be of no service in modifying his visual sensations.

The *treatment* of strabismus depends upon its character, and its degree of development. The most simple, and at the same time the most ancient curative method, consists in exercising the strabismic eye by itself. The healthy eye is covered with a bandage, and the affected eye is compelled to look at objects placed at a distance on the side opposite to the deviation. This exercise is performed several hours every day before a glass, so that the patient can observe the progress he is making toward a cure. After having pursued this ocular exercise for some time, he is then to endeavor to read a few moments, having the book placed in a direction opposite to that of the squint. The result of these prolonged manœuvres is to give more length to the shortened muscular tissue, and to gradually bring the eye in its normal direction. Unfortunately, this treatment requires great patience, and long perseverance, and most frequently fails in effecting any good result.

There are also other expedients; a German writer has advised the application of a patch of black silk upon the end of the nose, when the strabismus is divergent, and to the external and superior part of the cheek, when it is convergent, being careful to change the position of the patch every day, that the new sensation it determines may induce the patient to steadily look at it. By covering the normal eye, while this course is being practised, a more rapid and certain success may be had.

Goggles of various forms have also been used, in some cases with success. The best form is that in which the glass of an ordinary spectacles is replaced by a hard, caoutchouc shell, perforated at its center by a very small orifice, through which the light is to reach the eye; a piece of black silk is placed around the frame, so as to completely cover the orbit and prevent the least ray of light from entering the eye from that direction. This can be held in

place by an elastic band, passing from it around the head. If one eye is affected, the orifice in the rubber shell should be closed; if both eyes are distorted, both will require to be open. These means are only applicable to children, and have the objection of occasioning too much heat around the eyes.

If the patient be of adult age, we prefer spectacles with round glasses, a little larger than usual, so as to entirely cover the eyes, and so made that their centers correspond with the points which the two pupils ought to normally occupy. The glass on the healthy side is blackened throughout its whole extent by a dull opaque varnish, and that on the side of the affected eye is blackened vertically on only one half of it, and over the part which corresponds with the deviation. Around the eye-part of the spectacles black silk must be placed, as in the instance preceding.

There is a method preferable to this for adults, and which is the employment of prismatic concave lens, and which have, for the first time, been used successfully by M. Kurke, a German oculist. Indeed, the prismatic concave lens, of which the thicker edge is placed on the side toward which the eye should be directed, causes the image formed on the retina of the squinting eye to be shifted, or brought into such a position as to produce a diplopia very annoying to the patient, who, in order to relieve himself of it, is obliged to bring the relaxed muscle into a state of contraction, thus gradually effecting a cure, by persevering in the effort. One essential condition in applying this treatment, is to render the diplopia troublesome, and to so approximate it with simple vision, that an insensible effort of the eye will establish vision in its normal conditions. The angles of these lenses vary by degrees and half degrees. The use of them should always be commenced by a lens of a very obtuse degree; then, after eight or ten days, this is to be replaced by another one, which should be less obtuse by a half degree, and in this manner continue until glasses have been reached having parallel foci, when the patient will have his sight completely rectified. This mode of treating strabismus by means of graduated prismatic lenses, has in many instances given the most complete results. All other instruments for the same object are greatly inferior in value. A more prompt mode of effecting the cure of strabismus, is by means of an operation termed *Myotomy*, or, *Strabotomy*. It was first attempted in 1839, upon a child seven years of age, affected with convergent strabismus; it proved a complete success, and made a great noise throughout the scientific world. Since then, it has been repeated upon a great many patients, and with various results, sometimes fortunate and sometimes unfortu-

nate, so that some physicians, always ready to criticise and censure, and satisfied in being able to find a sufficient motive to banish it from their practice, do not hesitate to condemn it.

The object of the operation is to divide the muscle which causes the strabismus, and it has proved so generally successful, that the various other means of curing strabismus, are rarely if ever employed; which is to be regretted, as certain degrees of strabismus may be cured by a persevering use of them without an operation. Briefly, it is performed as follows: For convergent strabismus, the patient being seated, the eyelids are separated, and the globe is drawn toward the side opposite that of the deviation, then, after having raised a fold of conjunctiva with a mouse-toothed forceps, the portion of the conjunctiva raised being that over the lower edge of the internal rectus muscle, immediately over its insertion, and about two lines from the cornea, it is cut with a small scissors, so as to bring the muscle into view; a crotchet or probe-pointed knife is then passed under the muscle, and its section effected by scissors, or by the cutting edge of the probe-pointed knife. The operation with a fine, uniformly-rounded hook, and narrow, long, probe-pointed and sharp scissors, is generally preferred. The operation finished, the patient is requested to alternately open and close his eyes, so that we may observe whether parallelism is established. The consecutive treatment consists only of cooling lotions, as severe symptoms never occur; daily exercise of binocular vision with the stereoscope, in conjunction with glasses to correct any existing hypermetropia or myopia. When the strabismus is due to myopia or hypermetropia, the proper glasses to correct these defects must be worn, or the squint will return.—When the eye deviates to an extent of three lines or more, from the axis of vision, an operation may have to be performed on the internal recti muscles of both eyes.

It has been objected that myotomy often occasions strabismus in a contrary direction, with diplopia; this objection is not without some grounds; but, beside there being means by which to remedy this inconvenience, we may avoid it by attention, and by surrounding one's self with all the conditions indispensable to the safety and success of the operation.

In optical, fixed, and paralytic strabismus, and among old persons, the operation is never undertaken; the greatest success is obtained among those whose ages are between four and forty years. Persons who have very projecting eyes should not be operated upon, for it is with them that strabismus in a contrary direction is

produced with the greatest facility. When the strabismus is double, myotomy practised upon the eye having the greatest deviation, almost always suffices to straighten both eyes.

In divergent strabismus, the external muscle requires to be divided, the steps of the operation being similar to those already named for the convergent deviation. And in order to obtain a good result, especially in extreme cases, it is often necessary to force the eye to preserve an inversion for several days after the operation, so as to give the external muscle a chance to form its reunion with the eyeball at a point situated more posteriorly. This is done by putting a suture through a fold of conjunctiva at a short distance from the inner margin of the cornea, and carrying it through the skin at the inner angle. The eye should be kept as still as possible, until after three or four days, the suture cuts itself out, and the external muscle has formed the desired reunion. Concave glasses for the myopia, and exercises of binocular vision with the stereoscope, should likewise be practised subsequently.

Dr. James Dixon says: "The use of the ophthalmoscope should always be resorted to before an operation is performed. For some years past I have examined in this way nearly all the cases of strabismus which have come before me, and have detected a great variety of morbid changes in the deep tissues. In some instances, these changes were so considerable as to put all hope of improving vision quite out of the question, and yet no external sign of disease existed, except the faulty position of the eye. In most cases of single strabismus, there was marked impairment of sight in the squinting eye, and the ophthalmoscope showed the optic nerve to be smaller than natural, and of an oval form, the long axis of the oval being more or less transverse. I believe, therefore, that, in the large majority of cases of confirmed squint, the malposition of the eye is the result of morbid changes in the optic nerve itself."

Those who desire fuller details relative to strabismus and its treatment, are referred to Donder's work on the "Pathogeny of Squint," translated by E. P. Wright, M. D.; "Leçons sur le strabisme et la diplopie," etc., by F. Giraud Teulon; Wecker's "Études Ophthalmologique," etc.

The difference between strabismus and *lucitas* is, that in the latter affection the distorted eye is immovably fixed, so that it can not be directed upon an object when the healthy eye is closed, unless the head be rotated. It may be due to palsy, injuries, cerebral affections, tumors in the orbit, etc. The *treatment* will be that indicated for the cause of the difficulty. It is not always curable.

2. *Diplopia* or double vision may exist with two eyes, or with but one. If the former, when one eye is closed, the other will see objects single; this is due to misdirection of the two eyes, as in strabismus, paralysis of one or more muscles of the eyeball, morbid growths in the orbit which displace the globe, etc. Diplopy with a single eye is due to some defect in the dioptric apparatus,—a derangement in the refractive power,—it may also be due to partial opacity of the cornea, the lens, or its capsule, in which case, it can not be remedied until its cause is removed. In the other cases, the eyes should be bandaged and kept in a state of rest for some days or weeks, while general hygienic measures should be attended to. If these fail, the prismatic lenses, referred to under strabismus may be used, arranging them in such a manner as to shift the place of the image on one or on both retinae, thereby causing the objects to appear single. When the diplopy accompanies paralysis, or cerebral diseases, the cure of these will be followed by normal vision. Convalescents from severe febrile diseases, and those who study and overexert their eyes, are subject to double vision.

3. *Oscillation* of the eyeball, is a constant somewhat rotatory movement of the eyeball, to and fro on its antero-posterior axis, and is due to clonic convulsions of the oblique muscles. *Nystagmus* is a movement of the eyeball from side to side, round its vertical axis, and is due to clonic convulsions of the recti muscles. These irregular movements may accompany amaurosis, cataract, albinism, nervous affections, chorea, disease of the brain, etc., and especially in congenital cases. No successful treatment is yet known.

4. *Paralysis of the muscles of the eyeball or ophthalmoplegia.* The muscles of the eye are excited by three pairs of motory nerves, which are distributed as follows: The *third pair* to the levator palpebræ, the internal rectus, the superior and inferior recti, the inferior oblique, and, through the medium of the ophthalmic ganglion, to the circular fibres of the iris; the *fourth pair* to the superior oblique muscle; and the *sixth pair* to the external rectus.

This being the case, it would seem rational to study the paralysis of each of these nervous pairs in an especial paragraph, but as these affections are due to similar causes, as they manifest themselves by nearly similar symptoms, and as they require identical means of treatment, it will be better to condense their history in one and the same article, at the same time, however, noting those characters and

symptoms which establish important differences between them as far as diagnosis is concerned.

The *causes* of paralysis of the motor organs of the eye, are chiefly cerebral affections, rheumatism, or syphilis. With the first-named cause, the paralysis is always accompanied with numerous symptoms which attract the attention of the physician and serve to indicate its etiology; so that he may be led to attribute the paralytic affection to a vascular congestion, to a serous or purulent effusion, or to the presence of a cyst, tubercles, or tumors which compress the nervous filaments at their origin or at some part of their tract. With the second-named cause, the rheumatic nature of the disease may be deduced from previous exposures to cold and dampness, or to an anterior rheumatism affecting any part of the system. With regard to the third-named cause, the presence of an exostosis, gummatous tumors, cutaneous eruptions, glandular enlargements, or any primary or secondary syphilitic symptoms whatever, will materially enlighten the physician.—Other causes may also exist, as, lead poisoning, alterations in the blood, facial neuralgia, etc., all of which may give rise to paralysis of the nerves of the eye, and especially the third and the sixth pairs; in all these instances, aside from the paralysis, symptoms will be found which will reveal the true cause of the disease.

The *symptoms* of paralysis of the nerves of the eye, may be briefly summed up as follows:

1. *Paralysis of the third pair.* Hanging down of the upper eyelid; loss of the movements of the eyeball, upward, downward, and inward; a divergent strabismus, due to the activity of the external rectus muscle; mydriasis, or dilatation and immobility of the pupil; and diplopia, when the patient attempts to look in a direction opposite to the deviation of the eye. If to these symptoms, there is added an abnormal prominence of the eyeball at its inner part, we may affirm that the disease has its seat in the origin of the nerve. In cases where this prominence is very apparent, all the muscles of the eye are paralyzed, and the disease is called *ophthalmotopsis*.

2. *Paralysis of the fourth pair.* Diplopy characterised by the superposition of the two images, one being placed *above* the other, a diplopy which disappears when the patient leans his head to the side opposite to that of the paralyzed muscle. At the same time, when the patient carries his head alternately to the right and left, fixing his attention upon an object, it will be observed that the affected eye does not follow the movements of circumrotation of its fellow, but remains immovable.

3. *Paralysis of the sixth pair.* Fixed convergent strabismus (*lus-*

citae); diplopia; and difficulty or impossibility of turning the eye outward.

It will be seen that *diplopia* is a common symptom to each of these affections, but there is some difference in the character of this symptom, which will serve to indicate which nervous pair is paralyzed.—In paralysis of the third pair, the double vision is *crossed*, that is the image formed in the right eye is seen to the left, a feature readily appreciated by placing before the patient's eyes two glasses of different colors. Beside, the image formed in the strabismic eye appears confused and much less distinct.—In paralysis of the fourth pair, the diplopy is *superposed*, that is the upper image is formed by the healthy eye and the lower one by the affected eye.—In paralysis of the sixth pair, the diplopia is *homonymous*, that is the two images appear on the side of the eye where they are formed. If, for instance, we suppose that the left eye is affected, and consequently squints toward the inner angle, the image furnished by the diseased eye will be to the left of the one furnished by the healthy eye.

These differential characters are extremely important. It may be necessary to observe that the diplopia exists usually in the earlier stages of the paralysis, and after a certain time, patient's having acquired the habit of employing only the healthy eye, it completely disappears.

The *treatment* of these paralyzes consists of all the curative means applicable to the treatment of their causes, as, counter-irritants, stimulants, laxatives, specific agents, etc. In addition to which local measures may frequently be pursued with success.

Thus, in paralysis of the third pair, with hanging of the eyelid, and paralytic divergent strabismus, we may apply stimulating preparations about the eyebrows and lids, as camphor liniments, aromatic vapor douches, sulphur vapor douches, ointment of veratrina, aconitina, or of arnica; croton oil liniment to the temples, and in front of the ear, and when the paralysis is obstinate, strychnia may be applied to a denuded surface near the eye, and electro-magnetism be used.

Against the divergent strabismus, cauterization of the sclerotic conjunctiva with the fused nitrate of silver, upon the point corresponding to the paralyzed muscle, has been recommended. It may be repeated several times; and the eye should be exercised as named under strabismus. Dieffenbach and other eminent oculists have successfully pursued this course. It is especially indicated in those cases which are not due to some cerebral affection.

Mydriasis may be relieved by local stimulants applied in the

neighborhood of the eye, as Veratria, Aconitina, etc.; or a solution of Morphia, or of Calabar bean may be dropped into the eye. In some cases benefit will be derived by wearing dark opaque spectacles, having a small orifice in the center of each glass. Concave glasses are generally preferred.

Similar treatment will be required for paralysis of the fourth and sixth pairs of nerves.

5. *Neuralgia of the eyes.* The varieties of neuralgia more frequently met with, are, 1, *Frontal or supra-orbital neuralgia*; 2, *Infra-orbital neuralgia*; and, 3, *Ciliary neuralgia*. The *first* is characterized by a pain which commences at the supra-orbital foramen and extends to the eyebrows, forehead, upper eyelid, and root of the nose. The *second* is equally manifested by pain, but which emanates from the infra-orbital foramen, involving the lower eyelid, the ala of the nose, the cheek, and the inferior lip.

In each of these affections the conjunctiva of the eye corresponding to the side attacked, will be injected and red during the painful periods, and this injection will be accompanied by epiphora, photobia, and violent contractions of the lids; more frequently these maladies are intermittent.

The *treatment* will be the same in each, and consists of antiperiodics, narcotics, and in severe and obstinate cases, counter-irritants either behind or in front of the ear. The same internal agents may be given as described in the treatment of the following neuralgia.—Hypodermic injections of a solution of Muriate of Morphia will be found exceedingly beneficial in most cases.

Ciliary neuralgia has considerable analogy with the two preceding affections. Like them, it is remittent or intermittent, and often manifests itself after an exposure of the face to a current of cold air. In other instances, it results from an internal congestion of the eye, as, of the retina, and is then observed among persons who fatigue their eyes by prolonged reading, or who use too powerful glasses. It may likewise be due to twitchings of the ciliary nerves, the result of old adhesions of the iris.

This neuralgia is characterized by an exaggerated nictitation, a profuse epiphora, an intense photobia, and a violent contraction of the iris. At the same time, when the patients close the eyelids, sparkling luminous bodies appear to dance or flicker before their eyes, and, at intervals, they experience agonizing pains with tension and a smarting, burning pain in the interior of the eyeball. Some-

times the affection extends to the supra-orbital and infra-orbital nerves, occasioning a compound neuralgia.

Ciliary neuralgia is usually very obstinate, but if it be energetically treated from the commencement, it may disappear without being followed with any serious disturbance of the visual faculties. When it is allowed to become of long standing, it is very difficult to eradicate, discouraging both the patient and physician, and may lead to paralysis of the retina.

The *treatment* consists in keeping the bowels regular, attending to the skin, regulating the diet, exercise, etc., employing means to combat struma, anemia, or other conditions of the system, and also using internally antiperiodics and narcotics; in most cases counter-irritation will be necessary. The agents which may be employed internally, are the same as those laid down for Neuralgia, on page 306; and the Compound Tar Plaster should be worn behind the ear of the affected side, and be kept discharging for some time. Hypodermic injections in the temporal regions should not be forgotten.

Among the agents which have been found useful in these forms of neuralgia, are the following: 1. Take of Valerianate of Quinia fifteen grains; Extract of Belladonna, Extract of Hyoscyamus, three grains; mix, and divide into twenty pills, of which one may be taken every hour or two, according to their effect.

2. Take of Strychnia three-fourths of a grain; Sulphate of Quinia thirty grains; Extract of Aconite nine grains; Syrup of Morphia, a sufficient quantity to form into a pill-mass. Divide into twenty pills, of which one may be taken every four hours.

3. Valerianate of Iron one drachm; Extract of Belladonna forty-six grains; Extract of Aconite half a drachm; Simple Syrup, a sufficient quantity to form into a pill-mass. Divide into fifty pills, of which one may be taken every three or four hours. For anemic patients.

4. The following has been very strongly recommended: Take of Extract of Hyoscyamus half a drachm; Sulphate of Morphia a grain and a half; Strychnia a grain and a half; powdered Allspice half a drachm; Sulphate of Zinc fifteen grains; Simple Syrup, a sufficient quantity to form a pill-mass. Divide into forty pills. Dose, one pill every night and morning.

DISEASES OF THE EYEBALL.

EXTERNAL OPHTHALMIA.

1. *Chronic Inflammation of the Conjunctiva*, or *Chronic Conjunctivitis*. When any form of acute conjunctivitis is not cured, either from inefficient treatment, or from a continuance of the causes which gave rise to it, it will pass into a chronic condition, and will be attended with similar symptoms to those of the acute stage, but of much less intensity.

Inflammation of the conjunctiva presents a vermilion red or blood-shot appearance of the whole surface of the eye, or only a part of it; the color being deeper according to the intensity of the inflammation; the blood-vessels become enlarged, and tortuous, presenting the appearance of a finely-penciled *vascular net-work*, the color of which is deeper toward the orbit, but becoming more or less shaded as it approaches the cornea. Spots of extravasated blood are often seen under the conjunctiva. Increased mucous secretion generally attends the disease; and the pain accompanying is as though some rough substance, as sand, were under the eyelids, and which is generally worse in the morning, and does not extend to the head.

Chronic catarrhal conjunctivitis manifests itself under several forms, depending upon the character of the acute form and the various circumstances surrounding the patient. More generally the vessels of the conjunctiva seem to be in a state of complete atony; they increase in size, and extend in tortuous ramifications even to the circumference of the cornea; the eye readily weeps, secretes a more or less quantity of mucus, and becomes the seat of itchings or smartings, which are sometimes very severe. And these symptoms will often continue for months or even years, notwithstanding the most rational treatment. In some cases the eyes are red, weak, and irritable, the blood-vessels enlarged, and full of red blood, with more or less photobia, and a mucous, or muco-purulent secretion; the lids may be puffy and tumefied.

The *treatment* consists in the application of agents which will give tone and energy to the vascular and nervous vessels, arouse the absorbents, and thereby remove the chronic inflammation. Various agents have been employed for this purpose, the most efficacious among which are the following: Compound Myrrh Lotion; Com-

pound Lotion of Golden Seal; Compound Ointment of Oxide of Zinc; Compound Soda Lotion; Compound Lotion of Zinc; Lotion of Golden Seal and Aconite. One of these preparations must be dropped into the affected eye, three or four times daily,—a drop or two at a time.

Sulphate of Copper, as well as Sulphate of Iron, have also been found very excellent agents, in solution, to drop into the eye; either of them may be prepared by the solution of a grain and a half, or two grains of the sulphate to an ounce of water. Another collyrium, which has been used with considerable success is composed of Lapis Divinus* a grain and a half, Rock Candy one drachm, Tincture of Arnica two drachms, Distilled Water one ounce; mix.

In obstinate cases, counter-irritation to the temples, in front of, and behind the ears, alternately, will be found of much benefit.

The general health should be attended to, meeting anemia, rheumatic diathesis, struma, debility, syphilis, or any other conditions of the system, by appropriate treatment; and, also, removing the patient from the causes which produced the disease, the persistence of which is intimately associated with its chronicity. Change of air is frequently very beneficial.

If the disease be violent, the light should be excluded from both eyes; and it will be proper to carefully examine the palpebral conjunctiva daily, for the purpose of ascertaining whether they be rough and sarcomatous. If so, they will require the treatment named under *Granular Conjunctivitis*.

2. *Chronic Phlyctenular Conjunctivitis, or Scrofulous Ophthalmia.* This disease appears to more especially involve the *cornea* than the conjunctiva; and, although termed “scrofulous,” yet it will often be met with among patients who have no indications of such a taint, but who are anemic, or labor under some form of debility, etc. Children are more especially liable to it. It has been termed *Scrofulous* or *Ulcerative Corneitis*.

The *symptoms* resemble those present in the acute stage; epiphora, photobia, the eyelids being spasmodically closed, the eyebrows depressed, the cheeks drawn up, and the child holds his hands over the eyes to protect them from the light. On separating the lids, a

*Lapis Divinus is made by melting together, in a crucible, one ounce, each, of sulphate of copper, alum, and nitrate of potassa, and then adding to the melted mass a drachm and a half of powdered camphor. This is soluble in water; half a drachm dissolved in an ounce of water is employed as a collyrium to conjunctival vegetations.

flow of hot tears occurs, the edges of the eyelids will be found red and tumid, there will not be much vascular injection of the conjunctiva, although a few pinkish-colored vessels will be seen scattered around. Upon the cornea will be observed one or more slightly-elevated whitish points or phyletenulæ, a small, cloudy speck, or, more generally in the chronic form of the disease, one or more minute ulcers. And from this phyletenula or ulcer, may be traced a fasciculus of fine, pinkish-colored uleers, extending toward the circumference of the cornea. The cornea sometimes becomes hazy, with vessels traversing it in different directions; and softening, or a deposit of pus, may occur within its substance. Perforation of the cornea may result from the ulceration.

If the phyletenula recedes without bursting, the exudation of lymph which formed a sphere around the (now absorbed) pus, forms a round, smooth, slightly-elevated speck, which is opaque at its center, the opacity diminishing as the circumference is approached, and which speck is called *albugo*. If the phyletenula ruptures and forms an ulcer, the opaque cicatrix left by the ulcer is called *leucoma*. Protrusion of the iris (*myocephalon*), hernia of the cornea, iritis, etc., may be occasioned by this phyletenular disease.—It is often a very obstinate affection, and is very apt to return from slight exposure to the exciting causes, or from inattention. If ulcers exist, *leucoma* will undoubtedly remain; and, if the child be very young, and the speck be rather superficial, it may gradually be absorbed, so that, in adult age, vision will be restored.—Young persons who have once had an attack of this disease, are liable to amaurosis, glaucoma, etc., in after years.

The *treatment* of the acute form of this disease is rendered more difficult, owing to the opposition of the child to an examination of the affected eye as well as to the application of local remedies; and it will be found quite as difficult in the chronic stage, from the same causes. If we can secure the child's confidence and examine the eye with his consent, it will answer a much better purpose; but, if he is very obstinate, forcible means must be resorted to, by holding his head firmly between our knees, while making the examination, an attendant, at the same time, securing his hands.

Various methods have been advised for the cure of this disease, some of which have proved successful, while others are worse than useless. The treatment which has answered every purpose in my hands is the following: Take of Golden Seal two parts, Witch Hazel Leaves one part; make a strong decoction, and drop it into the affected eye, six or eight times a day. At the same time, drop into the eye, two or three times a day, a solution composed of Chlo-

ride of Gold and Soda three grains; Muriate of Ammonia six grains, Water one fluidounce. The whole surface of the body should be bathed daily with a warm, weak, alkaline water; the bowels should be kept regular; all acid and greasy diet must be avoided, and means be taken to neutralize acidity of the stomach; beside which, internal means must be adopted to allay irritability, strengthen the digestive power, improve the quality of the blood, and combat any peculiar constitutional abnormality that may be present. If the case be very obstinate, a powerful stimulating liniment may be applied to the back and sides of the neck, and upon the back as low down as between the shoulder-blades, every night; and, during the day, a sinapism to the back of the ear, and over the temple. This treatment, which I now publish for the first time, has never disappointed me.

Blisters, scarification of the conjunctiva, venesection or leeching, mercurial ointments, lotions of nitrate of silver, sulphate of zinc, lead, etc., should be wholly discarded in the treatment of this disease; although, sometimes, in case of vascularity and superficial ulceration, it has been recommended to divide the vascular ramifications, and to lightly touch the edges of the ulcers with the end of a well-polished pencil of Sulphate of Copper. And if the ulceration is central, threatening perforation of the cornea, the pupil should be kept dilated by a solution of Belladonna dropped into it; if, on the contrary, the ulceration is at the periphery of the cornea, the pupil should be kept contracted, in order to prevent prolapsus of the iris, and which may be effected by a few drops of a solution of Opium instilled into the eye, or a solution of the Calabar bean.

If, during treatment, any undue irritation should be manifested, lotions of Belladonna, Gelseminum, etc., may be dropped in the eye; or, it may be exposed to warm vapors from infusion of poppy leaves, lobelia leaves, hops, etc. The child must not be confined in a dark room; the eye may be protected by a thin, dark, silk shade. Local applications of the Compound Tincture of Myrrh, or of Tincture of Capsicum, have been recommended in this and the subsequent affection; but I have very seldom had occasion to employ them. When there is much pain in or about the eye, I apply cool or tepid water to the eye, stimulating applications to the temples, behind the ear, to the nape of the neck, etc., similar to the local course advised under the treatment of Chronic Sclerotitis. In obstinate cases, or in scrofulous persons, the mixture of Quinia, Black Cohosh, and Aconite, may be given internally with much advantage.

Any plastic deposit beneath the superficial layers of the cornea,

or on the conjunctiva, remaining as a result of phlyctenular conjunctivitis, may be removed, after several months of treatment, applying upon the part where the exudation exists, by means of a camel's-hair pencil, a drop of Oil of Turpentine, or, of equal parts of Oil of Turpentine and sweet Oil of Almonds. This may be applied every day, or every other day.

3. *Chronic Granular Conjunctivitis, Granular Conjunctiva, or Granular Lids (Trachoma)*. This morbid condition of the conjunctiva of the eyelids, and of the palpebral sinuses, is very apt to follow a long-continued conjunctivitis, especially those forms termed Purulent, and Catarrhal Ophthalmia. The affected conjunctiva presents a red, thickened, fleshy, rough and uneven appearance; and this lining membrane of the upper eyelid is more liable to the granulated condition, than the lower one. The disease rarely attacks the ocular conjunctiva.

Chronic granulations principally prevail among the poor, and those who are exposed to many privations; though the wealthy are by no means exempt from them. They are more frequently observed between the ages of fifteen and thirty-five, and very rarely previous to the eighth year of age, and after the fiftieth. Impure air, assembling of many persons in the same locality, imperfect or innutritious diet, exposures to dust, and contagion, are the principal causes. The disease is always of slow cure, requiring many months to effect it, if at all; and, in those cases where the patients are anemic, scrofulous, or cachectic, the disease will prove extremely intractable to treatment.

Although the term *granulation* has been applied to the peculiar condition of the palpebral conjunctiva under consideration, yet it must be remembered that the prominences observed are not true granulations, no ulceration of the conjunctiva having previously existed; but are merely the mucous follicles or papillæ of the membrane enlarged or hypertrophied from inflammation; or else, are "not an organized exudation, but a neoplasm due to a repullulation and to a division of the nuclei of the cellules of the cellular tissue* composing the conjunctiva." (*Wecker*.)

*"Two well marked kinds of granulations occur in practice. They may be scattered, buff-colored, translucent, hard granules the size of a pin head. These often produce a peculiar corneitis by their friction on the cornea; or the same result may ensue in another way. The granulations disappear, exudation matter is effused into the conjunctival tissue, and this by its contraction gradually bends in the lid to such a degree as often to occasion entropium, with all its

The disease must not be confounded with those minute phlyctenulæ which present themselves just within the margins of the eyelids, with more or less elevated yellowish points, arranged in a row, and which phlyctenulæ contain a grayish matter; these require to be excised or snipped to effect a cure. (See page 1375.)

Granulated lids are apt to be accompanied with epiphora, increased mucous discharge from the diseased conjunctiva, and irritation of the cornea with more or less vascularity and nebulosity; and, in long continued cases, pannus, epithelial thickening of the cornea, and opacity, and even ulceration. These conditions of the cornea are partly owing to the inflammation occasioning the granulation, and partly to the irritation produced by the granular lid, the roughness of which acts as a foreign body in passing over the surface of the eye. Wecker does not believe that the term "granulations," should be applied to enlarged or hypertrophied papillæ, but only to those formations that are a production of neoplastic tissue. He distinguishes three forms of granulation, all of which may be well examined by means of a magnifying lens and the employment of oblique light. These three forms are:

"1. *Simple Granulations*. We have these, when we observe the production of granules of neoplastic tissue, without the mucous membrane being inflamed. The conjunctiva is slightly injected, and the granulations are developed in the form of grayish, dispersed grains, and somewhat resembling cooked tapioca, the patient not being aware of the changes going on in his conjunctiva. Simple granulations are much more frequently observed when they are not of too old a date, and when they form upon the mucous membrane of the cul-de-sac, especially near the angles of the eye, slightly-elevated lenticular specks of a dirty-gray color; but we also meet with some cases in which the development of the granulations is very considerable, and in which, upon everting the superior lid, they form round semi-transparent grains, which look like pedicles to the orbital margin of the tarsus, without the mucous membrane manifesting any marked inflammatory reaction. This mode of appearance is far from being frequent; on the contrary, when the granules have once acquired a certain development, the

baneful consequences to the cornea. This form of granular conjunctivitis is the "conjunctivitis trachomatosa" of German authors. Or the granulations may be highly vascular and florid-red, bleeding at the least touch, large, closely-packed together, and assuming an angular contour from their mutual contact. This fungoid species of granulations occurs most frequently in Egyptian ophthalmia. The trachomatous variety of granulations is excessively difficult to cure radically." (Laurence and Moon.)

mucous membrane becomes inflamed, the papillæ commence to swell, to become more prominent, and then we have the second or mixed form of granulations.

“2. *Mixed Granulations.* Characterized by being formed partly of neoplastic tissue, and partly of swollen papillæ. It is not necessary that mixed granulations follow the simple form, that is to say, that the neoplastic formation alone must exist for sometime, and that at a later period the reactive inflammation of the mucous membrane must give rise to the swelling of the papillæ, and thus produce mixed granulations. It is much more frequently the case that a somewhat intense inflammatory action accompanies the development of the neoplastic tissue from its commencement, which favors the growth of hypertrophied papillæ, and which, being intermingled with the granulations, form what we term *mixed granulations*. On the other hand, we must not suppose that simple granulations must absolutely become transformed into mixed granulations.

“Some cases will be observed in which all the simple granulations, after having persisted some time, produce a slow inflammatory reaction, which, nevertheless, is not apt to produce papillary swelling, but which is sufficient for the resorption of the neoplastic tissue. When simple granulations are developed in great abundance, when the inflammatory reaction is active, and the papillæ acquire a great development, when mixed granulations are formed, and when the infiltration through the morbid tissue invades the deep-seated layers of the mucous membrane, we will have, after a short time, the third form of granulations.

“3. *Diffused Granulations.* Here a general infiltration seems to have invaded the mucous membrane; the granulations have lost their round, clearly circumscribed form; they are rather diffuse and are scarcely distinguished from a lighter color of the papillæ, which last form tubercles or rows of elevations with large pedicles, and are lost in the degenerated mucous membrane. Gradually the granulations lose their grayish color and become redder; the papillæ, in becoming covered with a thick layer of epithelium, acquire a grayish or brownish red color, so that at last it becomes almost impossible to determine whether the elevations on the conjunctiva are granulations or swollen papillæ. Microscopic examination can not clear up the question, because at this period the neoplastic tissue of granulations is transformed into the gelatinous mass heretofore named, a mass which seems as if infiltrated into the tissue of the mucous membrane. The papillæ have likewise changed, in consequence of their swelling and the serous infiltra-

tion, in their normal structure, and this gelatinous mass, not being limited, appears to be propagated into the tissues of the swollen papillæ.

"There are two signs that enable us distinguish these *diffused granulations* from a simple state of hypertrophy of the papillæ, signs that we have described with regard to purulent ophthalmia; 1. The cicatrices which result from an abundant production of granulations soon characterize this state by their presence; 2, the appearance of the cornea,—a more or less marked pannus will be observed, and will demonstrate the difference between the chronic state of purulence and that of diffuse granulations.

"Quite often the secretion will be much less abundant than it is in cases of chronic purulent ophthalmia. Beside, the papillary hypertrophy that accompanies purulent ophthalmia tends, from the relaxation of the mucous membrane and of the submucous tissue, to stretch the lids, and to the formation of an ectropion, while the contrary happens in diffused granulations, in which the production of cicatrices contracts the palpebral cleft, curves the tarsus, and causes an entropion with inversion of the cilia.

"*Complications.*—As a consequence of the profuse development of granulations, corneal complications often supervene. The pressure and the friction made by the granulations upon the cornea provoke alterations in this membrane, with a vascular development that we term *pannus*. This pannus almost always occupies the superior part of the cornea, so that upon seeing this limited vascularization, we may be certain of having a case of granulations without having yet examined the cornea. Opacification of the cornea is produced by an exudation between the epithelium and the transparent layer of Bowman. It disappears as soon as the injurious action from the friction of the granulations is removed. This pannus differs from that which is caused by the production of granulations on the cornea itself.

"In certain cases, the bulbar conjunctiva becomes invaded by the development of granulations which form small, grayish, non-vascularized protuberances, but surrounded by minute vessels. These granules become even developed upon the conjunctival limb; still later, we meet them on the cornea, where they present themselves under the form of small grayish infiltrations, between which the branches of the vessels run. The pannus due to this morbid production differs from the first in this respect. At a later period the surface of the cornea becomes very irregular and presents many small facettes; neither is the pannus so thoroughly limited to the superior part of the cornea, it may invade the whole of this mem-

brane. A considerable exudation is made between the epithelial layer and the membrane of Bowman, and many vessels pass from the conjunctiva upon the cornea. In consequence of this morbid transformation, the cornea soon loses its anterior consistence and becomes incapable of resisting the intra-ocular pressure; it yields and assumes a greater degree of curvature. This is a very grievous modification, for, should we be able to cure the granulations and cause the pannus to disappear, we can not remedy the amblyopia and the excessive myopia resulting from it.

“As soon as the purulence becomes associated with chronic granulations, ulcers and abscesses of the cornea may supervene, occasioning a perforation of this membrane, with all its terrible consequences, such as have been heretofore enumerated under purulent ophthalmia.—The pannus resulting from the friction of the granulations and the chronic irritation produced thereby, when it has become considerably developed and has reached over the whole extent of the cornea, seems to protect this membrane from the dangers which the purulent condition of the mucous membrane ordinarily induces against it.

“The *prognosis* will depend upon the amount and the extent of the neoplastic tissue deposited in the conjunctiva. Beside which, it will be dependant upon the period at which the patient places himself under treatment, and the hygienic conditions which he imposes upon himself. It is obvious that if the production of the granulations has not been very abundant, the patient may be cured after a certain interval, without the aid of treatment; on the other hand, if the production of the neoplastic tissue has been very abundant, if the infiltration through this tissue extends to the deep-seated parts of the mucous membrane, it will not be possible, even with the most careful treatment, for us to re-establish a normal state, because a certain part of the conjunctival tissue that has furnished the morbid production will be irrevocably lost. We will cure the disease more readily when it is submitted to treatment shortly after its commencement.

“The corneal complications, such as pannus, are especially to be dreaded when they are due to a production of granulations on this membrane, for a simple pannus on the superior part of the cornea becomes dissipated as soon as we cause the granulations to disappear and remove the friction they exert upon the ocular globe. It is not thus when the neoplastic production is in the cornea, a production which facilitates a softening of the corneal tissue, and which it is impossible to remedy. This membrane will then have lost forever its normal curvature, and a very considerable ambly-

opia due to the conicity of the cornea will persist, even after the mucous membrane returns to a normal condition. Beside the great danger presented by this complication, ulcers may be formed upon the cornea while the granulations are in the way of propagation, and a perforation, followed by a more or less complete loss of vision may be the result.

"As soon as we encounter a conjunctiva covered with granulations, with but little tendency of the mucous membrane to purulency, we should always be reserved in our prognosis. For we have to deal with a disease that is excessively slow to cure, and which, during the treatment, may present phases of purulence very pernicious for the cornea, so that we are never wholly certain what turn the disease may definitely take." (*Wecker.*)

In the *treatment* of granular conjunctiva great care must be taken to turn the affected lid (especially the superior) outwardly as much as possible when making our applications to it, so that they may come in contact with the whole of the affected surface; and, also, to retain the lid in this everted position for a minute or two after the application has been made. This is a very important measure, and to a neglect of which many oculists owe their failures in the treatment of this obstinate malady.

I generally make use of one of the Sulphate of Copper pencils, named in the note below,* moistening it and applying it thoroughly and carefully over all the granulated surface of the lid, and then immediately washing the part acted upon with cold water, by means

* I employ Sulphate of Copper with much advantage in the treatment of various affections of the eyes, in the form of pencils, made differently, thus:

1. Mix together pulverized Sulphate of Copper two parts, ordinary Potass Alum, pulverized, one part; place them in a porcelain vessel, and gradually melt them together. Pour the fused mass into a cylindrical mould of bronze or copper, in order to prevent the precipitation of metallic copper, the moulds having a diameter of about one-fourth of an inch.

2. Take of Sulphate of Copper one scruple, Alum half a scruple, White Sugar, Tragacanth, each, five grains. They must all be finely powdered. By means of a little water, form into pencils. This forms a mild caustic; in some cases the alum may be omitted.

3. Take of pulverized Sulphate of Copper four parts, pulverized Borax one part, mix, and briskly triturate together; the water of crystallization given out, unites them into a plastic mass, readily moulded into pencils.

4. Take of Nitrate of Silver one part, Nitrate of Potassa one or two parts, according to the strength desired. Mix, fuse together, and pour into silvered moulds. N. B. In all cases where these caustics are applied, after allowing them to exert an action upon the surfaces for a few seconds, the copper caustics should be washed off by means of a camel's-hair pencil and cool water, and a solution of Chloride of Sodium for the Nitrate of Silver caustics, thus neutralizing any excess of action.

of a camel's-hair pencil. In making this application, we must be careful not to injure any of the conjunctival tissue, lest we give rise to permanent cicatrices; the object is simply to excite, to develop a degree of vascularization or inflammation that will cause an absorption of the granulations. These local applications must not be made too frequently, but at certain intervals, every one, two, or three days, according to the effect produced by them; thus, when the irritation of one application has subsided, then make another, and so on—being careful never to overexcite the parts. During the intervals between these applications, the lids may be touched once or twice a day, with a strong solution of Salt; a weak solution of Perchloride of Iron; or, in some excessively irritable cases, with a weak solution of Sulphate of Morphia.

As a general rule, pannus, or opacities of the cornea, due to friction of the granulations upon the cornea, will disappear, as the granulations are removed; if the pannus should remain, it must be treated by pure Nitric Acid, as named hereafter. Should a low grade of inflammation become developed around the margin of the cornea, involving one or more of the coats of the eye, or, should an ulcer appear, decidedly the best treatment is to touch the parts two or three times a day with the preparation of Golden Seal, Tincture of Capsicum, Glycerin and Water, named under the treatment of Purulent Ophthalmia.—Other corneal difficulties that may remain after the disappearance of the granulations, must be treated as named under their respective heads.—Chronic granulations, under the best plans of treatment require many months for a cure; and, frequent relapses during the progress of the treatment are by no means uncommon, and should not discourage the patient nor the oculist. Their causes are not always easily determined.

In former years I made a successful employment of the following preparation, and have omitted its use of late merely because of the difficulty experienced in obtaining it: Through a stout piece of limb of Tag Alder (*Alnus Rubra*) bore lengthwise a hole about three-fourths of an inch in diameter, fill this with finely-powdered salt, and close it tightly at each end with a plug of hard wood. Place this into hot ashes, where it can remain three or four days, or until the limb is almost all charred, then remove it, split it open, take out the roll of salt, powder it very finely, and keep it in a well-closed vial. To use it, place some of it in a quill or other tube, raise the eyelid, and blow the powder beneath it. This may be repeated once or twice every day. Salt, if well prepared in this manner, is worth fifty cents per ounce.—Dr. Hays, of Philadelphia, recommends the use of Iodide of Zinc as a local application.

The solutions and powder of acetate of lead, and solution of nitrate of silver, ought never, in my opinion, to be used in this disease,—notwithstanding some oculists speak very much in praise of them.—Dr. James Dixon has found considerable benefit from undiluted Liquor Potassa, carefully applied to the palpebral granulations every three or four days.—Granulations of the lids may frequently be removed by the following ointment rubbed upon the affected parts two or three times a day: Take of finely-powdered Myrrh four grains, finely-powdered Elaterium two grains, Tallow one ounce; mix, and rub thoroughly together. I have used this with much success.

Finely-powdered Tannin is likewise an excellent application to granulations in many instances; or, a solution of Perchloride of Iron, or, of Chloride of Zinc. A concentrated solution of Chromic Acid has also been successfully applied, holding the lid from the eyeball until all the pain arising from its application has ceased, an indication that the acid has become inert and will not act upon the ocular conjunctiva. Whenever an application gives rise to inflammation, it must not be repeated until the inflammation caused by it has subsided, else the granulations will be apt to multiply.

Any undue irritation or inflammation of the conjunctiva, or of the eye, must be allayed by a solution of Morphia, or of Belladonna in Glycerin, which may be applied to the eye as often as required. Hypodermic injections of solution of Muriate of Morphia, in the temporal region will often be beneficial.

In addition to local measures, great attention must be paid to the general health of the patient, giving him tonics, chalybeates, antistrumous remedies, etc., according to the indications, having him protect himself from changes of weather, dust, smoke of all kinds, noxious vapors; regulating his diet, keeping the bowels, kidneys, and skin in as healthy a condition as possible, and allowing him a pure and bracing air.

4. *Chronic Ophthalmia.* This vague term may be applied to the several varieties of conjunctivitis, which have passed into a chronic form, and which is characterized by more or less redness about the edges and corners of the lids; tumefaction of the caruncula and semilunar fold of the conjunctiva; enlargement of the vessels of the conjunctiva, which presents a slightly villous appearance; watering of the eyes, especially when facing a cold wind; itching and pricking of the eyes by artificial light, with more or less of an iridescent halo observed around the flame of a lamp or candle by the affected eye;

and sticking together of the eyelids in the morning. One or several of these symptoms may be present, from a scarcely perceptible degree, to one of considerable severity.

In treating this disease the same measures may be pursued as advised under Chronic Conjunctivitis, page 1403. Artificial light should not be employed to read, write, or work by, unless the irritating effect of the light be modified by a pale neutral-blue chimney or shade. The excretory lachrymal apparatus should be carefully examined, when watering of the eyes is present, pressing upon the sac, and observing whether the discharged fluid is mucous, muco-purulent, or merely consists of tears. The lids should likewise be examined to ascertain whether any false hairs exist; the presence of these is frequently the sole cause of the intractability of many cases of chronic ophthalmia.

5. *Chronic Inflammation of the Sclerotica, or Chronic Scleritis.* Inflammation of the sclerotica presents a carmine or pink-colored appearance, under the conjunctiva, in a radiated or zonular form, the injected vessels being very minute, the color being deeper around the circumference of the cornea and gradually becoming lighter as it approaches the orbital periphery of the eye. No spots of extravasated blood are to be seen; there is no morbid discharge from the conjunctiva, and the pain is deep-seated and throbbing, and is described as being more around the eye, as in the temple, cheek, under the eyebrow, etc., than in the globe itself. Sometimes no pain at all will be experienced, or only a slight twitching pain. The pain, when present, is almost always worse during the night, commencing somewhere near sunset, gradually becoming more severe until midnight, then diminishing and passing away about daylight. Warmth is likewise apt to increase the pain.

The sclerotica being the fibrous coat of the eye, inflammation of it, has been termed "*Rheumatic Ophthalmia.*" It is very rare to meet with this disease in its simple form, it being more usually associated with catarrhal conjunctivitis, or "*Catarrho-rheumatic Ophthalmia,*" in which, the symptoms being mixed, we find the peculiar pink radiated appearance of the sclerotica, overspread by the vermillion-red vascular net-work of the conjunctiva. The disease may also be associated with iritis, and corneitis. Adults are more liable to the disease than children and old persons, and, ordinarily, one eye only is affected. The disease is almost always caused by exposure to cold and dampness.

The *symptoms* are similar to those of the acute form, but of much

less intensity; the severe pains in the temple, orbit, etc., are considerably diminished, or may not be at all experienced; there will be the peculiar redness of the inflamed parts; dimness of vision, as if a veil were before the eyes, and upon a close inspection, a slight cloudiness may be observed in the eye, the capsule of the aqueous humor being affected; when the iris becomes implicated, there will be a constant tendency to contraction of the pupil, and the movements of the iris will be less active than usual; an abundant flow of tears, especially when the conjunctiva is implicated; and more or less intolerance of light. In some cases, there will be more or less constitutional disturbance. Ordinarily, the chronic form of the disease involves only a part of the sclerotica, as indicated by the greater increase of vascular injection of the affected portion.—If the disease be left to itself, or be improperly treated, from a misunderstanding of its nature, vision may be destroyed from opacity of the anterior crystalline capsule, or closure of the pupil.

In the *treatment* of chronic sclerotitis, it is very seldom indeed that either local or general bleedings will be required. As revulsive measures, stimulating liniment may be applied behind the ear, to the sides and nape of the neck, and to the upper part of the back and spinal column; for this purpose the Compound Tincture of Camphor will be found especially useful. In addition to which, in very obstinate cases, sinapisms may also be applied to the same parts. The inferior extremities should be kept warm, especially in the night, during which period every precaution should be taken to avoid contracting a new cold, which is apt to occur in cold and damp weather, upon the slightest neglect. In order to prevent any structural changes in the iris from taking place, the pupil should, throughout its whole course, be kept under the influence of a mixture of Tincture of Belladonna twelve drops, Tincture of Gelseminum half a fluidrachm, Water, one fluidounce. This should be dropped in the eye, or be applied by means of a camel's-hair pencil, as often as found necessary to keep up dilatation of the pupil. Or a solution of Sulphate of Atropia, one to four grains to one fluidounce, may be used instead, applying a drop to the eye by means of a camel's-hair pencil, as often as required. A determination to the surface should also be maintained by diaphoretic agents, so as to produce gentle moisture. When the disease has lost its more active inflammatory symptoms, Sulphate of Quinia, one grain mixed with five grains of Compound Powder of Ipecacuanha and Opium, will be found extremely valuable in many cases. The bowels should be kept regular, but active purgation must be

avoided. While the rheumatic feature of the disease exists, the patient should be kept under the influence of the following preparation: Take of Tincture of Black Cohosh Root, Tincture of Colehium Seeds, each, one fluidounce, Tincture of Aconite three fluidrachms; mix. From ten to sixty drops may be administered in water, every two, three, or four hours, according to the symptoms, and the effects occasioned by the medicine.

If the disease obstinately persists, notwithstanding treatment, it will then become necessary, in addition to the measures already recommended, to administer agents indicated by the peculiar diathesis or tendencies of the system.

The diet must be regulated by the character of the symptoms, and in cool, damp, or windy weather the patient must remain within doors.

More commonly sclerotitis is associated with conjunctivitis, and the disease is then termed *catarrho-rheumatic ophthalmia*. This is a much more formidable affection than simple sclerotitis. The symptoms are a mixture of those peculiar to catarrhal conjunctivitis and to sclerotitis; sometimes the conjunctiva presenting more severe symptoms than the sclerotica; at other times, and indeed more frequently, the symptoms of sclerotic inflammation will be the more intense. The disease, like rheumatic iritis, appears to be limited to a period of three weeks, before a recovery will ensue from the acute attack; provided, in the meantime, no pupillary adhesions, or serious organic alterations occur, and which may generally be prevented by keeping up pupillary dilatation by solution of atropia, and subduing pain by the appropriate measures.

In the chronic form of this compound affection, the *symptoms* are much less severe than in the acute; the distinctive characters of the redness have already been pointed out; there will be more or less epiphora and intolerance of light; an adhesion of the lids in the morning; *chemosis*, or serous exudation of the subconjunctival cellular membrane, frequently occurs, occasioning an elevation or cedema of the conjunctiva around the cornea, this latter coat appearing, as it were, at the bottom of a circular cup; when this is present, the redness of the sclerotica will be concealed from sight; the cornea is also extremely liable to ulceration, or *onyx*, a deposit of pus between the layers of the cornea. The onyx may penetrate toward the outer surface of the cornea, or, it may burst into the anterior chamber, giving rise to *false hypopyon*. The ulcer is not usually very deep, but extends over the surface of the cornea, and

it often heals without any resulting opacity, but leaving the vision confused or indistinct,—when the ulcer does penetrate the substance of the cornea to any great depth, leucoma will be the result.

The color of the iris frequently changes, if blue, presenting a greenish tint; if blue-gray, a greenish-gray; if dark-brown, a reddish-brown; if bright-brown, a yellow-brown, etc.

By neglect or improper treatment, this disease may terminate in loss of vision from adhesion of the iris to the cornea, abscess of the cornea, partial staphyloma, obliteration of the pupil, etc. Among old persons, the disease is very liable to leave a greater or less permanent diminution of sight.

We may distinguish this disease from *catarrhal conjunctivitis* by the sclerotic vascular injection around the cornea, the pain in the temples and around the orbits, and by the cornea being much involved; from *simple sclerotitis*, by the conjunctivitis, the greater dimness of the cornea from exudation into it, and its abrupt marginal vessels; from *phlyctenular ophthalmia* by the age of the patient, and the pain in the temples and around the orbit; from *corneitis* by the great redness of the white of the eye, and the deep-seated grayish white opacity of the cornea, its roughness, dimness, and increased prominence; and from *iritis*, by the absence of any affection of the iris.

The *treatment* will be the same as advised in the preceding section for chronic sclerotitis, but more actively employed; and when the catarrhal conjunctivitis is very severe, the local means adapted to this variety of ophthalmia will be demanded, especially when the conjunctival affection does not yield to the other local measures pursued. In the chronic catarrhal form of this disease, after the more severe symptoms of the sclerotitis have subsided, the following collyrium will be found very valuable: Take of Elixir Vitriol six drops, Water two fluidounces; mix. Drop into the eye three or four times a day.

In this disease, when the eyeball feels tense, with orbital, temporal, or malar pains, compresses of cool or tepid water, applied upon the eye, changed frequently and continued, each time, for an hour or two will be found very valuable. Sometimes, a small stream of tepid water may be poured upon the temples for ten or fifteen minutes at a time. The following, rubbed around the orbit and temples will frequently afford great relief: Take of Aconitina four grains, Glycerin one fluidounce, Hydrocyanic Acid one fluidrachm; mix. It may also be safely applied upon the lids.

The following preparation will often be found of great benefit: Take of Sulphate of Quinia one scruple, Elixir Vitriol one flui-

drachm; mix, dissolve the Quinia, and add Tincture of Black Cohosh twelve fluidrachms, Tincture of Aconite Root two fluidrachms. The dose, is ten or twenty drops in a tablespoonful of water, to be repeated every hour or two. This will be found very valuable in all internal or rheumatic inflammations of the eye.—In many instances, the addition of one fluidrachm and a half of Tincture of Sulphate of Morphia* to the above, will be found to increase its efficacy very materially.

It may also be proper to state here that I have frequently seen the best results follow the use of the following solution, in all cases of rheumatic ophthalmia, in which the urine was of a low specific gravity, and deficient in urates and uric acid: Take of Tincture of Acetate of Iron one fluidounce, Acetate of Potassa half a fluidounce, Distilled Water seven fluidounces; mix. The dose is a fluidrachm or two every four hours. *Irido-choroiditis* may also be treated similarly.

A drop or two of a solution of Sulphate Atropia two grains, Distilled Water four fluidounces, may be placed upon the eye once or twice a day, to produce dilatation of the pupil, as well as for its anodyne effect.

6. *Scrofulous Sclerotitis. Sclerotico-choroiditis. Cirsophthalmia.* This is an affection frequently met with among strumous and debilitated constitutions, females being more subject to it than males, and may exist alone, or accompany any other inflammatory disease of the eye. In the first period, one or more enlarged and tortuous recto-muscular arteries will be observed running along the white of the eye toward the cornea, at or near the margin of which they ramify into smaller vessels; there is no general redness of the eye, nor much conjunctivitis, though there will be some thickening of the conjunctivitis; perhaps, also of the sclerotica; the pupil will be somewhat sluggish and dilated; and there may be more or less haziness of the cornea; with dimness of vision, intolerance of light, epiphora, and more or less pain. The disease may extend no further than just described, in which case vision may ultimately be restored after the subsidence of the inflammation.

If the disease progresses, however, the external coats of the eye become thinned and softened, so that the dark choroid membrane may be seen through the sclerotica, giving a blue or purplish color, and which symptom may be seen at a very early stage. This dis-

*The Tincture of Sulphate of Morphia for the above purpose is to be made by dissolving Sulphate of Morphia fifteen grains in Alcohol three fluidrachms.

coloration will vary in degree, according to the nature and obstinacy of the disease, and its most frequent situation is about a line, or nearly so, behind the margin of the cornea; it may be seen occupying only a portion of this margin, or completely surrounding the cornea. As the disease advances, this dark line gradually becomes broader.—In a short time the softened, thinned, and adherent sclerotica and choroid, bulges outwardly, usually near the cornea, between its margin and the attachments of the recti muscles, at which points the sclerotica is less firm. The protrusion may, however, occur at other points. There may be one or more protrusions, appearing like small tumors of various forms and sizes, in clusters or elongated rings, of a bluish-black color, with the separated fibres of the sclerotica appearing like whitish lines running from before backward. To these projections the name of *sclerotic staphyloma* has been given. Varicose vessels usually pervade the white of the eye.

In this disease, there may be aqueous effusions within the eyeball, either between the choroid and sclerotica, between the choroid and retina, or between the retina and the hyaloid, which effusions may either occasion, or augment, the staphyloma. The first is termed *subsclerotic dropsy*, the second *subchoroid dropsy*, and the third, in which the vitreous body is usually destroyed, *dropsy of the vitreous humor*. Permanent displacement of the pupil, slate color and projection of the iris, opacity of the cornea, especially of that part of its periphery near the diseased sclerotica, protrusion of the eyeball, etc., may also be the result of scrofulous scleritis. These staphylomatous tumors must not be confounded with certain blackish pigmentary spots which are frequently observed on the sclerotica; these spots are irregular, congenital, do not disturb the visual functions, and can not be removed.

When the disease involves the posterior part of the sclerotica, it is termed *posterior staphyloma*, which will be referred to hereafter.

When scrofulous scleritis has reached the chronic stage, it is rarely that its morbid results can be removed, although the progress of the disease may occasionally be completely checked. The best *treatment* is that calculated to remove the peculiar diathesis of the system, and which should be continued for a long time.

Regularity of the bowels and kidneys; attentions to the skin; tonics; alteratives, as, Iodide of Potassium, Iodide of Ammonium, Bromide of Potassium, etc.; Compound Tar Plaster, alternately behind the ear, to the nape of the neck, and between the shoulders; attention to diet, exercise, etc., are among the chief measures to be pursued. Local applications of Belladonna to the eye, and of

the solution of Muriate of Ammonia, and Chloride of Gold and Soda, on page 1405-6, may also be employed.

It is rarely, however, that any treatment will restore vision, or remove the staphyloma, or other morbid results; and when these become annoying, the case becomes a surgical one, in which the eye may be partially or totally extirpated; the former especially where an artificial eye can be adapted. (*See Sclerotic Staphyloma.*)

7. *Chronic Inflammation of the Cornea. Chronic Corneitis. C. Keratitis.* Although the cornea is more or less directly involved in most of the inflammatory conditions heretofore referred to in this chapter, yet there are certain affections which principally involve its proper substance.

In inflammation of the cornea the redness and vascular congestion is seated in the sclerotica, a plexus of very minute vessels being arranged in scattered radii around the upper or lower edge of the cornea, or in both situations, forming a crescent, a semi-circle, or almost a complete circle, and which may be readily seen by the aid of a magnifying lens. These vessels will extend into the proper substance of the cornea to the distance of from half a line to a line or more, resembling ecchymosed patches. Sometimes, the vascularity is so great, that the whole cornea becomes red, resembling light-red cloth, and which condition has been termed *pannus*; a white spot being observed at the center of the pannus or vascular radiation.

In chronic cases the *symptoms* are less severe than in the acute; there is epiphora, intolerance of light, but little or no pain, less vascularity of the cornea, though the blood-vessels running in the direction of the recti muscles will be considerably enlarged and extend over the cornea; the cornea is often rough, loses its transparency and polish, and presents a degree of dullness; dimness of vision, and slight haziness or opacity is a very early symptom, even when there is but little apparent vascularity. In some cases, especially among rheumatic and gouty persons, the blood-vessels on the surface of the eye will be found varicosely enlarged, and a bluish-white ring will be observed close to the edge of the cornea, with larger or smaller opaque spots in the cornea; there will also be much impairment of vision, lachrymation, and rheumatic or neuralgic pains around the orbit. And not unfrequently there will be a loose fold of thickened conjunctiva at the edge of the cornea, which may occasion so much irritation, as to demand its excision.

The consequences of corneitis are opacity of the cornea from

deposits in its tissue, suppuration or abscess, increased convexity of the cornea, softening of the cornea, etc.

Corneitis may be caused by exposure to cold and moisture, by living in small and badly-ventilated apartments, by bad, or insufficient food, by overexertion of the eyes, by injuries to the cornea, by some morbid condition of the fifth nerve, etc. It is usually a very obstinate disease, is apt to attack both eyes at the same time; or, if but one eye is attacked, the other becomes implicated as the first is getting well. Young children, and especially persons from ten to twenty years of age are more liable to it; and particularly those of a strumous habit; and also females at the period of puberty. Persons of strumous habit are very apt to be affected with some disease of the ear at the same time. The rheumatic or arthritic form is more apt to occur with persons further advanced in years.

The *treatment* will be very similar to that recommended for Scrofulous Ophthalmia; keeping the bowels regular; the skin in as healthy a condition as possible; administering tonics and alteratives, especially Sulphate of Quinia, and the Iodide or Bromide of Ammonia, with Pills of Chloride of Gold and Soda, as: Take of Chloride of Gold and Soda five grains, Muriate of Ammonia, or Starch, two drachms, Alcoholic Extract of Black Cohosh, a sufficient quantity. Mix, and form into a pill-mass, and divide into sixty pills, of which one is a dose; the dose may be repeated two or three times a day. Nourishing diet, warm clothing, and regular but moderate exercise in the open air, with protection of the eye from the light, if required, will also be necessary.

The local applications named for scrofulous ophthalmia should also be employed in corneitis; with Belladonna if there is any suspicion of iritis; and counter-irritants on the neck, and behind the ear, when the disease proves refractory. In the rheumatic variety, warm fomentations to the eye, the local employment of Belladonna, and internal remedies to produce a determination to the skin and overcome the rheumatic tendency, are indicated—similar to the treatment named under Catarrho-rheumatic Ophthalmia. In some cases, a treatment of twelve or eighteen months will be required in order to effect a cure of the disease. As a general rule, unless adhesions, ulcerations, abscesses, or other structural changes take place, the *prognosis* of the diseases referred to in this chapter, may be regarded as favorable.

Division of the ciliary muscle has been recommended for the cure of keratitis by Mr. Hancock, and has proved successful in the hands of several oculists. It is not, however, to be undertaken in inter-

stitial or syphilitic corneitis, in which antisymphilitics are especially indicated.

Ulcerations, and the other consequences of these affections will be treated upon hereafter.

CONTAGIOUS EXTERNAL OPHTHALMIA.

1. *Gonorrheal Ophthalmia. Gonorrheal Conjunctivitis.* This is one of the most formidable affections to which the eye is subject, being sometimes mild in its character, but, frequently, very violent in its attack and rapidly destructive in its results. It is undoubtedly caused by the application of gonorrheal matter to the eye, at least such has been the case in the instances that have occurred in my practice. It has been supposed to be metastatic, but I have no confidence whatever in such a supposition, and can only wonder that it should ever have been entertained for a single moment. There are various ways in which careless, filthy, or ignorant persons may convey the gonorrheal matter to their eyes, as, by means of the fingers, towels, handkerchief, etc. The disease is more common among males than females, and is, ordinarily, confined to but one eye, in which respect it differs from Egyptian ophthalmia; I have, however, met with several cases in which both eyes were affected.

The *symptoms* are, great vascular congestion; intense redness of the eye; excessive tumefaction of the conjunctiva; great chemosis; swelling of the lids; profuse yellow puriform discharge; general haziness of the cornea, etc. This history of the disease will afford us a clue to its character; but, we must not forget, that a person affected with gonorrhea may have an ophthalmia, without its necessarily being of gonorrheal origin.

Instances have occurred in which the eyes were lost within thirty-six hours from the period of inoculation, sloughing of the cornea having taken place in this short time.

In the severe form of the disease, there is more or less severe pain, both in the eye and in the head; the pain is often of a burning character, the eye also feeling as if it would burst. Sometimes there will be little or no pain experienced. As a general rule, the first stage is marked with pain, swelling and redness of the conjunctiva and lids; the second, by the puriform discharge and more intense chemosis; the swollen conjunctiva frequently overlapping the cornea all around, so that this, together with the swollen lids, will render it difficult, if not impossible to get a clear view of the cornea. In the third stage, the cornea becomes involved in the disease; it

becomes dull and hazy before it sloughs, but afterward it presents a dirty-yellowish, or brownish-opaque appearance, without polish or transparency, and wholly void of vitality. The more severe the attack the more rapidly will it run its course, depending somewhat on the general character of the constitution.

The *diagnosis* of the disease may be assisted by its history. In purulent ophthalmia the palpebral conjunctiva is the first affected; in gonorrheal, the ocular conjunctiva. The eyelids are swollen to a much greater extent in the purulent form. Purulent ophthalmia generally attacks both eyes at the same time; gonorrheal, ordinarily but one. Purulent ophthalmia presents granulations of the lid; gonorrheal, does not. The cornea is often destroyed by sloughing in the gonorrheal, but never or very rarely in the purulent form of ophthalmia.

The *prognosis* depends upon the severity of the disease, and the mischief it has effected. Where the whole cornea has sloughed off, or where a protrusion of the iris or lens occurs, vision can not be restored. If the cornea be hazy and dull, or white and nebulous, sight will be lost; if, however, the cornea retains its natural clearness, or if it only slough off partially, or if the ulceration be not extensive, the eye may often be saved without injury to vision. Great chemosis, profuse yellow discharge, intense redness and swelling of the upper eyelid are unfavorable symptoms, indicating excessive inflammation.

Gonorrheal inflammation of the eye may result in a flattening of the front of the eye, staphyloma, obliteration of the anterior chamber, obliteration of the pupil, opacity of the cornea, anterior adhesion of the iris, prolapsus of the iris, escape of the humors, and collapse of the globe, etc.

In this disease the *treatment* must be prompt and energetic. Active measures must be taken to promptly subdue the inflammatory symptoms, as, by sinapisms along the whole course of the spinal column, and behind the ear; with internal administration of a mixture of Tincture of Gelsemium one fluidounce, Tincture of Aconite one fluidrachm, of which twenty drops may be given for a dose, in a teaspoonful of water, repeating it every half hour or hour, according to its effects and the urgency of the case. The eye should be covered with a light compress, moistened with cold or warm water as may be found best suited to the case, as the effects of different temperatures will vary with patients. More generally cooling applications will be found the best. And, whether used warm or cold, the compress should be remoistened with the water, every ten or fifteen minutes, and then be re-applied, continuing

these measures unceasingly, until the inflammation has subsided. As a general rule, warm applications increase the heat, and thus augment the vascular disturbance. It will be proper to add Tincture of Belladonna, or Tincture of Stramonium, to the water, say, every three or four hours, in order to keep the pupil dilated, as the iris and other internal structures are apt to become implicated.—Hypodermic injections, a solution of the salts of Morphia, or of Atropia, made in the temporal region around the affected eye, will frequently reduce the intensity of the inflammatory action for a short time, so as to enable our other means to act with greater certainty.

Every half hour or hour, the following solution should be applied to the eye and beneath the eyelids, either by means of a camel's-hair pencil, or a small syringe, viz.: Take of Chloride of Gold and Soda ten grains, Distilled Water one fluidounce; mix. This course will generally save the eye, if commenced in time. If the chemosis be considerable, scarification or incision of the chemosed conjunctiva, close around the corneal margin has been found very advantageous; but I should hesitate to do this until after having well cleansed the eye of virus. The swelling of the parts may be so great as to render this operation almost impossible, unless the patient be placed under the influence of chloroform. After the incisions have been made, warm fomentations should be applied and continued for twenty-four hours or longer; and then astringent solutions, or one of the solutions named below, may be applied. Not forgetting, however, that we must not neglect in the meantime our antigonorrheal applications.

If, after the inflammation has been checked and the gonorrheal virus destroyed, there still remains a profuse purulent discharge, with paleness and flabbiness of the conjunctiva, the following preparation may be applied to the eye three or four times a day: Take of Strychnia one grain, Distilled Water two fluidounces; Nitric Acid four drops; mix, and dissolve. Or, the following may be used: Take of Sulphate of Quinia ten grains, Elixir Vitriol half a fluidrachm,—dissolve the Quinia in the Elixir, and then add Camphor Water half a fluidounce, Distilled Water one and a half fluidounces, Solution of Iodide of Iron fifteen minims. In some cases a solution of Tannin three or four grains to the ounce, will be found useful. But I generally prefer a continued use of the Gold solution.

The general system must be attended to during the treatment, keeping the bowels regular, the skin moist, allowing only a light diet, and having the patient in a state of quiet and rest, with the eyes carefully protected from the light, in the first stage; and per-

mitting a more generous and nourishing diet, with tonics, if necessary, and gentle exercise in the open air, in the second.

My colleague, Prof. A. J. Howe, has found the following a prompt and successful treatment in many instances: Place the patient under the influence of Chloroform, then evert the eyelids, cleanse them, and apply over their whole conjunctival surface, concentrated Nitric Acid. The acid is applied by means of a soft piece of wood, of proper shape, which is to be dipped into the acid, and any superfluous acid removed from it, by wiping the stick once over with a piece of bibulous paper. If chemosis be present, apply the acid likewise upon the chemosed part. If necessary, this application may be repeated two or three times. The treatment, in the meantime, is similar to that already named.

Dr. H. M. Collis states that he has found this formidable affection to yield with marvellous rapidity to repeated weak injections, as follows: Puncture the inflamed and œdematous conjunctiva, or, if necessary, snip it with the scissors. Then inject underneath the upper lid, from the external canthus across the eyeball, a weak solution of Nitrate of Silver, repeating the injections regularly every half hour for twenty-four or forty-eight hours, without any intermission. In very acute cases, a solution composed of one grain of Nitrate of Silver to four ounces of Distilled Water, should be injected every ten minutes for the first hour or two; after that a solution of two grains to the ounce of Water, should be used carefully every half hour. He has pursued this plan successfully for nine years.

2. *Purulent Ophthalmia. Granular Ophthalmia. Egyptian Ophthalmia. Military Ophthalmia.* This disease at its commencement resembles ordinary Catarrhal Conjunctivitis, but its progress is much more rapid. There will be great vascularity, bright redness, excessive tumefaction of the membrane and of the lids, and profuse discharge. The tumefaction of the conjunctiva (*chemosis*) is often so great, that this membrane will overlap and cover nearly the whole of the cornea. A sensation as of sand in the eyes, or of some other foreign body, is always experienced, and there is a deep-seated pain in the eyeball, more or less severe; with itchings of the eyes, incessant and excessive discharge of a thick and yellowish matter, with epiphora, and intolerance of light. The cornea becomes hazy, and granulations will be seen covering the palpebral conjunctiva. These granulations may be so small as to give a velvety appearance to the part, or they may attain the size of a lentil. The largest are

generally toward the middle of the palpebral conjunctiva, and become flattened by angular pressure against the eyeball. They vary in color from the darkest blood-red to the palest brick, or may be yellowish, depending upon the degree of vascular turgescence; and when excised or cauterized, no ulceration follows. The disease is originally seated in the conjunctiva of the eyelids, from which it extends to other parts from neglect or bad treatment; and sometimes, notwithstanding treatment, it will extend, frequently producing injurious effects upon the cornea and iris. Of course, these symptoms will be found to vary from a mild character to one of great violence; and, ultimately, the general system will suffer from the influence of the disease, in the more severe cases.

The *cause* of the disease is not fully understood. It is supposed to be propagated by contagion, though medical men differ on this point. It frequently occurs epidemically, and seems to depend upon some peculiar condition of the atmosphere; and, under some circumstances, there is no doubt but it may be produced by exposures to high winds, dust, cold, and moisture, by injuries, and by the other causes that may develop the catarrhal form.

The *diagnosis* of this disease is not very difficult.* The bright-

* Dr. J. De Kabath, of St. Petersburg, states that for more than twenty years he has had ample opportunities to investigate the nature of this disease in different localities throughout the Russian empire; that he has treated over twenty thousand cases, and has had three different attacks of it in his own person. He adds: "Facts prove that catarrhal ophthalmia, under certain conditions, as, for instance, certain atmospheric influences, the concentration of too great a number of soldiers into a barracks, want of air and light, damp soil, as well as other unfavorable hygienic conditions, that is to say, bad or insufficient nourishment, excessive fatigue, frequent colds, bad clothing," (exposure to dust, dry sand, or the hot rays from the sun), "may be transformed into a purulent or military ophthalmia, which then usually spreads itself by immediate contagion."

He classes conjunctival inflammations as follows: 1. *Catarrhal Conjunctivitis*, which is seated in the epithelium of the mucous membrane. The mucous membrane being a continuation of the skin, this disease may be compared to erythema of the skin. 2. *Granular Trachomatous Conjunctivitis*, also seated in the epidermis of the conjunctiva, but only in its deeper part, where the microscope granules of the conjunctival epidermis (trachoma) are found, and which are only verruca of the skin. 3. *Purulent Conjunctivitis* seated in the whole of the conjunctiva; it is the phlegmonous erysipelas of the skin. 4. *Diphtheritic Conjunctivitis*, also seated in the conjunctiva, with the difference that it furnishes more membranous plasma than purulent matter.

"Beside the means that should be taken to prevent immediate contagion, which are always of the highest importance, I adopt the cure of conjunctivitis by the abortive method, which consists in the introduction of a sufficient quantity of a saturated solution of Nitrate of Silver under the eyelids, so that the whole of the inferior and superior conjunctival surface is touched or moistened with it; after which the eyelids are to be covered with dry camphorated com-

red membrane, the chemosis, and the purulent discharge will discriminate it from catarrhal conjunctivitis. Beside, although one eye only may be affected, it is more common to observe the disease attacking both eyes. It may be determined from gonorrheal ophthalmia, which is usually confined to one eye, and in which the chemosis is greater, but the eyelids are not so much tumefied. Gonorrheal ophthalmia presents no granulations. It is of the utmost importance in this disease that the cornea be often examined; a thickened secretion over it may be mistaken for a haziness or opacity, but which mistake will not occur if the cornea be carefully wiped. Again, although ulceration may not be seen in the central part of the cornea, it may be situated at its margin, and be concealed by the overlapping of the chemosis.

The *prognosis* of purulent ophthalmia in the adult is not very favorable, especially when the inflammatory symptoms are intense, in which case the disease is frequently unmanageable. The cornea is the part most subject to the destructive effects of the inflammation. If it retains its natural transparency, vigorous treatment may arrest the inflammation; if it be dull, with deep-seated pain of the eye and head, indicative of extensive inflammation of the eyeball, the result will be doubtful. When the disease arises from contagion, it is apt to prove more severe and dangerous; epidemic and endemic cases are apt to be inveterate; sporadic cases are usually the mildest. Inflammation of a torpid character, especially in strumous systems, is less yielding to treatment, and more apt to affect the cornea, iris, etc.; irritable cases, also, present an unfavorable prognosis. After partial suppuration, considerable ulceration, or interstitial deposition, recovery of sight may happen, especially if these morbid changes in the cornea occur toward its circumference, and not at its center.

Purulent Ophthalmia may result in bursting of the cornea, suppuration of the cornea, ulceration of the cornea, interstitial deposition into the conjunctival covering, or throughout the corneal layers, opacity from cicatrization of ulcers, prolapsus of the iris,

presses—as the application of moisture upon the eyes appears to interfere with the action of the nitrate of silver. The instillation should be repeated once or twice a day, according to the severity of the purulent conjunctivitis. As soon as the purulent secretion ceases, the use of the silver must be omitted; the rest is the result of time. It is never necessary to destroy the mucous membrane in order to cure the disease. Not only have I never failed with this method, but I have never seen any unpleasant result from it.”—“Bestow all your attention to an investigation of the diseases of the mucous membrane, they are the most important diseases of the eye; more than half of the blind lose their moral and material existence, in consequence of attacks of these diseases.” (*Grubbi*.)

anterior synechia, loosening and thickening of the corneal mucous membrane, staphyloma, ectropium, or entropium.

In the *treatment* of the acute form of this disease, prompt and vigorous measures must be taken to subdue inflammation as promptly as possible, and to prevent the cornea from becoming involved in the disease; for the methods of doing which see "Scudder's Manual of Practice," and translation of Wecker, in the "Eclectic Medical Journal," Dec., 1865, and Jan., Feb. and March, 1866.

In the chronic form of the disease, cauterizations should be applied, and repeated, according to the degree of inflammation present. And they should be carefully brought into contact, not only with the conjunctiva of the lids, but also that of the cul-de-sac, as much as possible; and, if the ocular conjunctiva be affected, as it often is secondarily, and its vascularity and swelling do not disappear soon after our applications upon the palpebral conjunctiva, we will also have to make a few gentle cauterizations upon the affected ocular conjunctiva itself. Modified Nitrate of Silver, or pure Nitric Acid, upon a soft-wood porte-caustic, may be employed, re-applying them every day or two, so as to keep up a moderate degree of action in the parts, but not too much irritation or inflammation; and, during the intervals between the cauterizations, frequently bathing the eyes with a solution of Chloride of Gold and Soda; or, with a strong decoction of Golden Seal and Witch Hazel or Geranium; or of Black Cohosh and Geranium. Preparations of these articles will keep for a long time, when consisting of equal parts of Water (boiling at first) and Glycerin.

If there is a low grade of inflammation present, a kind of stasis in the vessels, or a tendency to ulceration of the cornea, the following may be applied once or twice every day with the most marked benefit, omitting its use whenever the parts have recovered a more healthy action, or when the irritation produced by it becomes persistent: Take of Golden Seal, in powder, one drachm, boiling Water half a fluidounce; mix together, and shake frequently. When cold, add Glycerin half a fluidounce, and let the mixture stand several days; then filter, and add Tincture of Capsicum six fluidrachms.—The vapor of Bisulphuret of Carbon applied to the eye, for about five minutes at a time, and repeated two or three times a day, will also be useful in many cases.

Sometimes much advantage will follow the application of an irritating lotion, or of a small blister, upon the temple and in front of the ear.

Constitutional treatment is also required, administering altera-

tives, tonics, chalybeates, etc., according as there is a tendency to struma, debility, or anemia, etc.

If granulations alone remain on the lids, the cornea and ocular conjunctiva being little, if at all injured, the same measures may be pursued as advised for Granular Conjunctivitis, on page 1412. If the granulations prove intractable to these means, they may be carefully touched, every five or six days, with pure Nitric Acid, by means of a soft-wood porte-caustic, as heretofore named.

3. *Ophthalmia Neonatorum. Ophthalmia of New-born Infants.* This affection is more generally due to inoculation with some morbid discharge from the vagina, as well as to the application of irritating substances to the infant's eyes. The principal *symptoms* are, a glueing together of the eyelashes, slight swelling and redness of the margins of the lids, red and swollen conjunctiva, and the conjunctival sac is filled with a yellow or greenish-yellow fluid, followed by a purulent secretion. These symptoms vary in intensity with different patients; the lids become red, smooth and velvety, and the purulent discharge may become so profuse as to flow over upon the infant's cheeks. If not promptly checked, the disease may terminate in corneal opacity, myopia, amblyopia, strabismus, corneal ulceration, corneal necrosis, capsulo-lenticular cataract, or staphyloma, etc.

I introduce this disease* here merely for the purpose of remarking that I have been very successful in treating it, in an advanced stage, when the tissues were not destroyed, by internal means addressed to the general system, and by the following local applications:

1. Take of Chloride of Gold and Soda four grains, Distilled Water one fluidounce; mix. Apply this three times a day. 2. Take of Golden Seal, Witch Hazel and White Indian Hemp, each, equal parts; make a strong decoction, filter, and when cool apply every hour or two, cleansing the eye with it. These collyria must be carefully applied beneath the lids, in the cul-de-sac, and on the eye, by means of a camel's-hair pencil; and between the application of the first and the second fluid, an interval of an hour should always be allowed to elapse. In some rare instances, a solution composed of Nitrate of Silver one or two grains, Distilled Water one fluidounce, may be substituted for the gold solution.

* For treatment of this malady from its commencement, see translation of Wecker, in "Eclectic Medical Journal," March No., 1866.

INTERNAL OPHTHALMIA.

1. *Chronic Inflammation of the Iris. Chronic Iritis.* Iritis may be produced or accompanied by rheumatism, gout, syphilis, etc., to which conditions the names have been applied of "rheumatic iritis," "syphilitic iritis," etc.; but, although the disease has been thus subdivided, in all instances these subdivisions are only modifications of one and the same affection.

In Iritis, the intensity of the redness of the vascular zone in the sclerotica, around the margin of the cornea, will convey some idea of the intensity of the inflammation; the color of the iris also changes, becoming green if the iris were naturally blue or gray, and reddish-brown if it were brown or black; the pupillary circle is somewhat of a pinkish color; the brilliancy of the iris is impaired or lost; the pupil becomes more or less deformed, losing its normal mobility; and one or several exudation spots of blood may be seen on the surface of the iris. Vision may be destroyed in a few days.

Chronic Iritis usually succeeds the acute form; sometimes, however, it may arise so imperceptibly, and progress so slowly to effusion of lymph, or loss of sight, as to hardly attract the patient's attention. In some cases, it is characterized by the vascularization of the iris, formed by two or three very delicate vessels which ramify around the pupillary opening; in others, by a mass of vessels which form variegated arborizations on the surface of the iris. At a later period, plastic exudations unite the borders of the pupil, which have become irregular; adhesions occur between the anterior crystalline capsule and the diaphragm of the iris; exudation spots appear on the surface of the iris, and their incomplete absorption leaves small black or yellow spots, appreciable at the bottom of the anterior chamber. These successive modifications are effected without any severe reaction, and the patient is aware of his disease only by the more and more considerable disturbance which diminishes his visual faculties. Frequently there is more or less pain, and intolerance of light, but these gradually disappear.

With these symptoms there will be a scrofulous, rheumatic, or syphilitic, condition of the system, which will modify the iritis by adding to it the symptoms peculiar to such condition, and render it, accordingly, more or less rapid in its progress, and more or less obstinate in its character. In the syphilitic form, the smaller circle of the iris is copper-colored, the pupil angularly deformed, the pupillary field will present lymphatic exudations, and on the pupil-

lary or ciliary margin of the iris, yellow or reddish-brown fibrinous, condylomatous growths, of various sizes, may often be observed.

Iritis may be *caused* by over-exertion of the eyes, long-continued examinations of minute or bright objects; blows on the eye; exposures to cold, and dampness; and by the application of gonorrhoeal or chancreous matter to the eye, constitutional syphilis, scrofula, etc.

The change of color in the iris; the deposition of lymph into the texture of the iris, usually confined to its inner circle, and which occasions the change of color in the iris; yellow, yellowish, or reddish-brown, small drops or tubercles, of varying sizes, deposited in any portion of the anterior surface of the iris; protrusion of the iris; sluggish motions of the iris; excessively-contracted pupil; dimness of sight from the commencement, gradually resulting in entire loss of vision; pain in the temple, brow, or cheek, together with the symptoms previously named, will assist in the *diagnosis*.

The *prognosis* will depend entirely upon the changes which have taken place in the eye. If the chronic form follows the acute, vision will probably be permanently lost; but, if it come on gradually, without having been preceded by the acute form, the eye may be restored to health, if taken in time, and the proper treatment be pursued. Any of the following results having taken place, the prognosis will be unfavorable:

The results of iritis which are unfavorable to vision, are, opacity of the cornea, considerable lymphatic exudation, adhesion of the iris, dropsical enlargement of the anterior chamber, with closed pupil, staphyloma scleroticæ, disorganization of the iris, adhesion of the pupillary margin, false cataract, or opaque adventitious membrane in the pupil, more or less complete closure of the pupil, atrophy of the globe, fluidity of the vitreous humor, amaurosis, etc. Myodesopia is a common result.

In the chronic stage of the disease, when the inflammation has wholly subsided, the effects of the disease upon the retina and the vitreous humor may be observed by the ophthalmoscope. (*See Ophthalmoscopic Examinations of the Retina, and of the Vitreous Humor.*)

Treatment. Any active inflammation must be subdued by a poultice applied over the eye, consisting of fresh Stramonium Leaves, bruised, and moistened. Or, if the fresh leaves can not be obtained, a drachm of the Extract of Stramonium may be dissolved in Glycerin a fluidounce, to which ten drops of Oil of Lobelia may be added; and this solution should be added, together with a sufficient quantity of Water, to Elm Bark, enough to form a poultice

for both eyes. This local means must be aided by purgatives, diuretics, and sudorifics; as well as by constitutional measures to combat the rheumatic, serofulous, or syphilitic condition of the system.

If there is a probability that the effusion of coagulable lymph, or the adhesions may be overcome by treatment, I would advise the following:

Apply to the eye, every two hours, a wash, composed of Chloride of Gold and Soda ten grains, Distilled Water one fluidounce. I have saved the eye in several instances by this wash, where chancreous matter had accidentally entered it, giving rise to symptoms threatening its rapid disorganization. In addition to this wash, the pupil should, if possible, be kept dilated by the occasional application of Belladonna, or solution of Atropia, which, however, will often be found an impossibility when there is an adhesion of the iris to capsule of the lens. Yet, these adhesions may frequently be detached, or elongated, by the use of atropia, so as to allow the iris to move freely, and prevent the formation of new adhesions. When the adhesions can not be removed or loosened by this means, a surgical operation may be required for their detachment.

Any debility or morbid sensibility of the eye remaining, in the chronic form of iritis, may, if the above solution of Gold and Soda be not stimulating enough, be overcome by one of the stimulating collyria heretofore named under the several forms of conjunctivitis. For the purpose of preventing lymphatic deposits, or causing their absorption when deposited, I know of no better agents than the Iodide, or Bromide of Ammonium, one of which may be administered during the whole course of the disease, commencing its use as soon as the more active inflammatory symptoms have subsided.

An irritating plaster should, in obstinate cases, be alternately placed behind the ear, and to the nape of the neck; if the patient be rheumatic, etc., adopt the constitutional treatment named for Rheumatism, Serofula, or Secondary Syphilis, together with tonics or chalybeates if he be debilitated or anemic. So long as zonular redness of the sclerotica, and dimness of vision exist, we may be certain that disease has not left the eye, and must persevere in our treatment.

2. *Chronic Crystalloïditis. Chronic Inflammation of the Crystalline Capsule.* This has been described as a disease coming on slowly, with little or no pain, or if pain be present, it is dull and seated in the forehead, the crown of the head, or deep in the orbit; there is also a varicose condition of the vessels; if the anterior hemisphere

of the capsule be affected, a vascular wreath may be seen upon its surface at about the distance of a quarter of a line from the pupillary edge of the iris, forming a concentric circle within the pupil, from which vessels radiate toward the circumference of the capsule; if the posterior hemisphere be affected, a deep-seated opacity will be observed, and the vessels are stellately arranged. *Muscæ volitantes* and more or less dimness of vision are usually present.

The *cause* of this affection is not well understood. It is undoubtedly more often a result of iritis, choroiditis, or the two combined. It proves exceedingly intractable to *treatment*, which should be similar to that pursued for chronic iritis.

3. *Chronic Aquo-capsulitis. Kerato-iritis.* This is an inflammation of the walls of the aqueous chambers, and especially of the membrane of Descemet, (posterior elastic lamina of the cornea), and the anterior surface of the iris. In the acute form the *symptoms* very nearly resemble those of rheumatic ophthalmia. In the chronic stage there is more or less dimness and opacity of the cornea; a diffused muddiness in the anterior chamber; a number of circumscribed grayish or yellowish-white spots, often very numerous, and generally on the lower half of the internal surface of the cornea, giving a mottled appearance to it. The iris loses its brilliancy and color; the pupil is sluggish, or immovable, and when the corneal opacity is not too great, flakes of lymph may be seen in the aqueous humor; there is an increased accumulation of aqueous humor, causing a distension, if not prominence of the cornea, or the iris may be pressed backward assuming a funnel form. Sometimes, hypopium is present. The patient usually complains of a sense of fullness and distension in the eyeball, a dull aching pain in the forehead, and sometimes in the back part of the head. The pains are generally worse at night. Vision is disturbed according to the opacity and lymphatic exudation; though sometimes the patient will hardly see at all in the morning, but much better toward evening, in which case the minute spots, or depositions of lymph on the inner surface of the cornea, above referred to, will be observed to spontaneously appear and disappear.

The disease most commonly affects persons below middle age; and is liable to relapses. Its *causes* are long-continued overexertion of the eyes; suppressed perspiration; slight blows on the eye, exposure to cold, etc.

The disease may be *distinguished* from *corneitis* by the deep situation of the corneal opacity, or of its mottled appearance; and this

opacity, together with the changes in the iris, will determine it from simple *iritis*. The chronic form of the disease is very obstinate.

The *treatment* for chronic aquo-capsulitis will be the same as that named for Chronic Iritis, with tonics and alteratives internally. The Quinia and Cohosh Tincture on page 1418, will be found very valuable. Belladonna to dilate the pupil, is especially of use to prevent adhesions of the iris, or to loosen them when formed but slightly. The opaque depositions may often be removed by exposing the eye to the vapor of hydrocyanic acid or of bisulphuret of carbon, for ten or fifteen minutes every day.

4. *Chronic Choroiditis. Chronic Inflammation of the Choroid. Arthritic Posterior Internal Ophthalmia.* The history of choroiditis has remained in obscurity for a long time; and it is only since the discovery of the ophthalmoscope, that correct views of it have been held. Until this discovery, the morbid changes produced in the choroid by inflammation, as well as those developed in the retina, two membranes of great vascularity, were unknown or confounded under the names of *internal ophthalmia* or *amaurosis*, when they were associated with a subacute or chronic state. I will endeavor to briefly relate what properly belongs to this affection.

Choroiditis may exist in the acute form, which more generally supervenes on the chronic; it is a rare affection, and runs through its course rapidly, sometimes destroying vision in a single night; and the greater part of patients laboring under it, require medical assistance only after the acute stage has nearly passed, and then not for the inflammation itself but for the lesions occasioned by it. More commonly, choroiditis is chronic in its character, advancing slowly and insidiously, and presenting itself under two forms, viz.: 1. *Hyperemia or congestion of the choroid*, and, 2, *Exudative Choroiditis, or Chronic Choroiditis proper*. Properly speaking, these two forms are only two subsequent degrees of one and the same malady. Some authors describe a third form under the name of *Atrophy of the Choroid*; this will be referred to hereafter.

Choroidal congestion is generally serious according to the length of time it has lasted. One eye alone may be affected, but sometimes both, the affection in one generally succeeding that of the other.

It is very important to know the *causes* of choroiditis, for upon them rests the principal indications upon which the treatment is based. These causes are numerous, and have been divided into predisposing and exciting. Among the *predisposing causes*, it has

been remarked that persons advanced in life, and especially females, who have suffered from piles, headaches, derangements of the digestive organs, etc., are more predisposed to it. Also that individuals with black hair, dark complexion, prominent, expressive eyes, of robust appearance, are more frequently attacked with the disease than those who do not present these particular conditions. It is also met with among rheumatic subjects. Persons subject to this affection are apt to have large and indolent pupils; large varicose vessels running across the dark and dirty-looking white of the eye; the margins of the eyelids swollen and pervaded by large vessels; a sense of fullness in the eyeball; muscæ; occasionally seeing bright sparks or luminous spots, flame, etc.; and temporary dimness of vision after stooping, or being heated, etc. (*Jones.*)

The *exciting causes* are fatigue of the eyes by labor requiring a constant application of them, as, among watch-makers and jewelers; examinations with the microscope; the abuse of too strong lenses, which keep up an increased activity of the visual organ; sudden suppression of the menses, or of a hemorrhoidal flow; obstinate constipation; mental distress; strong light; cold, and all causes which favor cerebral congestion, may occasion that of choroiditis.

The *anatomical symptoms of hyperemia of the choroid* can be ascertained only with the aid of an *ophthalmoscope*, and, in some cases, this examination becomes impossible, because the inflammation exists at the same time in other tissues of the eye, as, in the iris, the retina, and the conjunctiva. Very often, however, it exists alone, and then the reflector will enable us to distinguish a scarlet-red tint at the bottom or fundus of the eye, much deeper than the normal tint, and a considerable turgescence of the tortuous vessels of the choroid, and the pigment becomes less distinguishable, or disappears partially or entirely. At the same time, if the disease persists, the subconjunctival vessels distend, and a bluish or red circle, according to the intensity of the congestion, surrounds the cornea. At a later period, the globe of the eye becomes hardened, the pupil sluggish in its movements, the iris dull and discolored, pervaded by varicose vessels, its pupillary margin retracted, its middle part inclined toward the cornea, the sclerotica bluish, and perhaps bulging out, and the disease degenerates into *glaucoma*, or *phlegmon of the eye*.

The *subjective symptoms* are; at first the patient experiences only a slight tension in the globe, a tension which may eventuate in painful twitchings, if he fatigues himself with a slightly prolonged

labor, reading, writing, etc. A dimness of vision, as if a cloud, net-work, or spider's web were constantly before the eye, is complained of, and of which he endeavors to give a very complete description. When the congestion is more active, the tension and accompanying pain is replaced by lancinating pains which shoot into the temple, the forehead, and beneath the orbital arch; light is supported by the eye with difficulty; the patient seeks the shade, and is tormented by the appearance of black, yellow, or green spots, sparks, and luminous points, due to the influence exerted by the engorged choroid upon the retina. Indeed, it is rare that hyperemia of the retina does not exist at the same time. Optical illusions of various kinds are frequently present.

The progress of choroiditis is ordinarily slow; it advances by starts or paroxysms; thus, the disease comes on, then follows a great improvement, then an aggravation of its symptoms, and so on, until after a certain time when the disease is supposed to be checked, all the symptoms re-appear with greater violence, owing to some imprudence, as a prolonged exposure to the sun, a prolonged reading, writing, etc. This second attack passes off more slowly than the first, to re-appear and disappear again, and so on. These successive attacks at length effect serious morbid changes in the substance of the choroid; which are the exudations.

In *exudative choroiditis* the *ophthalmoscope* alone will enable us to recognize the changes undergone by the choroidal tissue under the influence of this second degree of inflammation. If the exudation is *serous*, we will perceive through the transparency of the retina a large whitish patch, elongated, irregular, ordinarily encompassed by a blackish border and fringed with the pigmentary layer of the choroid, and around this patch will be seen the deep vessels of the choroid filled with blood. If the exudation is *plastic*, we will see either grayish or silvery-white patches which conceal the parts beneath, or small yellowish-white points spread over the surface of the choroid. These thin or thick exudations sometimes detach and elevate the retina, causing it to press upon the vitreous humor; at other times they condense between the choroid and the sclerotic. At the same time, it is by no means rare to observe in the neighborhood of the papillary region small yellowish, circular patches, surrounded by a circle of black pigment. These patches which are due to the disappearance of the pigmentary layer, at a later period appear of a pearl-white, for the vascular layer of the choroid becoming atrophied, we are then enabled to see the normal color of the sclerotic. We will also sometimes meet with small black spots formed by a certain amount of accumulated pigment,

and small reddish points produced by the extravasation of blood, following the spontaneous opening of a small artery or vein.

To sum up, I will say that *exudative choroiditis* is characterized anatomically by the presence of exudations, by yellow patches resulting from the disappearance of the pigment, by pigmentary accumulations, by pearl-white patches due to the sclerotica, and by hemorrhagic reddish points. I will also observe that the vitreous body is ordinarily softened, containing grayish flakes in suspension, and that the retina almost always participates in the morbid action.

The *subjective symptoms* consist especially in the perception of fixed muscæ of various forms and colors; in micropny; luminous visions; and sometimes in photobia, lachrymation, and a painful sense of fullness.

The progress of this affliction is essentially chronic, but like the preceding it is subject to exacerbations, which occur by intervals. Its *prognosis* is always unfavorable.

The *treatment* in the first form of the disease, will depend somewhat upon the cause of the attack; if this be menstrual suppression, means must be taken to promptly recall this flow; if it be difficult menstruation, this must be remedied as speedily as possible; and so with any other suppressed habitual discharge. The eyes must not be employed for any purpose whatever.

In addition to the measures just hinted at above, the following must also be pursued. Every night, warm pediluvia should be used, composed of half an ounce of powdered mustard seed, one ounce of soft soap, hot water two or three gallons; the feet and lower portion of the legs should be bathed in this for ten or fifteen minutes, and then be well dried. The Compound Tincture of Camphor should be well rubbed upon the temples, behind the ears, upon the nape and sides of the neck, and along the whole course of the spinal column; after which sinapisms should be applied to the same parts. This stimulating treatment should be practised every night, or every other night, as the symptoms demand, and as the patient can bear it. And upon retiring to bed in a properly-warmed room, hot irons should be kept to the patient's feet during the night, which will produce more or less perspiration, and increase the action of the stimulating tincture upon the surface.

If there be any pain or sense of fullness in the eyeball, no matter how slight, light compresses moistened with cold water may be placed upon the eye, and should be frequently renewed, for an hour or two at a time. These may be applied once or twice daily, as long as the symptoms, just referred to, continue. If there be much pain around the orbit, or in the temples, some anodyne may be employed

in frictions over the parts, as, Tobacco Ointment, Stramonium Ointment, Belladonna Ointment, etc., or plasters of the extract of one of these anodynes may be worn for a time over the painful part. Or, the following may be rubbed upon the painful parts, afterward covering the parts with oil-silk: Take of Chloroform, Fluid Extract of Aconite, Tincture of Camphor, Laudanum, each, equal parts; mix. In many instances hypodermic injections will be found useful.

To keep the bowels regular, prevent renewed exacerbations, and to aid in completing the resolution of the disease, moderate doses of the Compound Pills of Aloes may be given, or, the Compound Pills of Gamboge, especially when a habitual hemorrhoidal discharge is suppressed, or where there are sympathetic pains in the head from an obstruction of the circulation of the abdominal venous system. If there is a sluggishness or inertia of the bowels, the Compound Pills of Podophyllin may be given; or, one of the following: 1. Take of Aletridin one scruple, Extract of Nux Vomica two grains, Podophyllin five grains; mix, and divide into twenty pills, one or two of which may be taken every night. 2. Take of Extract of Hyoscyamus, Extract of Aloes, Sulphate of Iron, each, one drachm, Extract of Nux Vomica ten grains; mix, and divide into sixty pills, two or three of which may be taken daily.

If menstruation is difficult, the Tincture of Gelsemium, either alone or combined with Tincture of Aconite may be administered, or, one of the following: 1. Take of Compound Decoction of Aloes two and a half fluidounces, Borax one drachm, Tincture of Aloes, Tincture of Castor, each, three fluidrachms, Cinnamon Water, a fluidounce and a half; mix. The dose is half a fluidounce or more daily. 2. Take of Tincture of Blue Cohosh, Tincture of Guaiacum, Tincture of Cinnamon, each, one fluidounce; Tincture of Belladonna, four fluidrachms; mix. The dose is from thirty to sixty drops three times a day, in a little water.—And so on with other conditions, as, recession of a cutaneous disease, scrofulous or rheumatic diathesis, suppression of perspiration, suppressed menstruation, syphilitic taint, etc.

The bowels must be kept regular; the functions of the skin and kidneys be attended to; the diet must be moderate but nourishing; the patient must avoid the least fatigue of the eyes, and a drop or two of solution of Atropine may be placed in them two or three times a week, at bed-time; neutral-tint glasses, without any green in them, should be worn; and on fine days the patient should walk out in the open air.

In the *exudative form*, the treatment is rarely as efficacious as in the preceding one. However, after having overcome congestion

when present, treat the complications, and remove the causes when we can discover them.

We may apply the Compound Tar Plaster to the back of the neck, and behind the ear, alternately; keep the bowels, skin and kidneys in as normal a condition as possible; administer internally the following preparation: Take of Chloride of Gold and Soda four grains, Water Distilled eight fluidounces, Muriate of Ammonia one ounce; mix and dissolve, and then add Compound Solution of Iodine ten fluidrachms and a half. The dose of this is thirty minims, three times a day, in a tablespoonful of water; and, after having used it thus for six or eight weeks, take only two doses per day. This preparation, which I now make known for the first time, will be found a very efficacious remedy in nearly all forms of chronic disease; I have employed it largely and successfully for the last twenty-five years, and consider a knowledge of it, to any physician, equal to a hundred times the price of this work.—Other agents, however, may be used, and frequently with benefit, as Iodide of Ammonium, Bromide of Ammonium, Bromide of Potassium, etc.

Frictions around the orbit, on the temples and cheeks, should be made every night and morning, and be continued daily for several months, with the following preparation: Take of Tincture of Arnica, Tincture of Conium Maculatum, Water, each, one fluidounce; Muriate of Ammonia two drachms; mix, and make a lotion.

The patient should avoid efforts at accommodation, prolonged reading or writing, great light, minute examinations, and should use neutral-colored glasses.—Section of the ciliary muscle has been followed by beneficial results in chronic choroiditis, with or without hydrophthalia being an accompaniment, as well as pain, hardness of the globe, etc.

5. *Chronic Retinitis. Chronic Inflammation of the Retina.* Since the discovery of the ophthalmoscope, our knowledge of retinitis, like that of choroiditis, has been more correct. Acute retinitis is rarely met with in practice; but the chronic form is of frequent occurrence, being met with daily. By means of the ophthalmoscope we are enabled to distinguish it from sthenic or congestive amaurosis, with which it has been for a long time confounded. Chronic retinitis is hardly ever primitive; it is often accompanied with a certain degree of congestion or inflammation of the choroid, or else results from the compression produced by a sclerotitis which has existed for some time.

The *cause* of an affection so common is very important in a therapeutic point of view. Persons of feeble constitution, with clear complexion, light hair, eyes transparent and brilliant as a mirror, with a bluish sclerotica, and whose look presents a peculiar expression of mildness, appear predisposed to it. Their sight, although good, is easily fatigued, their ocular conjunctiva becomes injected readily, and if their business requires them to make prolonged efforts of accommodation, they expose themselves to a hyperemia of the retina, which, kept up by the continued action of the same causes, gradually progresses and ultimately terminates by determining material morbid changes in the texture of the retina.—The affection is frequently met with among watch-makers, engravers, and microscopists who constantly work with or use very strong lenses; among dyers, metal-forgers, and those mechanics who are nearly all the time in presence of very bright colors, as, scarlet, red or fire; and also among seamstresses, laundresses, and embroiderers, whose eyes are more or less constantly receiving the rays of light reflected from white surfaces. Persons who write or read constantly, and especially by artificial light, are also disposed to this malady; on which account, the constant reading of small print is very injurious. Among predisposing causes may also be named the excessive use or abuse of liquors, which facilitates hyperemia of the retina by favoring cerebral congestions; also venereal excesses, masturbation, use or abuse of tobacco, opium, etc.; and, frequently, nurses or mothers who suckle their children for too long a time, or who severely employ their eyes too soon after confinement, become attacked by this malady.

Retinitis, like choroiditis, presents two well-marked degrees; the first will be described under the name of Choroido-retinal and Papillar Hyperemia, and the second under that of Exudative Choroido-retinitis.

1. *Choroido-retinal and Papillar Hyperemia.* Retinal congestion may be either partial or general; in the first instance the papilla is more frequently in a state of hyperemia. The *anatomical symptoms*, as determined with the *ophthalmoscope*, are, a reddish aspect of the papilla, due to very minute vascular ramifications which extend from the center of the papilla to the surface of the retina. When the congestion is general, the whole fundus of the eye appears deep red, and the red papilla itself is so masked by the vascularity, that it is difficult to recognize it. At the same time, if, in consequence of some portion of the retina yet remaining normal, it be possible to discern the choroidal vessels, they will appear swollen and turgescient. The papilla seems to be blended altogether, or in

great part, with the rest of the fundus. Sometimes it will be so red as to resemble pannus of the cornea, or it may present the appearance of fascicular redness, similar to what we see in pustular corneitis, etc.

This first degree of retinitis, which has for a long time been confounded with *copyopia* or *fatigue of vision*, is remarkable for its *subjective symptoms*. Patients complain that working for a short time, or a lengthy reading or writing, produces uneasiness and heat in the eyeball. If they continue, their eyelids become heavy, they experience a feeling of pain and tension in the orbital cavity, and their vision is disturbed. The letters, etc., seem to be confused, smaller than they are in reality; they seem to be displaced; the lines appear irregular, and, if they still persist in reading, etc., their eyes water, the pain augments, and a thick mist is spread over all objects. At the same time, they complain of seeing sparks, flames, black specks, cobwebs, etc., and luminous spots or shadows of various colors.*

2. The *Anatomical Symptoms of Exudative Choroido-retinitis*, as determined with the *ophthalmoscope*, are as follows: The fundus of the eye always appears blood-red, the papilla more or less covered with vascular ramifications; we may also discern small, whitish patches which mask and interrupt a portion of the papillar and retinal vessels. We must not confound these retinal exudations with those of the choroid, for, in these last, the retinal vessels pass

* Desmarres says that hyperemia of the retina is exceedingly common. "The patients complain of an uneasy sensation in the eyes after reading or working. On commencing work, the sight is good, and remains so for a variable period; in some, for many hours; in others, for a few minutes only. There then supervenes a sensation of fullness and aching in the eyes, which feel hot and dry; the eyelids also feel dry and stiff; the sight becomes confused. If the patient be reading, the letters appear unsteady; and, if he persists, disappear altogether. In some cases there is slight temporary strabismus, and double vision. Some complain of acute pain darting through the eyeball; others of dull pain in the situation of the frontal sinus. Slight temporary relief is obtained by rubbing and pressing the eyes; but, as soon as work is recommenced, the symptoms return, and continue to increase. In more advanced cases, the pupil, though it does not lose its mobility, is generally much contracted; while the eye is being used, the cornea becomes of unusual brilliancy, and is surrounded by a faint circle of sclerotic injection, which disappears after an interval of rest; in some instances there are *muscæ volitantes* of various colors. These symptoms disappear, and there is good vision, in cases which are not of long standing, and in which the patient gives his eyes perfect rest; but, if the affection has lasted long, and especially if work has been persisted in, the impairment of sight becomes permanent; small objects can not be distinguished clearly, and large and distant objects are seen as through a veil. Ultimately hyperemia passes on to chronic retinitis."

in front of the exudation formed on the choroid, while, in the former, the vessels of the retina appear to be interrupted in their tract as far as the exudative patch extends. The central arteries and veins are larger than in health.

The *subjective symptoms* are pain or headache, but more frequently no ocular pains are complained of; fixed and dark muscæ are more or less constantly present; the vision loses its clearness, and becomes more or less completely obscured; there is an encroachment upon the visual field, in accordance with the seat and extent of the exudative spots; small, or distant objects, are no longer sharply defined; various spots, flashes of light, rings, brightly-colored spectra, etc., are complained of as annoying the eyes; and if the progress of the disease be not checked by proper treatment, vision will ultimately be permanently destroyed.—The *prognosis* of chronic retinitis like that of choroiditis is unfavorable; being rather more favorable in the first degree, or hyperemia, than in the second.

The *treatment* of retinitis rests upon the same basis as that of choroiditis. In the *first stage or form*, we must employ means to lessen the exalted sensibility of the retina, to remove the sanguine congestion, and to diminish the plasticity of the blood, in order to prevent the structural morbid changes which characterize the exudative period. We must also remove all causes which may produce the inflammation, endeavor to overcome the complications, and to prevent any relapses. To fulfill these indications, we make use of cold applications over the eyeball; sudorifics, diuretics, and cathartics, so as to remove the congestion, and produce a depletion of the lymphatic system; in addition to which, sinapisms may be applied alternately and for a long time to the temples, behind the ear, to the nape of the neck, and along the whole course of the spinal column. Every night a warm foot-bath should be had, and during the night the patient should have hot irons or bricks kept to the soles of his feet, as hot as can be borne.

When the more active symptoms have been subdued, (or when they are not present at all), cold applications to the eyes must be prohibited; the bowels must be kept regular; the functions of the skin and kidneys be attended to; and a few drops of Solution of Atropine may be placed in the eye every day or two, to keep up a dilatable state of the pupil. The eyes must be kept quiet and not be used at all for a long time, and the patient should wear an eyeshade with neutral glasses. Internally, the following may be given with advantage: Take of Sulphate of Quinia one scruple; Elixir of Vitriol one fluidrachm; mix, and dissolve, and then add Tincture of Black Cohosh fourteen fluidrachms. The dose is from twenty to

sixty drops, in a wineglass half full of water; to be repeated every four hours. And, if necessary, adopting such other measures as will strengthen and invigorate the nervous system generally.

In the *exudative form*, beside the means which have been named, we must employ powerful counter-irritants, as, the Compound Tar Plaster alternately to the nape of the neck, and behind the ear; with Croton Oil Liniment to the temples and in front of the ears; and active stimulating liniments along the whole course of the spinal column. The suppurative discharges should be kept up for a long time. Also give internally, in connection with the above preparation of Quinia and Black Cohosh, the Compound Gold mixture recommended under Choroiditis, on page 1440.

When the disease has been of long standing, and the phenomena of irritability of the retina have disappeared to be replaced by those of paralysis, to the preceding measures may be added local excitant applications, as, douches to the eye, of Water made stimulating by the addition of Brandy, Compound Spirits of Lavender, Tincture of Prickly-ash, or Tincture of Arnica, etc.; also stimulating ointments containing Ammonia, Strychnia, etc. The vapor of Bisulphuret of Carbon to the eye, will sometimes prove useful; and we may even have recourse to electricity or electro-galvanism, the action of which is undoubtedly indicated to recall the vitality of the retina. Hypodermic injections of Strychnia in the temporal region, may also prove useful. Yet, the prognosis is highly unfavorable.

6. *Syphilitic Choroido-retinitis*.* Chronic or exudative syphilitic

* A few remarks on the *acute* form of this disease may be proper here. It is characterized by excessive sensitiveness of the eyes; an intense photobia which obliges the patient to avoid the least ray of light and to seek darkened places; a general feeling of indisposition; pains in the head, heat and weight in the eyeball; and a marked disturbance in the function of vision. If the patient be questioned as to the presumed cause of the disease, he will attribute its appearance to the influence of such cause or causes as more commonly give rise to congestion of the retina. If we examine the affected eye, we observe nothing abnormal; there is neither redness nor swelling; the pupil preserves its mobility and its color, and the center of the eye appears transparent. The *ophthalmoscope* alone, will enable us to detect an intense injection of the fundus of the eye and a superabundance of vessels which nearly completely conceal the papilla of the optic nerve.

These symptoms, which indicate the first stage of the disease, improve rapidly under the influence of an antivenereal treatment, similar to that for iritis due to a syphilitic taint. But it frequently happens that the disease which commences in this manner, and of which we have not been able to discover the real cause, is only combated by other measures for the purpose of diminishing the congestion, but which are insufficient to destroy the specific principle which holds the inflammatory phenomena under its direct dependence, then the retinitis soon passes

retinitis is characterized by the presence of small whitish patches, *under ophthalmoscopic examination*, which are limited, regular, surrounded with a red-brown halo, and have their seat in the posterior segment of the eye. The papilla seems slightly prominent, and appears in a confused manner through a cloud of greater or less thickness, of a grayish color, and which is nothing but a syphilitic exudation. The retinal vessels are either engorged, or diminished in size; the retina appears œdematous, thick, and here and there may be observed masses of decolorized pigment, and a little disturbance in the posterior part of the vitreous body.

Patients laboring under this disease complain of a progressive, and sometimes a sudden diminution of their vision. Among the greater part, a large grayish or blackish spot appears in the center of objects at which they are looking, and which is called *scotomata*, or *muscæ volitantes*. Ordinarily syphilitic chorido-retinitis remains but a short time in the acute form, and often the chronic stage becomes established without any preceding acute phenomena. It usually attacks but one eye. Its progress is slow and irregular, and its *prognosis* is less unfavorable than that of idiopathic choroido-retinitis. It is subject to relapses, and always leaves some visual disturbances, which are due to the fact that the fundus of the eye never returns to its original color and transparency.

The *cause* of this malady is a syphilitic taint of the system, and it is rarely met with unaccompanied by secondary or tertiary syphilitic symptoms, as morbid conditions of mucous membranes, vegetations, ulcerations, exostoses, gummy tumors, etc., which it is important to discover. We may suspect it whenever the ophthalmoscope reveals limited exudations on the posterior segment of the choroid, and an œdematous infiltration of the retina and of the papilla.

The *treatment* will be similar to that named for Choroiditis of a syphilitic character, on page 1440; occasionally placing a drop or two of a weak solution of Atropia into the eye. The bowels, kidneys, skin, diet, etc., must not be neglected.

DISEASES CONSEQUENT UPON THE OPHTHALMIA.

1. *Conjunctival Xeroma, or Xerophthalmia. Cuticular Conjunctiva.*

from the acute or congestive to the chronic or exudative stage, a frequent form, known commonly under the name of *syphilitic amaurosis*, not that the symptoms accompanying it tend to reveal its character, but because the antivenereal treatment, which is often resorted to as a last hope, proves efficacious and thus makes known the specific nature of the disease.

This is a rare affection, is sometimes congenital, but more frequently is the result of a chronic conjunctivitis, or a constant exposure of the eyeball to the contact of foreign bodies, as, dust, sand, the improper use of collyria, or too active ointments which disorganize the conjunctival tissue and suppress the mucous secretion designed to lubricate the eye and facilitate its movements. This morbid change of the conjunctiva is accompanied with considerable dryness of the eye, suppression of the lachrymal fluid, and loss of sensibility of the eyeball; the conjunctiva becoming thickened, corrugated, of a dusky appearance, and ultimately assuming a parchment-like appearance. If the epithelium of the cornea participates in the pathological alteration, the sight becomes impaired in proportion to its dimness, and may even disappear wholly.

The *treatment* is merely palliative. The conjunctiva may be bathed occasionally with a tepid liquid composed of Water one fluidounce, Liquor Potassa two or three drops. In the intervals, the Gold Collyrium named on page 1405-6 should be frequently applied. In addition to which, general hygienic measures should be adopted. Cures are very rarely performed. The application of Glycerin to the eye, two or three times a day, has been recommended as a palliative.

2. *Pterygium*. This consists of a morbid alteration or thickening of the conjunctiva and subjacent areolar tissue, with enlargement of the vessels of the part, which comes on slowly and insensibly, without any pain or uneasiness, in the form of a triangular growth, the base of which is almost always toward the oculo-palpebral surface, generally on the nasal side of the eye, while the apex is directed toward the cornea, either being arrested at the circumference of the cornea, or extending over its edge without, however, passing beyond its center. The disease may exist either on the nasal, temporal, superior, or inferior side of the eye, or upon two or more of these sides at the same time; when upon all four sides, it resembles a Maltese cross. It is more common among old persons than young; and very often extends so far over the cornea as to interfere with vision.

The *cause* of pterygium is involved in much obscurity. Its origin has been attributed to a chronic conjunctivitis, to the contact of foreign bodies drawn toward the inner angle of the eye by the lachrymal fluid, as, particles of dust, powder, sand, etc., and it appears to be common among seamen who have spent much of their time in tropical climates.

The disease usually commences on the white of the eye or con-

junctiva, that is by its base. The pterygium is then simply *cellulous*, (*pterygium tenue*), thin and semitransparent, and most commonly stops at the corneal circumference. At a later period, it may advance upon the corneal tissue and slightly disturb the visual functions. At other times, the pterygium is muscular, (*p. crassum*); thick, of a fleshy appearance, reddish, and furrowed by numerous vessels, having almost the appearance of a thin muscle; should this encroach upon the cornea it becomes a great impediment to vision, and interferes with the movements of the eye. If the disease be not treated, it will not disappear spontaneously; if improperly treated, it may degenerate into a fungous excrescence covering the whole cornea.

The *treatment* varies; sometimes it may be removed by frequent cauterizations with Sulphate of Copper, or Nitrate of Silver; or even by frequently dropping Wine of Opium into the eye. The best method, however, is that originating with Prof. A. J. Howe, and which he has used, to my knowledge, with great success. A small pencil of soft wood with one end as broad as the part near the base of the pterygium, is dipped into chemically pure Nitric Acid, and then wiped off with soft paper. The wood absorbs enough of the acid to produce all the cauterization desired, and prevent the caustic from spreading to the surrounding tissues. This is then gently applied upon the part above designated, or directly upon the largest of the vessels beyond the margin of the cornea; and its application may be repeated every three or four days, being careful to apply the acid always upon the same point, or as nearly so as possible. It occasions a severe burning pain, which soon passes away. The vessels soon contract or become obliterated, and the haziness of the cornea, as well as the pterygium, gradually disappear. The acid should be kept in a glass-stoppered vial.

A European oculist has recommended a layer of neutral acetate of lead, to be placed over the whole extent of the pterygium; allowing it to remain there for a few moments, and then removing it with a small pencil moistened with clear water. Repeat this for eight or ten days, when the morbid growth completely disappears. The application of a drop of Oil of Turpentine, once or twice a day, or once in every two or three days, has likewise been found very effectual in removing this and other deposits upon the surface of the eye. It should not be re-applied at any time until all irritation resulting from the last application has disappeared. This will also be found a very useful agent to remove habitual injection of the vessels of the conjunctiva; and which may likewise be often

removed by frequent applications of a solution of Hydrochlorate of Ammonia, six or eight grains to a fluidounce of Water.

When these therapeutic measures fail, the growth may be removed by an operation; raising the pterygium with a small hooked forceps, passing a small iris knife beneath its middle, being careful not to wound the sclerotica, and detaching it by cutting inward as far as the margin of the cornea, and no further, at which point the knife must be made to cut itself out. Then, still holding the growth with the forceps, separate the pterygium in the same manner, (or with a pair of curved scissors), toward its base, being careful not to extirpate the entire base, or encroach too near the semilunar fold, if it be an internal pterygium. It is not desirable to cut away from the sclerotica more of the conjunctiva, than has really become degenerated and unsightly; and, as a general rule, if the portion between the corneal margin and the center of the growth be excised, the rest of it will disappear more or less rapidly. I might say here, that as a general rule, unless the pterygium be very unsightly, or interferes with vision, it should be left alone.

3. *Pinguecula. Pterygium Pingue.* This is a small tumor of lenticular form, of a fatty appearance, yellowish color, developed in the subconjunctival cellular tissue, toward either angle of the eye. It is common to old persons only, and usually both eyes are affected. The *causes* of its production are not known, though supposed to be a natural alteration of the part. It never invades the cornea, nor occasions any inconvenience. No *treatment* is desirable unless it becomes large, when it may be raised with forceps, and snipped off with convex scissors.

4. The ocular conjunctiva may also be attacked with *tumors, cysts, polypi, fungous excrescences*, etc., which require *treatment* only when they become a cause of permanent irritation, or interfere with the functions of the eye and lids. They may then be removed with the curved scissors.

5. *Sclerotic Staphyloma. Choroid Staphyloma.* Inflammation of the sclerotica, wounds, bruises of the eyeball, etc., may give rise to one or several bulgings out, or, prominences of the coats of the eye. These prominences are due to the softening, thinning and distension of a portion of the sclerotica, and are termed "sclerotic staphyloma."

The affection presents itself under the form of a bluish black projection, of variable size from that of a pin's head to that of a pea, and placed near the margin of the cornea. In some instances there may be several projections by the side of each other around the cornea, the white of the eye being pervaded by engorged and varicose vessels, and the globe projecting between the eyelids. This affection has an unfavorable prognosis. It is the usual indication of an inflammatory condition of the deep-seated membranes of the eyeball, and always more or less wholly extinguishes vision, and, after a time, renders the eye liable to burst, from rupture of the membranes forming the tumor, and thus evacuate its fluid.

These staphylomatous projections are due to the bulging out of the choroid or corpus ciliare through the thinned sclerotica, and should not be confounded with certain blackish pigmentary patches which are sometimes observed on the sclerotica, but which do not disturb the functions of vision. These patches do not stand out in relief, are irregular, and always congenital. (See page 1419-20.)

The *treatment* of staphyloma is purely palliative, for the purpose of diminishing the size of the eye, and to lessen the pains caused by the distension of the globe, and which is generally effected by puncturing the projecting point. Or, the eye may be removed for the purpose of ultimately wearing an artificial one. Division of the ciliary muscle has been highly recommended in this affection.

6. *Opacities or Specks of the Cornea.* These usually attend acute or chronic corneitis, or else follow an injury to the cornea. They are superficial, central, or deep-seated; and are distinguished by different names, as follows:

a. *Nebula.* This presents itself under the form of a superficial, bluish-white, semi-transparent exudation, with its circumference so shaded off as to present no defined or precise limits, never projecting below the surface of the cornea, and occasions very slight disturbance in vision, the patients being able to see, but as through a cloud.

b. *Albugo.* These are formed by a more abundant, thicker, and better circumscribed exudation than the preceding, of a whitish, chalky, or pearly appearance, and is usually seated under the anterior elastic lamina of the cornea; sometimes it assumes the form of a whitish track setting out from the center of the cornea, and extending to its margin. When these opacities are central, they may completely prevent the person from seeing objects placed directly in front of him.

c. *Leucoma.* This is the result of an opaque cicatrix due to a

traumatic lesion, or to an ulcer of the cornea, according as their form is circular or linear. Leucomata have nearly the same characters as albugos. The difference, however, is, that in the first there is often an adhesion of the iris to the opaque corneal spot, or else when the eye is examined by oblique light the opacity will be observed extending backward even as far as the posterior surface of the cornea. In albugo, on the contrary, oblique light enables us to recognize in front of the spot, or behind it, the still normal and transparent layers of the cornea.

These three opacities do not always present themselves so well marked as theory would seem to indicate; it is, indeed, common to observe a speck presenting a leucomatous center surrounded with a halo of albugo. In this case, it is termed a mixed speck.

The *prognosis* of specks of the cornea is unfavorable in proportion to their extent, depth, and central proximity. When they are seated on the margin of the cornea, they disturb vision but little, though sometimes they occasion strabismus; if they are in the center of the cornea they cause *nystagmus*.

The *treatment* of opacities of the cornea is general and local. The first consists in the employment of tonics, alteratives, antiscrofulous agents, etc., for it is more commonly at the termination of scrofulous ophthalmic affections that these opacities manifest themselves, and it is of great importance to modify the constitution and the temperament, if we desire to have any chances for removing the local lesion.

The second or local treatment demands great attention on the part of the oculist; it will vary according to the nature of the opacity, and according as the inflammation which has produced it is still impending, or has completely disappeared. In the first instance, we must treat the ophthalmia; in the second, the condition of the ocular membranes being in a proper condition, we must employ topical means for the purpose of favoring absorption of the plastic deposit which constitutes the opacity.

In *nebulæ*, we may employ one of the following collyria, viz.: 1. Take of Muriate of Ammonia eight grains, Sydenham's Laudanum twenty drops, Glycerin four fluidrachms; mix. 2. The Gold and Soda Collyrium, on page 1405-6. 3. The vapor of Hydrocyanic Acid. 4. The vapor of Bisulphuret of Carbon. 5. Sulphate of Cadmium two grains, Laudanum twenty drops, Rose-water four fluidounces; mix. If these agents prove inefficacious, we must have recourse to more active medication.

In *albugo*, we may employ an ointment of Borax or of Sulphate of Copper, or one of the following, viz.: Take of Iodide of Potas-

sium three grains, Iodine one grain and a half, Fresh Butter one drachm; mix well together. 2. Take of Cyanide of Zinc one part, Lard twenty-five parts; mix. 3. Caustic Potassa one grain, Extract of Opium four grains, Distilled Water one fluidounce; dissolve and filter. Some of the European oculists employ a collyrium composed of equal parts of Cod Liver Oil and Walnut Oil. And, sometimes, when the speck has a cretaceous appearance, the following: Take Walnut Oil one drachm, Cod Liver Oil one drachm and a half, Caustic Potassa four grains and a half; mix, and apply with a small camel's-hair pencil.—Equal parts of Oil of Turpentine and Oil of Sweet Almonds, mixed together, will also be found an excellent application.

In *Leucoma*, powders are generally preferred, thus, Urate of Ammonia may be placed in the eye by means of a camel's-hair pencil; or, a mixture of Iodide of Potassium twenty-five grains, Powdered Orris, Rock Candy, each, one grain; mix. Nitrate of Bismuth fifteen grains, Red Precipitate seven grains and a half, Sugar one drachm, mixed well together, has been recommended, but I have never used it. If the opacity does not cover a great portion of the pupil, it may be dilated with a solution of Sulphate of Atropia; or else, if this artificial dilatation is insufficient, the operation for artificial pupil may be performed.—Section of the ciliary muscle is said by eminent oculists to have been attended with marked benefit in leucoma.

It may be proper to state here, that, although these applications do sometimes cause the opacities to disappear, yet, as frequently they will pass away without the employment of any local means whatever. In young persons they are always absorbed much more rapidly than in old ones. It is useless to attempt the removal of an old speck, with abruptly-defined margins; though I know of one instance in which such an one was successfully removed in twelve or fourteen weeks, by the careful application of pure Nitric Acid upon the opacity, by means of a piece of soft wood, pointed, the application being repeated every four or five days.

7. *Ulceration of the Cornea.* Ulceration of the cornea may occur as a consequence of purulent and scrofulous ophthalmia, inflammation of the external coats of the eye, of great debility of the system, of disease of the fifth pair of nerves, etc. The ulcers may be superficial or deep-seated, the former, of course, being less unfavorable than the latter; also, an ulcer near the edge of the cornea being more favorable to vision than a central ulcer.

Some ulcerations are in the form of facettes (or planiform), resulting from a kind of wearing or abrasion of the most superficial parts of the cornea at a limited point. They are flat, round, and transparent, often passing unperceived unless by careful examination with oblique light. They almost always follow a semi-transparent phlyctenula, and their cicatrization is obtained with difficulty. They may likewise be produced by an injury. *Other ulcers*, again, are cupuliform or cup-shaped, resulting from the rupture of a pustule, or the evacuation of an onyx. They usually extend deeply into the cornea, are round, funnel-shaped, of a grayish aspect, and are almost always seated at the center of the cornea; their prognosis is still more unfavorable than the preceding. A *third variety* of ulcers are annular, and, more frequently, are a complication of purulent ophthalmia, having their seat ordinarily at the margin of the cornea. They always coincide with a considerable chemosis, and threaten complete destruction of the cornea. Their prognosis is eminently unfavorable. A *fourth variety* resembles a scratch, which has the form of a segment of a ring, and is met with at the corneal circumference. Its margins present a slight opaline cloud, and are not vascular. They are more readily cured than either of the preceding kinds.

These several varieties of ulcerations may at length assume particular characters, and mask themselves with a grayish-white detritus, a sloughy-looking matter, which interferes with their progress and cure; they are then called *pulpy*, or *atonic ulcers*. They are frequently followed by perforation of the cornea, and leucoma.

The *treatment* of ulcers must be in accordance with the ophthalmia or cause which has given rise to them. Generally, when the inflammatory disturbance is arrested, the ulcers will soon heal; and when we find the ulcer is healing, the best plan is not to disturb it, save by occasional tepid ablutions. If palpebral granulations be present, they should be properly attended to. Where there is a tendency to spreading of the ulcer, attended with considerable debility, tonic and stimulating treatment will be indicated, as, the Collyrium of Golden Seal, Tincture of Capsicum, etc., on page 1429. In cases of great vascularity and superficial ulcerations, the vascular fasciculus may be divided, and the edges of the ulceration be lightly touched with the end of a well-polished crayon of Sulphate of Copper; if cicatrization goes on slowly, it may be stimulated by the Gold Collyrium named on page 1405-6. Dr. Dixon highly recommends a drop of perfectly fresh Castor Oil or Sweet Oil to be occa-

sionally placed upon the corneal surface in cases of abrasion of the cornea, or superficial ulceration; it affords instantaneous relief.

If the ulceration is central, and threatens to perforate the cornea, the pupil should be kept largely dilated with a solution of Atropia; if, on the contrary, it is at the circumference, some drops of Laudanum, or of a solution of Calabar Bean may be placed upon the eye to contract it, and thus oppose a prolapse or hernia of the iris. This opiate application is also useful on account of its anodyne influence.

When the ulcers are very indolent, and appear to be slowly augmenting either in breadth or depth, they may be touched with a solution of Salt, one part to fifteen or twenty parts of Water; or with a solution made by adding half a drachm of Tincture of Aloes to one fluidounce of Water; or, the Collyrium referred to above, composed of Golden Seal, Tincture of Capsicum, etc. Among the other means which have been found very successful in the treatment of ulcers of the cornea, are applications of solution of Vegetable Caustic, Compound Tincture of Myrrh, or, Tincture of Capsicum; these are painful, but exceedingly efficacious. They should be applied once or twice a day, and of full strength, if the patient can possibly bear it. In obstinate cases, the Compound Tar Plaster placed behind the ear, and over the nape of the neck, alternately, will prove of great value in the treatment. Constitutional and hygienic measures must be fully attended to, according to the indications present; they are of as much importance as the therapeutical means.—A mixture of one part of Cyanide of Zinc with twenty-five parts of Lard, applied once or twice a day, has been found effectual in healing ulcers of the cornea, and absorbing opacities.

8. *Onyx and Abscess of the Cornea.* *Onyx* or *Unquis*, is an exudation of yellowish matter formed between the lamellæ of the corneal circumference, and exactly resembling in form the white mark at the root of the nails. It is a symptom complicating some external ophthalmic affections, and generally appears at the inferior margin, though sometimes, it may be seated at any part of the cornea, even over the pupil. The seat and form of onyx is not disturbed by a change in the position of the patient's head. Onyx should never be punctured; the proper *treatment* for it, is, the removal of the particular ophthalmia in which it originates. If not cured it is apt to occasion destruction of more or less of the cornea, etc., and perhaps loss of vision. Warm Anodyne fomentations to the eye, Compound Tar Plaster alternately to the nape of the neck

and behind the ear, Iodide of Ammonium internally, and solution of Atropia to maintain dilatation of the pupil, are the means to be depended upon for a cure, if this be at all possible, aided by proper hygienic measures.—Sometimes, local applications every day or two of equal parts of Oil of Turpentine and Oil of Sweet Almonds, continued for several months, will answer an admirable purpose.

Abscess of the Cornea forms in the same manner, and under the same circumstances as onyx. It is sometimes superficial, and sometimes deep-seated, and ruptures externally, producing an ulcer which ultimately cicatrizes, or, inwardly, giving rise to *hypopium*, in which the matter is effused into the anterior chamber. In some fortunate cases this matter is gradually absorbed. The treatment for abscess is the same as that for onyx.

9. *Hernia of the Cornea. Keratocele.* This occurs when a portion of the thickness of the parenchyma of the cornea has been destroyed, or, when the part which remains has no longer a sufficient resistance to support the pressure of the fluids of the eye which are pushed forward. The hernia has the form of a small, thin vesicle, sometimes opaque, sometimes transparent, and which disappears under pressure. Once produced, it may remain stationary for a long time, or it may rupture and give rise to numerous unpleasant results. The predisposing *causes* are wounds and ulcerations of the cornea; when the latter exist, sneezing, coughing, blowing the nose, straining at stool, etc., may cause the thinned cornea to give way and protrude through the ulcer.

The *treatment* consists in keeping the pupil well dilated, to prevent the iris from being involved, and then lightly touching the *ulcer* with Sulphate of Copper, or solid Nitrate of Silver; or applying pure Nitric Acid to its edges, by means of a soft-wood porteaustic.

10. *Perforation of the Cornea*, from wounds, is almost always followed by an immediate loss of sight. Perforation from ulceration, may be central, or peripheral. In the former instance, the iris has but little tendency to protrude between the lips of the solution of continuity, but, on the contrary, the cicatrization always gives rise to an opaque leucoma which may destroy the visual function; or else, to a fistula, especially when the perforation is considerable. In the latter instance, hernia of the iris more readily occurs, and is almost always produced; then the pupil becomes deformed, even

wholly disappears, adhesions take place, and the sight is lost. In either case the *prognosis* is very unfavorable, and it is seldom that an incurable blindness does not result. The only chance of cure is dilatation of the pupil, kept up by means of solution of Atropia.

11. *Fistula of the Cornea* is the result of a corneal perforation, which does not fill up and heal; sometimes giving issue to the aqueous humor. It involves the fundus of the eye, and loss of sight. The *treatment* which has been recommended is, to cause the engagement of the iris in the fistulous opening and to favor its adhesion to the fistulous walls, for the purpose of preventing the eye from discharging its contents.

12. *Vascular Cornea. Vasculo-nebulous Cornea. Pannus.* This disease is characterized by a vascular state of the cornea, and a thickening of its epithelium or conjunctival layer. When present in a slight degree, it is named "vascular cornea;" and when the thickening and vascularity is so great as to appear as if a reddish foreign substance was lying upon it, it is termed "pannus." This reddish thickened mass has been likened to a piece of red cloth, or a red cherry; but I think with a lack of accuracy. Pannus, however, does not require to be red, as the term may be equally applied to exudations which remain after the inflammatory symptoms have disappeared.

Pannus is the result of chronic ophthalmic affections, and principally the granular forms. At first, it exists in the form of a white web or veil, semi-transparent, with very small vessels pervading it, still allowing the pupil to be perceived, and occasioning only some disturbance and confusion in the visual perceptions; it is then called *membranous pannus*. But frequently the vascularity increases, the membrane becomes thicker and organized, a plastic exudation is formed, and the pannus assumes a reddish aspect analogous to that of erectile tissues; it is then called *fleshy pannus*. The deep-seated parts are then entirely hidden, sight is almost wholly destroyed, and this protuberant mass becomes the seat of severe pains, hemorrhages, and various inflammatory attacks attended with photobia and weeping of the eyes. The first form is more frequently met with in practice; the latter variety is rare.

The *treatment* consists, first, in removing the causes giving rise to the growth, as, inflammation, granulations of the palpebral conjunctiva, evulsion of inverted eyelashes, etc. After which, if the

pannus still remains, it may be carefully touched every two or three days with Perchloride of Iron in solution, or pure Nitric Acid. Bleennorrhagic inoculation has been recommended by some eminent oculists, and has been successful especially in cases where the matter used was taken from the eye of an infant affected with purulent ophthalmia; it must be recollected, however, that this method is not always followed by success, and that in many instances it has occasioned a complete destruction of the eye.—Fleshy pannus, if it can not be removed after a fair trial of one of the above agents, may require to be removed by a surgical operation.

13. *Conical Cornea. Hyperkeratosis. Staphyloma Pellucidum.* This is a rare disease, almost always attacking both eyes at the same time. It is characterized by a particular deformity of the cornea which protrudes in the form of a cone without losing its transparency, and which may be readily observed when viewed in profile and by oblique light. From a distance, the eye presents a peculiar bright and sparkling appearance, as if a tear were hanging on the center of the cornea. Viewed in profile, the cornea looks like a drop of water, or like a solid piece of glass projecting from the front of the eye. The center of the cornea, one side of it, or the whole of it, may be involved in the projecting cone. Sometimes the conical portion may be nebulous or opaque. At first it is accompanied with more or less myopia, and at a later period with disturbance of vision. Its development is very gradual and sometimes, after reaching a certain degree of projection, it remains stationary.

The *treatment* of this affection consists in the use of very concave glasses; when the cone has become more developed, a blackened thin metal or horn plate, pierced along the middle with a very narrow slit may be substituted for the glasses, or be worn in front of them. At a still further advanced period, it has been recommended to evacuate the aqueous humor by puncturing the cornea at any convenient point near its edge, and exercising gentle and uniform pressure upon the eyeball. Dr. Bowman, of London, proposes an operation to favor adhesion of the margin of the pupil to the cornea. I have no knowledge of its success.—Division of the ciliary muscle has also been found advantageous in many cases.

14. *Excrescences of the Cornea.* Sometimes excrescences or morbid growths are developed on the cornea. Their *treatment* consists in

the use of dry Collyria, Perchloride of Iron, slight cauterizations, or removal with curved scissors, or the knife.

15. *Arcus Senilis. Circulus Adiposus. Gerontoxon.* Is a whitish opacity developed in the form of an arc or ring, of greater or less breadth, and situated just within the circumference of the cornea, leaving between it and the sclerotica, a portion of the cornea still transparent. This change is due to a fatty degeneration of the corneal substance, the result of a deficient vitality of the cornea. It is almost always met with among old persons, does not interfere with vision, and requires no treatment. It is often an accompaniment of heart disease.

16. *Hernia of the Iris. Irido-corneal Staphylomæ.* Hernia of the iris may be caused by everything susceptible of producing perforation of the cornea, as, penetrating wounds, ulcerations, scrofulous, purulent, granular, and other forms of ophthalmia. In the more simple cases, the cornea is perforated, the aqueous humor flows out, the iris collapses upon the cornea, and partly engages between the lips of the wound. The hernia is then formed, and presents itself as a small, round, grayish or black tumor, very much resembling the head of a fly, and is termed *myocephalon*.—If the solution of continuity is more extensive, instead of a small tumor, we will observe a flattened protuberance, somewhat resembling the head of a nail, and termed *clavus*. When the cornea has several apertures in it, the iris protrudes partly through each of them, and the tumor, resembling a small bunch of grapes, is termed *staphyloma racemosum*.

The different varieties of protrusions of the iris produced at the expense of the corneal substance, commence as described. The tumor once formed, ulceration ceases, the aqueous humor reaccumulates, and the iris returns to its normal position, or else becomes inflamed and forms adhesions with the lips of the wound, which is termed *anterior synechia*. In this case, the patient has the sensation of a foreign body under the lids, with epiphora, photobia, and more or less violent pains which remain as long as the inflammation is not subdued, the iris gradually becomes flatter, leaving only a hardly perceptible projection beneath the cornea. If the inflammation progresses, either because the treatment employed is inefficacious, or from the contact of air, dust, friction of the eyelids, etc., the tumor of the iris becomes organized and assumes the aspect of a purple mushroom, with a fungous appearance which ultimately becomes a thick and resisting membrane, of the nature of cicatricial

tissue, and blended at the base with the remaining healthy portion of the cornea; thus constituted, the tumor is called *partial staphyloma of the iris and cornea*.—As to *total staphyloma*, the mechanism of its formation is the same.

The progress of these several kinds of staphyloma is variable; sometimes they remain stationary after having acquired a certain development; at other times they increase in size, degenerate, and terminate by rupturing, furnishing a ready issue to the humors of the eye, which flow outside, leaving only a deformed stump which retracts to the base of the orbital cavity.

The *treatment* of hernia of the iris at the commencement when there are no adhesions, or when these adhesions are slight, consists in reducing the hernia. For this purpose a few drops of a weak solution of Atropia may be dropped upon the eye, and frictions of Belladonna Ointment may be made upon the eyelid, and around the orbit. Gentle friction upon the superior lid, will aid in reducing the hernia.—At a later period when the adhesions are firm or when the tumor is staphylomatous, and presents the appearance of an organized fungous mass, the eye is lost forever, and it only remains to cut away the tumor.

17. *Synechia* is the term applied to a morbid adhesion of the iris,—generally its pupillary margin,—with the cornea, or with the anterior capsule of the lens; in the first instance it is termed “*anterior synechia*,” and in the latter, “*posterior synechia*.”—Anterior synechia may, as has just been named, follow hernia of the iris, but it also supervenes upon simultaneous inflammation of the cornea and iris, may follow effusions of pus or lymph into the anterior chamber which wholly or partially disappears according to the degree of adhesion.

Posterior synechia is generally the result of iritis, and in this case the iris appears concave in front, the anterior chamber is larger and the posterior smaller; the pupil is almost always contracted, and often filled with plastic exudations.

The *treatment* of these affections consists in keeping up dilatation of the pupil by a mydriatic solution; and if the pupil is obstructed by false membranes (*atresia of the pupil* or *atresia iridis*), the operation for artificial pupil may often be successfully practised. (See *Treatment of Chronic Iritis*, page 1432.)

18. *Tremulous Iris. Iridonesis.* Trembling of the iris is a phenomenon which is always symptomatic of an affection of the eye-

ball. It consists in oscillations of this diaphragm forward and backward whenever the eyeball is rapidly moved about. It is observed in a fluid state of the vitreous humor, hydrophthalia, and following the operation for cataract by depression, and in some old amauroses. It affords an unfavorable index of the state of the vitreous humor, and perhaps, of the retina; and is incurable.

19. *Tumors of the Iris.* The iris is occasionally the seat of condylomatous, vascular, and fungous growths, cysts, etc. These affections are very rare, and their treatment is wholly surgical.*

* A few brief remarks may be given here, concerning the *Operation for Artificial Pupil*. This operation has for its object the formation of a new opening in the iris when the natural pupil is marked by an indelible spot, or when it is obstructed by false membranes interfering with its functions. It is one of the finest and most important operations in ocular surgery. It may be advantageously performed: 1. When the pupil is masked by a spot on the cornea which can not be cured; 2. When the pupil is completely obstructed by plastic deposits, or false membranes; 3. When there is an anterior synechia, and the pupil is masked by a spot; and 4. When a cataract is complicated with posterior synechia with considerable contraction of the pupil. These are the lesions which require the formation of a new pupil, but we must ascertain previously that there exists no contra-indication to the operation. Thus, we must never operate, 1, when one of the eyes is capable of seeing; 2, when the other eye is affected with simple cataract, in which case, we will at first operate for the cataract, and if sight thereby becomes restored we leave the other eye to itself; 3, when that portion of the cornea which is to correspond with the pupillary orifice of the new formation is not wholly transparent; 4, when there is glaucoma, amaurosis, hydrophthalia, paralysis of the retina, total staphyloma of the cornea, atrophy of the eyeball, inflammation of one of its membranes, softening of the vitreous humor, etc., or when there are evident indications of a constitutional affection; in all other instances, the operation is practicable, and the oculist may select for the purpose one of the following three methods:

1. *Incision, (iridotomy, or corcctomia)*, which simply consists in an incision of the iris.—2. *Excision, (iridodialysis, or coredialysis)*, or method of laceration or separation from the ciliary ligament.—3. *Separation, (iridectomy or corcctomia)*, which consists in excising a portion of the iris.—Of these three proceedings, the first is but little employed, and does not give very satisfactory results. The second, on the contrary, frequently succeeds, but it may give rise to formidable inflammatory phenomena, because of the seriousness of the wounds of the iris from laceration. The third is the one to which preference is almost always given.

Having carefully devised the position in which the artificial pupil can best be made, the surgeon penetrates the cornea, close to its junction with the sclerotic, with a broad cutting needle, so as to enable him to pass in readily a small blunt hook, which he firmly fixes in the portion of the iris to be removed; then, he rotates the handle of the instrument so as to bring the convexity of the short, bent part of the hook forward or toward the cornea, and gently and slowly withdraws it and a portion of the iris at the same time. An assistant, standing

20. *Hydrophthalmia. Anterior Hydrophthalmia. Dropsy of the Aqueous Chambers.* This is a frequent consequence of corneitis, and consists of a morbid accumulation of watery fluid in the aqueous chambers. It may also follow other affections of the eye.

The *symptoms* are as follows: The cornea is uniformly larger or more prominent than usual; sometimes it increases in diameter and becomes thinner, instead of projecting; it may be transparent, a little cloudy, or opaque. The sclerotica around the corneal margin will be distended, thinned, and of a bluish color, with enlarged, tortuous vessels on the conjunctiva. The iris appears dark, dull, more or less immovable, sometimes tremulous; the pupil is in a medium state between contraction and dilatation, with its internal margin sunk backward, and the lens more or less opaque; the lids close over the eyeball with difficulty; and the patient complains of pressure and distension in the eye, with short-sightedness, and muscæ floating before the eyes.

As the disease advances, the iris contracts adhesions to the opaque capsule, becomes torn and absorbed from dilatation of the surrounding parts; objects appear multiplied; the eye, at first hard to the feeling, becomes flexible from thinning of the cornea and sclerotica; the globe is moved about with difficulty; amaurosis, and even total blindness may supervene; the retina becomes insensible; and the eye atrophied. The *prognosis* is almost always unfavorable.

The *treatment* consists in purgatives, diuretics, sudorifics, Compound Tar Plaster alternately behind the ears, and to the nape of the neck, solution of Chloride of Gold and Soda, on page 1405-6 to the eye, and moderate diet. Jumping or anything else that will give rise to a shock, blows, etc., should be avoided, as the eye may thereby be ruptured, from the distended and thinned condition of the cornea. Paracentesis oculi, or puncturing the eye has been advised, but I have little confidence in it. The general health of the patient must be improved by every appropriate means.

21. *Dropsy of the Vitreous Body. Posterior Hydrophthalmia.* The symptoms in some respects resemble those of the preceding dropsy. The eye is very hard to the touch; there is pain in the eye from

ready with a pair of fine scissors, cuts through the iris, in the required direction, and close to the hook or further from it, as the orifice is designed to be small, or large. Any portion of the iris which may hang in the corneal wound is carefully returned into the aqueous chamber, by means of a little spatula, and the wound soon heals. Many instruments have been recently devised to facilitate this operation, and dispense with the necessity for an assistant.

the commencement, which increases in severity, and extends to a great distance in the neighboring parts; the aqueous humor is diminished; the iris pressed forward, perhaps in contact with the cornea; and loss of sight occurs.

The *treatment* is the same as recommended in the preceding section, but it will rarely be of service, from the fact that the vitreous humor is in a dissolved state. As the dropsy is generally connected with an impaired or scrofulous condition of the system, the remedies should be especially addressed to the condition present; and to afford relief to the patient from his excessive pain, the vitreous humor may be diminished in quantity by tapping the eye through the most prominent part of the sclerotica and choroid, or else, about two lines beyond the margin of the cornea; after the tapping, gentle pressure should be kept for some time upon the eye by compresses moistened with a solution of Muriate of Ammonia. Continuing the other treatment.

22. *Hypopium. Hypopion.* This is a collection of pus or purulymph in the anterior chamber of the eye. It is frequently observed in corneitis and iritis. The matter is of a yellow aspect, and, being heavier than the aqueous humor, it sinks to the bottom of the anterior chamber, its superior surface forming a horizontal level line; when not too thick and viscid, it will shift its position as the head is moved from side to side. *True* hypopium is where the pus proceeds from the walls of the aqueous chambers; and *false* hypopium where it proceeds from a rupture inward of an abscess of the cornea. But there is hardly a reason for this distinction. In *onyx* the exudation appears nearer the surface of the cornea than in hypopium, and is never movable. Hypopium and Onyx may, however, exist together at the same time.

Hypolympha is a term applied to an effusion of lymph instead of pus, in the chambers of the aqueous humor, and which sometimes occurs in iritis.

Hæmophthalmos. Hypæmia, or a sanguineous effusion into the eye, more commonly results from blows, injuries to the iris, etc., and is recognized by a red mass floating in the aqueous humor, which is more or less speedily absorbed, according to the healthy condition of the eye. This effusion may also be vicarious of menstruation, or be due to syphilitic or rheumatic inflammation, etc., and, at times, may occur without any attributable cause. It has also occurred in purpura hemorrhagica.

The *treatment* of *hypopium* and *hypolympha* rests entirely upon the

removal of the inflammation giving rise to it, which, when accomplished, will, as a general rule, be followed by a disappearance of the matter. Should this fail, the eye should be bathed with the Gold Collyrium on page 1405-6; counter-irritation should be applied to the nape of the neck and behind the ears, alternately; the eye should be exposed for ten or fifteen minutes daily to the vapor of hydrocyanic acid, or of bisulphuret of carbon; the bowels be kept regular; the skin be attended to; and either Bromide or Iodide of Ammonium be administered internally. The cornea should by no means be punctured, as has been recommended; beside, if this were done, the matter being so thick it would not flow out. But, if there is so much matter as to threaten rupture and entire destruction of the eye, by giving exit to it, we relieve the patient, and preserve a form of the eyeball that will admit the wearing of an artificial eye.

In *hæmophthalmos* absorption may be favored by cold applications, Arnica, St. John's Wort, etc., with purgatives, and internal use of Bromide or Iodide of Ammonium. Keeping the eyes shaded, the pupils under the influence of Belladonna, and employing the proper measures for the constitutional conditions. Very rarely, puncture of the cornea is admissible. In those effusions coming on spontaneously, vicariously, or from disease, the prognosis is apt to be still more unfavorable than with the others, as, frequent recurrences terminate in destruction of more or less of the structures of the eye.

Cysticercus is the name applied to a worm or hydatid observed in the aqueous humor. It is of very rare occurrence, and almost invariably destroys vision.

DISEASES OF THE CRYSTALLINE SYSTEM.

1. *Cataract*. This is a partial or complete opacity of one or several of the parts composing the crystalline system. Its *causes* are numerous. In some instances, the opacity is the result of a prick, a blow, or a violent concussion of the eyeball, and is then termed *traumatic cataract*.

More frequently, it is developed without any attributable cause, without being preceded by an inflammation of the eye, and, in a word, without being able to associate it with any substantial cause. Considerable obscurity is still connected with the etiology of cataract. It is undeniable that it is hereditary; all observers agree on this point. Climate also appears to exert an influence in its pro-

duction, as the inhabitants of the East, and particularly those of Egypt, are very subject to it; it is also met with more frequently in the northern parts of France than in the southern. Again, old persons are more frequently affected with it than young. Infants are not free from this malady, as it is sometimes met with among them from birth, and is then termed *congenital cataract*. A European physician has thrown out the opinion, based upon his anatomical investigations, that cataract is intimately associated with atrophy of the anterior part of the choroid, the same as lesions of the vitreous body are under the direct dependance of atrophy of the posterior portion of the same membrane. It is to be hoped that this first step toward a knowledge of the morbid changes of the internal eye will lead to important results in the way of treatment.

The *objective symptoms*, supposing for clearness of description that the cataract is fully formed, are as follows: The first thing which strikes our sight is a speck situated behind the pupil, generally of an ash color, steel-gray, or bluish-white, more opaque sometimes at its center, at other times at its circumference. In the second place, if we place the patient obliquely near a window, we will observe a blackish circle delineated upon that part of the opacity corresponding to the pupillary orifice. This phenomenon, called *shadow thrown by the iris*, is easy to explain; if we place a ring of iron, for instance, between a lamp and a sheet of white paper, at a certain distance, and then look at it obliquely, the shadow of the ring will be seen upon the paper; in the eye, the pupil may represent the ring, and the cataract the white paper. As will be observed hereafter, this phenomenon, which is appreciable in certain kinds of cataract, is incomplete or wholly wanting in some others, especially in soft and fluid cataracts. These symptoms, the opaque spot and the shadow thrown by the iris, always indicate the presence of cataract. The existence of the subjective symptoms will render the indication still more certain.

The *subjective symptoms* are as follows: Sometimes, the patients state that their affection commenced by a disturbance of vision, which caused them to discern objects, at first, as it were, through a thin cloud, but which gradually became thicker. At other times, they say it commenced by seeing spots of various forms and colors floating for some time before their eyes, as, a thread, a hair, a fly, a spider's web, etc., which disappeared and returned at indeterminate intervals. Patients have also been heard to complain that their sight was worse in the morning, or on a bright sunlight day, and better toward evening, or in the shade. There are also some who observe that if they look at the flame of a lamp or candle, it appears

to them as if surrounded by a circle of fire of a much larger size than the flame itself.

As the opacity increases, the visual sensations gradually become more and more confused, distant objects can not be perceived, and ultimately the patient can only tell day from night. These symptoms are the most common, and are those to which the attention of patients is usually given, and which demand the consideration of the oculist.

The *progress* of cataract is very variable. With some subjects the opacity becomes complete in a very little time, even suddenly; with others, on the contrary, it is not matured until two, three, or even ten years have passed. It has also been observed that the disease progresses more rapidly in one eye than in the other, and there are some with whom the cataract will be complete in one eye, while it has hardly commenced in its congener. This great variability in the progress of the disease renders the prognosis very difficult.

We have defined cataract to be an opacity of one or several of the parts composing the crystalline system; this consists of the crystalline lens, the anterior capsule, and the posterior capsule. Each of these parts may become singly or simultaneously opaque, giving rise to the several varieties following, viz.:

A. Lenticular or True Cataract. When the term cataract is made use of without any designation, lenticular cataract is ordinarily meant. It presents three different examples, which it is very important to know, as, *hard, soft, and fluid cataracts.*

a. Hard Cataract is more frequent among old persons than adults. It is generally of small size, is rather distant from the pupil, which last preserves all its movements and free action, and the shadow thrown by the iris is very apparent upon the cataract. The opacity almost always commences in the nucleus of the lens, and gradually diffuses itself toward its circumference. It is dark ash-colored, or greenish-yellow; occasionally it has been found black. It progresses slowly; vision in this, is relatively less disturbed than in the other varieties, for more commonly the patient preserves for half a day the faculty of distinguishing small objects when very near to him. The green, gray, black, bony, and stony cataracts of some authors may be ranked in this first category.

b. Soft Cataract may occur also among old persons, but it is still more frequently met with among adults and children; it progresses in an inverse direction from the preceding, that is to say, the opacity extends from the peripheral layers to the central. Ordinarily it commences by one or several opaque striae, emanating from the surface of the lens, like rays emanating from the center

of the circumference of a circle. At first, these striæ only are opaque, but the portions of the crystalline substance comprised between them, and which yet preserve their transparency, become turbid at a later period, and assume a tint analogous to that of the striæ. At length, the nucleus itself participates in the morbid change; the soft cataract is then matured or complete, and presents a uniform, general, bluish-white, milky, or sometimes yellowish-gray, color. Its size is considerable; the posterior chamber exists no longer; the iris is pushed forward, and its movements are difficult or even wholly abolished; and, lastly, the shadow thrown by the iris is either partly or completely wanting.

The progress of this variety of cataract is more rapid than that of the hard kind; though, sometimes, it may require a number of years before it becomes completed. Vision is but little disturbed at the commencement; but, if the opacity advances, it diminishes slowly, and terminates in total abolition, so that the patient can hardly distinguish day from night. Cataracts with three branches, striated, stellated, deliscent, dotted, barred, glaucomatous, etc., make part of this second type of lenticular cataracts.

c. Fluid Cataract. In this form, the opacity always commences at the circumference, or at least throughout the whole extent of the lens. Its color is uniform, and ordinarily of a dull white, milky, or yellowish, without striæ or rays. Its size is very considerable; the uveal circle is very apparent, the iris is strongly projected forward, the movements of the pupil are impossible, and there is no shadow thrown from the iris. The progress of this form of cataract is slow at first, but, after a little time, when dissolution of the substance of the lens is somewhat advanced, it is rapid. It often results from a traumatic cause.

The disturbance of vision is very considerable. Sometimes, when the cataract is wholly fluid, the complete absence of sensibility to light, and immobility of the pupil, may cause one to believe it complicated with paralysis of the retina; but a phosphenic examination will aid in dissipating doubts and enlightening the diagnosis. In this third category are ranked Morgagnian or interstitial, cystic, and purulent cataracts.

The following is a resume of the differential characters of the preceding cataracts:

LENTICULAR OR CRYSTALLINE CATARACTS.

HARD CATARACTS.

They more generally develop themselves among old persons.

They are of small size.

The shadow thrown by the iris is very apparent upon them.

The uniform opacity progresses from the center to the circumference.

They are never whitish, but grayish-blue or dark ash-colored; in some cases, greenish or black.

Sight is less disturbed than in the other varieties.

The pupil is very mobile.

The progress of the disease is slow.

SOFT CATARACTS.

They more generally develop themselves among adults.

They are of considerable size.

The shadow thrown by the iris is hardly apparent.

The opacity is not uniform; it is more frequently striated, and progresses from the circumference to the center.

It is milky-white or bluish.

The sight is more disturbed.

The pupil is less movable.

The progress of the disease is variable; sometimes it is very rapid.

LIQUID CATARACTS.

They are more generally developed among children.

They are very large.

The shadow thrown by the iris is null; the black uveal circle is very apparent.

The opacity is milky-white.

The anterior surface of the capsule appears convex.

Vision is very much disturbed.

The pupil is restrained, and often immovable. The progress of the disease is much more rapid than the preceding.

B. CAPSULAR CATARACT has its seat either in the anterior or posterior walls of the crystalline capsule. It is almost always the result of an exudation of plastic matter emanating from the surrounding parts, and especially from the iris. This cataract is, also, frequently complicated with adhesions of the iris, and, in its progress is subordinate to the causes which produced it.

a. Anterior Capsular Cataract. The opacity is presented under the form of a chalky or pearl-white spot, with an unequal surface, and speckled with small vegetations or rugous asperities of various tints, sometimes brilliant, and especially appreciable when the eye

is examined by oblique light. This spot appears to be very close to the iris, on a level with the pupillary margin, the iris is often decolorized, carried backward, with its pupillary margin adherent to the capsule of the lens (synechia posterior). The pupil is often deformed, and rarely free in its movements. If it is wholly free, the shadow thrown by the iris exists fully, especially if the cataract is complete, an exceptional case, because capsular cataract almost always consists of a white, opaque point, situated on the surface of the anterior capsule. The vision becomes disturbed in proportion as the opacity extends.—A variety of this cataract is sometimes met with, especially among children who have been attacked with purulent ophthalmia, called *pyramidal* cataract, a serious variety, because the operations for its removal are very seldom successful.

b. Posterior Capsular Cataract. This has been denied by some authors. The particular characters assigned to it, are, its concave form, and its depth behind the iris. To diagnose it, the pupil must be largely dilated with some mydriatic solution. It seldom involves complete loss of vision, the patient being able to read letters of medium size, or with the aid of a lens. It is more rarely met with than the anterior variety.

DIFFERENTIAL CHARACTERS OF CRYSTALLINE CATARACTS, AND CAPSULAR CATARACTS.

CRYSTALLINE CATARACTS.	CAPSULAR CATARACTS.
1. The <i>opacity</i> is never preceded by inflammation.	1. The <i>opacity</i> is always preceded by inflammation.
2. It is gray, dark, green, black, or bluish-white, presenting striæ converging toward the center.	2. It is chalk-white, and is never striated regularly.
3. Its surface is always smooth.	3. Its surface is unequal, presenting asperities, and morbid excrescences or growths.
4. Its size is very large or very small.	4. Its size is always small.
5. The iris presents no adhesions.	5. The iris is often adherent and deformed.
6. The shadow thrown by the iris is complete, or null.	6. The shadow thrown by the iris is almost always null.
7. Sight is lost, but is often better in the shade.	7. Light is fully perceived.
8. Its progress is unceasing, and invasive.	8. It is stationary.

C. CAPSULO-LENTICULAR CATARACT presents at the same time the characters of lenticular and capsular cataract. It is *complete* or *incomplete* according as the opacity is confined to a spot of limited

extent, or as it invades the whole of the capsule and lens. In this case, the capsule being wholly opaque, it is impossible to be assured of the condition of the lens; this is an exceptional case.

a. Partial Capsulo-lenticular Cataract is central, and consists of a chalk-white, limited, opaque spot, which may remain thus for a lifetime, without changing. It is met with among children, rendering them myopic, and so deficient in sight as not to be able to read or write. It is often congenital, and complicated with retinal insensibility; the sight is then wholly lost. This variety, common to newborn children, is frequently accompanied with an oscillatory movement of both eyes which does not always disappear, even after a successful operation; an operation, however, is rarely required. When this variety of cataract attacks only a single eye, strabismus is apt to be caused.

b. Complete, or Common Capsulo-lenticular Cataract is almost always the result of a wound of the capsule, a fall on the head, or a blow in the vicinity of the eye, accidents which may occasion a suppurative inflammation. The lens is then completely fluidified, and the cataract presents the characters of a fluid cataract. . . . A few words may be said concerning the following varieties which are of interest to the oculist:

a. Siliculose or Siliquose Cataract is a very rare affection, and is hardly met with except among children; it is due to interrupted nutrition in the crystalline apparatus, or to absorption of the lens, leaving the two capsular hemispheres wrinkled and juxtaposed in the form of a thick, hard, and opaque membrane. Some authors suppose that convulsive diseases, so frequent among young children, are the most common causes of this form of cataract. In the adult, it is the result of an injury following which the aqueous humor penetrates into the lens, and dissolves the external softer layers of the lens, leaving only the central nucleus. It is then accompanied with diffuence of the vitreous body. It is of small size, brilliant aspect, and a golden yellow color.

b. Tremulous Cataract is characterized by more or less marked oscillatory movements from right to left, left to right, or from in front backward. It is due to hydrophthalmia, softening of the vitreous humor, displacement of the lens from a violent shock, etc. Sometimes the motions of the lens are hardly perceptible; at others, the oscillations are so distinct that the lens may be observed to nearly touch the posterior surface of the cornea.

c. Black Cataract has already been referred to. Its symptoms are those of hard cataracts, and its diagnosis rests wholly upon an ophthalmoscopic examination. Some authors have attributed its color

to the presence of iron, or manganese, and others to a peculiar mode of condensation of the crystalline molecules.

D. COMPLICATIONS OF CATARACT. Although cataract is often exempt from complications, it is of importance, however, to carefully examine the visual organ, when it is proposed to operate, to ascertain that it is in conditions favorable to success. The complications are of two orders.

a. Local Complications, as ophthalmic inflammations, films or specks, staphyloma, etc. When they are recognized, the oculist should endeavor to remove them by proper treatment before undertaking the operation.

Adhesions between the iris and the capsule may also be met with, a complication which may be known by the existence of bands or bridles thrown out between the pupillary margin and the capsule, by the irregularity and disfiguration of the pupil, and by the difficulty in its movements. We should bear in mind that these disorders may reveal the existence of an inflammation not yet wholly removed; and we should ascertain the extent of these bridles, and also whether the capsule is not wholly adherent to the iris, in order to form a more or less unfavorable prognosis.

Softening of the vitreous humor is also an untoward complication, and which we may determine by the softness or hardness of the eyeball, by the prominence of the iris forward, and its tremulousness when the eye is moved. This complication will influence the oculist in the choice of the method for operating.

A still more serious complication is that of *glaucoma*, which is, fortunately, very readily recognized. In this instance, the cataract is of a sea-green color, of considerable size, the iris is pushed forward, and sometimes projects considerably into the anterior chamber; the pupil is irregular, dilated, and immovable; the iris pale, discolored, and often covered with grayish, slate-colored or somewhat grape-colored spots; the sclerotica is lead-colored and bluish, often staphylomatous, the conjunctiva is varicose, the cornea insensible, and the eyeball hard to the touch. The patient also states that the disease has been preceded or accompanied by severe pains and photopsy.

Another complication is *paralysis of the retina*, which is very difficult to recognize at its commencement; but which, when complete, may readily be detected by a phosphenic examination.

b. General Complications. These are very numerous, but are less important than the preceding, at least as far as the prognosis is concerned. The principal ones are scrofula, rheumatism, syphilis, gout, etc. Some authors have pointed out characters by which it

may be possible to distinguish a rheumatic cataract from a scrofulous one, a syphilitic from an arthritic, etc., but this is of no practical service. The antecedents of the patient, and the actual condition of his constitution can alone lead to any correct views in this respect.

E. DIAGNOSIS OF CATARACT. The diagnosis of diseases of the crystalline system has at present reached such a degree of precision, that it is almost impossible to confound even a commencing opacity with the various conditions heretofore designated by the generic name *amaurosis*.

When the cataract is confirmed, exercising the eye will suffice to diagnose it without artificial aid; but when it is commencing, it is accompanied with a group of phenomena which may cause it to be mistaken for an affection of the choroid, or of the retina, and thus the patient be submitted to the severe treatment required for these affections. In all cases, no opinion should be formed, nor treatment instituted until the eye has been examined carefully, while the pupil is fully under the influence of belladonna.

In difficult cases, the ophthalmoscope is of great value, especially during the commencing morbid changes in the lens. These changes, which give rise to *lenticular cataract*, appear at first under the form of blackish striæ or dark lines, sometimes radiating from the poles or surface of the lens, at other times under the form of three dark lines, starting from the center of the lens, as in the cataract with three branches. By means of the reflector, these concentric or ex-centric opaque striæ can not escape observation. They are shown so clearly, as it were, on the red fundus of the eye, that if the pupil be largely dilated and the light be somewhat intense, they become delineated in such a manner as to render it impossible not to perceive them. All these opacities upon or in the lens are fixed; the direction of their curves indicates their situation in the front or back part of the lens. Between the striæ the lens may be transparent or hazy; or there may be a general haziness with few or no striæ.

In *capsular cataract*, the reflector projecting the light directly into the eye, will show blackish spots disseminated here and there, as it were, on the red fundus of the eye. If, on the contrary, we throw the light obliquely in the eye, the spots appear whitish, dotted, rough, and sometimes slightly prominent. These opacities consist for the most part of lymph and uveal pigment derived from the iris. The lens itself is transparent.

The slightest lesions of the crystalline system may be recognised by the ophthalmoscope; but in order to perfect the diagnosis, we

must ascertain if any of the complications, heretofore referred to, exist. We commence by examining the eyelids, the conjunctiva, the cornea, the iris, etc., and if the opacity is not complete, we will search for complications in the deeper-seated structures, as softening of the vitreous humor, various morbid changes of the retina, papilla, choroid, etc., all of which lesions have a major importance in the diagnosis and treatment.

If the cataract is complete, the lesions which may exist in the posterior hemisphere of the eye are not appreciable; they are concealed from our means of direct investigation; however, we may still interrogate the *sensibility* of the eye by the phosphenic examination, and by exploration with the taper.* These two explorative

*The examination with the *taper* is based on the fact that in cataract, where the retina still remains sensible, the flame of a candle, when moved at some distance before the eye, can be distinguished to a certain extent. The patient being seated in a dark room, a lighted candle is held in front of the eye under examination, at about three or four yards distance from it. If the patient sees the flame or illumination from it, we may conclude that the central portion of the retina is sensible. The candle is then to be placed in other directions, requesting the patient to follow it with his eye. The points at which the flame is not distinguished correspond to the points where the retinal sensibility has undergone an abnormal change.

This method of examination not only renders certain the seat of a morbid change in the retinal sensibility, but it also enables us to determine the exact degree of this change, according as the patient can more or less distinguish the light at variable distances.

Dr. J. B. Nevins, in speaking of Sanson's catoptric test, says:—"As commonly described, this test is, however, likely rather to confuse than to assist the surgeon who has only occasional opportunities for using it; though when properly employed it is easy of application and of the greatest possible value. In the first place, the observer must be on his guard that he does not expect to see too much. It is usually said that when the lens is transparent there is a bright, erect image from the cornea, and another erect image from the front of the lens; and lastly, that there is an inverted image reflected from the posterior surface of the lens; and the surgeon therefore naturally expects to see two erect images in a healthy eye, and one inverted one. Now the fact is, that he will scarcely ever be able to detect the second erect image if the eye is sound, and it will require no small care to find the inverted one at all; and even when found, not one observer in twenty can see whether it is erect or inverted. What may be really looked for is the following: When the room is darkened, and the pupil widely dilated by Atropia, the flame of a clear, bright, burning taper should be held as near the eye as can be done without giving pain, and a bright erect image will be seen without any difficulty. If, however, the observer looks with great care into the pupil, and keeps moving the taper about, he will at length discover an *extremely small spot* of pale light, which will move in the opposite direction to the candle. If this is carried to one side of the eye the minute speck of light moves to the opposite side. If the flame is raised the speck descends, and if the candle is lowered the image ascends; and by this means the observer at length gains certainty that it

methods ought always to be employed, because they aid in determining the existence either of a diminished sensibility of the retina, due to a deep-seated lesion, or else, of a rare but possible complication, termed *amaurosis*, that is to say, a more or less complete impairment of vision without any material morbid change.

The catoptric condition or reflecting qualities of the lens may also be tested by causing a concentrated pencil of light to play obliquely on it. This is best done as follows: Having the pupil dilated with Atropia, darken the room, and shade the face of the patient, who must be seated with a lamp placed at his side, the flame being on a level with the eye. Now, take one of the convex magnifiers belonging to the ophthalmoscope, and concentrate the light obliquely upon the eye. By successively moving the convex glass, the concentrated rays of light may be focussed upon any part of the surface or depth of the crystalline and its membranes, and can so accurately light it up as to enable us to discern the slightest deposit, whether plastic or pigmentary, and to note the earliest traces of central or circumferential opacity. This plan will likewise be found valuable in examining the condition of the cornea, iris, etc., when diseased.*

The *prognosis* of cataract varies according to the particular kind, its complications, age and general health of the patient, the length

is an inverted image he is looking at; but he will probably never recognize the difference between the base and the apex of the flame in the image, and as there is no visible reflection whatever of the candle itself, he will have nothing to guide him as to its erect or inverted character except the direction of its motion being opposite to that of the taper itself. So long as the lens and its capsule remain transparent this inverted image may be discovered, and accordingly we shall decide upon the absence of cataract when it is present, and shall have no doubt of the existence of an opaque lens or false membrane if it is absent.

"This is all that we shall generally see if the eye is healthy; but if glaucoma is present, or the vitreous humor is becoming milky, we can then see the second erect image, very pale and indistinct, and looking more like a ghost than a candle, behind the first bright erect one. This second image is somewhat larger than the first, so as to extend beyond it in every direction; and it is so pale and indistinct that it is generally only recognized as being erect by its moving in the same direction as the candle. If then the inverted image is seen without the second erect one, we are sure that there is no cataract, and the tissues are healthy; but if the second erect image is tolerably distinct, it is evidence of some morbid change going on in the structures of the eye, though not of a cataractous nature."

* According to Desmarres, "all doubtful cases of cataract can be diagnosticated with certainty by the ophthalmoscope. For this purpose the convex lens is not required; and the light in examining the lens should be moderate, as a very strong light prevents faint opacities from being readily visible against the vivid red of the choroid. The light being thrown upon the eye by the mirror, the faintest speck or streak of opacity stands out as a dark mark upon the red field

of time since vision was lost, etc. The practitioner should be very reserved, and always guard against assuming any responsibility.

When the lens is thoroughly dense, a careful examination of the retinal phosphenes by pressure, will prove valuable in certain advanced cases, tending to define the utility of extraction in given instances. When all the phosphenes are produced, the augury as to the healthy condition of the retina is very favorable; and in proportion as they are feeble, or partially present, or altogether absent, is the prognosis unfavorable.

The *treatment* of cataract is entirely surgical, and therefore not within the limits of this work; however, a few brief remarks relative thereto, may not be amiss.—Three conditions may be presented to the practitioner, viz.: 1. The cataract may be just commencing; 2, it may be almost complete or fully matured without any serious complications; or, 3, the cataract may be complete or incomplete with serious complications.

For the *first condition*, a medical treatment may, probably, be successful, and concerning which more will be said hereafter. For the *second condition*, an operation is required, as extraction, depression, or division; the particular mode must be determined upon by the operator, according to the circumstances connected with the case. For the *third condition*, the disease complicating the cataract, must be treated, if it be susceptible of cure. Then, if there are no contraindications, we operate. Operations for cataract should not be performed during the hot summer and autumnal months.

After-treatment. After the operation, in order to keep the eyelids still, and to prevent the patient from attempting to use his eyes, strips of court-plaster should be carefully placed obliquely across them, but not so as to interfere with the flow of tears, or keep the eye too closely covered. The patient should then be placed in a large, airy room, at first lying upon his back, with his head slightly raised, and light compresses moistened with cool water, be kept upon the lids for four or five days, unless the eye feels cool and easy. During the first and second day, these should be changed every half hour; on the third day, every hour, and afterward every two or three hours, not allowing the eye to become too much heated or loaded by them. In some instances the “Donna Maria Gauze,” secured on either lid by collodion, as recommended by Dr. Goddard, will be found preferable. The patient should be kept neither too

of the choroid, and its situation, whether on the anterior or posterior surface of the lens, may be determined as follows: The patient should be directed to throw his head very much backward; if the opacity be posterior it becomes concealed behind the lower segment of the iris; if anterior, it still remains visible.”

warm nor too cold, should not be allowed to exert himself in dressing, going to bed, or in anything else, should avoid coughing, laughing, or crying, and should be watched upon awaking lest he suddenly moves the eye or applies his hand to it; the food should be fluid, so that mastication may be avoided. It is better not to have an alvine evacuation until after forty-eight hours from the time of the operation. Every means should be adopted to keep down inflammatory action, and favor adhesion of the wound, without restraining the patient unduly. If everything goes on favorably for five or six days, and an examination of the eye shows everything progressing satisfactorily, the patient may be allowed a little more freedom; in ten or twelve days the eye may be exposed to a weak light, gradually increasing its strength, and allowing the patient to walk out doors with a shade and very dark glasses.

. At about the end of a month, neutral-tint cataract glasses should be worn, either double-convex, plano-convex, or menisci, of a focus adapted to the particular case under treatment. The weight of them should be as light as possible; and if the glasses be placed in a metallic diaphragm of a small diameter and colored black, this will remedy the aberration of sphericity, and consequently give a much clearer image at the center. Two pairs should always be used, one for ordinary vision, and the other for reading and writing; generally those of a focus of two inches to one and a quarter are required for reading, and those of a focus of six to four and a half inches for distant objects. The patient should act prudently in commencing the use of his glasses; and not definitely fix his choice upon any particular focal number until the sensitiveness of the eye to light has completely disappeared.

Medical Treatment of Cataract. With regard to the medical treatment of cataract, there is, and has been, considerable difference of opinion, although, heretofore, the prevailing view in the profession has been that cataract was not affected by therapeutical treatment, and that the cases which have been reported as cures, were not true cataracts, but lymphatic effusions on the surface of the capsule, or glaucoma, etc. Recently, however, some of our most eminent oculists have suggested that, probably, under some circumstances, cataract may be curable by other means than a surgical operation.

Thus, Dr. Richardson, of London, having corroborated the views of Dr. Mitchell, of Philadelphia, relative to cataract being caused by an osmotic action, and which were published in *Am. Jour. Med. Sci.*, July, 1860, p. 257, suggests the idea that an evacuation of the aqueous humor, followed by a refilling of the chambers

of the eye with distilled water, might aid in effecting the removal of an incipient cataract. Not long after these statements, Prof. Sperino, of Turin, announced that he had effected cures of cataract by puncturing the cornea, introducing a small probe into the wound to prevent it from healing, and thus keeping up a constant discharge of the aqueous humor. It has also been stated by other eminent physiologists, that detraction of the water from the body, as, by the introduction of sugar or sulphate of soda into the intestinal canal, causing the water of the blood to flow into the intestines, has produced a loss of transparency in the lens, with convulsions, etc. It has also been ascertained that these pathological conditions are removed by the addition of water to the blood; also, that when the introduction of water exceeds a certain limit, its beneficial results cease, and morbid changes occur.

In accordance with these views, we find that cataract is apt to occur among persons who have had a lessening of the water in their system, as, among old persons, and those laboring under diabetes, profuse leucorrhea, diarrhea, or other excessive discharges. A very interesting article on this subject, by Dr. Hays, of Philadelphia, may be found in the *Am. Jour. Med. Sci.*, July, 1863, p. 119, who expresses a hope that cataract, in its incipient state, or among young persons, may find a cure in some treatment based upon the above facts; senile cataract, however, he does not suppose will ever be amenable to any therapeutical measures.

Again, a local and general treatment designed to produce alkalinity of the fluids of the system, has, it is stated, effected cures of cataract. This treatment was based upon the following facts: If three saline solutions be prepared, one *neutral*, another *alkaline*, and the third *acid*, and we place in each of these solutions a normal beef's eye, it will be observed, after a few hours, that the eye placed in the acid solution has become wholly opaque, while those in the other two solutions retain their transparency. If we place the crystalline cataract in the alkaline solution, the lens returns to its normal transparency in the course of twenty-four hours. In consequence, therefore, an alkaline treatment, consisting of Iodide of Potassium internally, and constant applications of a solution of Muriate of Ammonia applied upon the eye, with free use of water and a vegetable diet, is said to have proven successful. I will state here, that, with three diabetic patients under my treatment, affected with opacity of the lens so as to materially interfere with vision, the opacity disappeared while the patients were under the influence of Nitrate of Ammonia,—fifteen grains in a tablespoonful of water being given for a dose, and repeated three times daily.

Since having prepared the above, Prof. A. Von Gräfe, of Berlin, Prussia, has presented a new and very successful method of operation for the extraction of cataract, to which I can merely call the attention of the profession. The operation briefly consists in an incision through the sclerotica, just above the margin of the cornea and parallel with it, having a length of from four and a half to four and three-quarters lines; then iridectomy, or the removal of a portion of the iris, in order to allow the lens to escape readily, and also to prevent any subsequent iritis; then laceration of the capsule; and finally, removal of the lens, by gentle pressure, a double hook, or a spoon. The instruments required for this operation are eight in number: an adjustable speculum, a peculiar, long, narrow and delicate knife, spring forceps, a very small, straight pair of iridectomy forceps, a pair of iris scissors, a cystitome armed with a fleam, a peculiarly-formed, blunt hook, and a wire scoop. The operation is termed "modified linear extraction."

DISEASES OF THE VITREOUS HUMOR.

1. *Synchysis*. The vitreous humor is rarely, if ever, primarily affected; its softening or dissolution, termed *synchysis*, is almost always due to an inflammation of the choroid. This peculiar state of the vitreous humor may be determined by the touch, which detects a great softness or considerable flaccidity of the eyeball; the ophthalmoscope will reveal very delicate, gauze-like webs of the broken dissepiments of the hyaloid membrane, and these flocculent shreds move very rapidly to the lowest place, being tossed about by the communicated movements of the eyeball. The fundus of the eye presents a dull, yellowish-white appearance, and the papilla and yellow spot are more or less obscured; this, however, is not always the case. When the softness is advanced, the iris will be found pushed forward, and tremulous, especially when the eyeball is moved rapidly, and there will also be slight myopia. In the *ophthalmoscopic* examination of the vitreous humor, a diffused light, and the plane reflector, will show the changes much better than the convex reflector. Minute, sparkling plates, resembling gold spangles, may sometimes be observed, moving up and down in the eye, which are crystals of cholesterine. This is called *sparkling synchysis*, or *synchysis scintillans*.

Synchysis hardly admits of being remedied; the *treatment* must be directed to the cause under the influence of which it has been produced. Vision is not always seriously interfered with by *synchysis*,

although the patient will complain more or less of spots, flakes, or shreds floating before his eyes, (*muscæ volitantes*).

2. *Other lesions* in the vitreous humor may be observed by the ophthalmoscope, as whitish filaments, exudative patches, opaque floating bodies, clots of blood, parasitic animalcules, etc., and which are sometimes seen better by oblique illumination. These conditions are ordinarily symptomatic of deep-seated lesions, for which no successful treatment has yet been laid down.

A condition of the vitreous humor, termed *jumentous*,* has been described; it is characterized by a turbid and muddy appearance of the substance of this humor, due to very tenuous, yellowish-red corpuscles which float and move in all directions under the influence of the movements of the eye. The deep-seated membranes are hardly to be seen, and the papilla seems covered by a cloud. The sight is impaired, and the patient complains of *muscæ volitantes*. This morbid condition is susceptible of being removed; when the vitreous body returns to its original transparency, and vision becomes better.

The *treatment* consists in the use of collyria, and frictions with ioduretted preparations, together with the internal use of alteratives.

DISEASES OF THE CHOROID.

1. *Posterior Staphyloma. Posterior Sclerotico-choroiditis.* (See *Note to Strabismus*, on page 387.) This is a disease of common occurrence, especially among short-sighted persons, and which, since the discovery of the ophthalmoscope, has become well known. It is an atrophy of the choroid at its insertion around the optic nerve, and is characterized by a thinning of the sclerotica and choroid, and an abnormal conical projection at the back part of the eyeball, on the outer side of the optic nerve. The disease usually manifests itself at the period of puberty, among those young subjects whose eyes have been exposed to too great a degree of activity. It is frequently met with among literary persons, jewellers, engravers, printers, embroiderers, and persons who labored under ophthalmic affections in childhood. Myopia predisposes to it; indeed, when posterior staphyloma occurs without myopia being present, it is an exceptional case.

* *Jumentoux*, Fr., turbid and yellowish. | *Corps vitr jumentoux*, turbidity of the vitreous humor. (*Desmarrès*.)

The disease appears also to be transmitted. "There is usually a predisposition, perhaps hereditary, to this affection in the congenital formation of the eyeball, but the exciting cause appears to be the state of congestion of the eye produced during accommodation for near objects; during such accommodation, a certain pressure upon the eye, and increased intra-ocular tension always occurs, the venous circulation within the eye becomes retarded, and a more or less considerable state of mechanical congestion is produced." (*J. S. Wells.*)

Symptoms. The eyeball often appears larger, more prominent, and of an ovoid shape, the eyelids being more widely apart, which is particularly noticeable when only one eye is affected. The shape of the eyeball is changed, it appears lengthened in its antero-posterior diameter, it is more oval and the infundibulum or hollow which appears in the normal eye between the outer canthus and the globe (when the eye is much turned inward), has disappeared, so that the posterior segment of the eyeball looks lengthened and square, showing often also a bluish tint. If the disease is considerable, the lateral movements of the eyes are often somewhat curtailed.

At the commencement, the patients complain that their eyes are easily fatigued, that they weep as soon as they attentively fix them upon an object, and that they experience at the bottom of the eye a painful tension and fullness, as if the eye was too large for its socket. At the same time, as they are generally myopic, they complain that they are near-sighted, that they can not read for a short time without the letters becoming enveloped in a mist, and what annoys them the most is, that they can not find any spectacles to remedy their condition. It is by no means uncommon for them to experience deep-seated, vague pains in the eyeball. With others the myopia is the first and only symptom announcing the commencement of the disease. This pathological state is often accompanied with dilatation of the pupil, and a considerable augmentation of the anterior chamber.

Phenomena like these with a young subject, should arouse the attention of the oculist; the *ophthalmoscope* alone will reveal the existence of the staphyloma. By it, we will find that the center of the eye has preserved its transparency; that the deep-seated membranes present their normal color; but the papilla or optic disc will appear deformed or jagged, larger in its transverse than in its vertical diameter, of a yellowish-red color, and its outer side elongated in the form of a crescent, apparently prominent, but in reality concave, of a pearly or brilliant white color; it is by no means rare to find a slight congestion of the retina, or of the choroid, at the same time. These symptoms may be called those of the *first stage*.

In the *second stage* there is an increased myopia, painful twitchings as soon as the patient attends to labor requiring any efforts of the eyes, perception of sparks or bright spots, flames, and various muscæ volitantes, and, finally, a thick mist before objects upon which they fix their gaze. At this period, the *ophthalmoscope* will reveal that the pupil is dilated and sluggish in its movements, that the anterior chamber is enlarged, and that the fundus of the eye presents a brilliant white reflection. At the same time, the crescentic spot, referred to above, extends by its convexity in the form of a cone, the base of which embraces the semi-circumference of the papilla, and the apex of which is directed toward the inner side of the eye. The circumference of this cone is sometimes covered over with a small black or dark-gray band, irregularly indented, formed by the accumulation of pigment; at other times, this dark band or line is regular, which indicates a disposition on the part of the disease to cease further progress. The conical spot of pearly appearance, indicates that the normal elements of the choroid are deficient or have disappeared at this place; it being formed by the sclerotica. This stage of the disease may remain stationary for a long time, and the oculist, by proper attentions and treatment, may prevent it from passing into the third stage.

The *third stage* of posterior staphyloma is attended with very unfavorable symptoms. The patients complain of considerable dimness of sight, a great difficulty in recognizing very near objects, an extreme sensibility to the light, and a perception of flashes of light, bright stars, luminous spots, or of black spots of variable forms. An examination of the eye will show the iris dull, without lustre, the pupil very much dilated and almost immobile, and the anterior chamber deep; if we have the patient turn the eyeballs strongly inward, we may perceive a bluish reflection situated deeply and posteriorly, corresponding with the staphylomatous projection. The *ophthalmoscope* will detect more numerous and more advanced lesions than in the former stages; the vitreous humor will be liquefied, holding in suspension some filamentous and opaque bodies, and presents the jumentous aspect heretofore referred to. As to the white spot, it has now changed its form; it has become very large, extending even to the region of the yellow spot or macula lutea. Its margin becomes jagged, irregular, and bordered by blackish lines of pigment, more or less discolored. Finally, another white and brilliant spot appears on the inner side of the papilla, smaller than the preceding, and which is the indication of the continued development of the disease. It is by no means rare to observe disseminated here and there other small

whitish or yellowish spots of less development, which indicate a general abnormal condition of the choroid; this is the last stage of the staphyloma, and the patient is blind.

Sclero-choroiditis posterior may be complicated with opacities of the vitreous humor, infiltration of pigment in the retina, detachment of the retina, or, opacity at the posterior pole of the lens.

"Sometimes this disease is progressive, causing serious injury to vision; more commonly it remains stationary after having merely altered the focus of the eye. If we observe that the eyes of a short-sighted person are convergent, that the sclerotic is of a bluish color, and slightly prominent when the eye is turned inward, and that the concave glasses which he uses are rather deep, we may have a strong suspicion that he is affected with sclero-choroiditis posterior; and this suspicion will almost amount to a certainty, if we find that the vision is becoming shorter, that there are *muscæ volitantes*, photophobia, etc. The ophthalmoscope will at once decide the point." (*J. Hogg.*)

The progress of the disease is always slow. If it be properly treated, we may keep it in the first or second stage, that is, preserve sufficient vision for the patient to walk about and attend to business; if, on the contrary, we abandon it to itself, and if the patients who are affected with it do not avoid the conditions under the influence of which it is developed, it constantly progresses and terminates by becoming complicated with incurable morbid changes which destroy the function of vision. More frequently both eyes are affected at the same time, but in different degrees; the right eye is that in which the disease attains its greatest development.

The *prognosis* of this disease is always unfavorable, and it is only by constant attention, and well directed measures, that we can expect to improve it and check its further advance. "When the myopia is progressive, and the vitreous opacities are considerable, we should be very guarded in our prognosis. It becomes still more questionable if the choroidal changes make their appearance about the macula lutea, if the vitreous opacities are very diffuse, and if the upper or lower portion of the field of vision becomes clouded, for the latter is premonitory or symptomatic of detachment of the retina." (*J. S. Wells.*)

Staphyloma posterior has been for a long time known as *amaurotic amblyopia*, until the ophthalmoscope revealed the true character of its lesions. Its symptoms are so well marked that it can not be confounded with any other disease. An examination of the eye, and the efficacy of well chosen concave glasses will prevent us from confounding it with a very prominent myopia.—In the third stage,

when the pupil is immovable and dilated, the eyeball hard and deformed, and the sight nearly gone, it may be mistaken for glaucoma. But the ophthalmoscopic symptoms are so different that it is impossible for an experienced observer to entertain the least doubt as to the character of the affection.

The *treatment* of sclerotico-choroiditis posterior is principally hygienic. Patients should absolutely avoid fatiguing their eyes, working for any length of time at near objects, or with their head bent forward, for venous congestion within the eye is thus easily produced. It is also very injurious to read in a recumbent position, or to expose the eye to the direct glare of the light. Indeed, if it can be done, it is better not to employ the eyes at all, for a time, in reading, writing, work, etc. The myopia which attends this malady renders the use of concave glasses indispensable but they should be employed as seldom as possible; their use is injurious, as they increase the refractive power of the eyes, and consequently their faulty conformation, as well as the obstruction to the circulation.

Sinapisms, or very active stimulating, or rubefacient liniments, to the temples, behind the ears, and to the nape of the neck, will relieve the showers of bright stars and flashing lights complained of by the patient. And to protect the eyes from sunlight, or too intense a light of any kind, and avoid the "dazzling," which often annoys the patient, cobalt-blue spectacles should be worn, of not too dark a tint. It is the orange ray and not the red that irritates the retina, and blue excludes the orange ray. The feeling of heat in and around the eye is best allayed by evaporating lotions, and frequently douching the eye with *cool* water, or water to which a few drops of Arnica Tincture have been added. Or, the eyelids, eyebrow, forehead, temples, and side of the nose may be bathed several times a day, with the following mixture: Take of Aromatic Vinegar five drops, Spirit of Nitric Ether one drachm, Water five ounces and seven drachms; mix, and apply with a small piece of clean soft sponge. The bowels should be kept free, which will aid in overcoming biliary and venous congestion. The following will be found very useful for this purpose: Take of Podophyllin, Leptandrin, Scammony, each, half a drachm, Extract of Belladonna ten grains, Syrup of Ginger a sufficient quantity; mix, and divide into sixty pills, of which one may be taken every night and morning.

Another preparation, employed in Europe, has been highly recommended. It is prepared as follows: Take of Resin of Jalap, Scammony, each, forty-six grains, Cream of Tartar one grain, Extract of Belladonna nine grains, Extract of Stramonium seven and a half grains, Syrup of Chicory, a sufficient quantity; mix, and

divide into sixty pills, to be taken the same as the preceding pills. The advantage of these preparations is that they operate without causing fatigue or weakness, removing any obstinate constipation which may be present, keeping up a constant gentle derivation from the digestive tube to the advantage of the visual organ, causing a permanent expansion of the muscles of the eye, in antagonism to their tendency to contract, arousing the arterial circulation in this organ, and hence counteracting the further progress of its deformity.

Frequent bathings of the surface, and the use of the Spirit Vapor Bath, once or twice a week, but not to cause fatigue or debility, will also prove very advantageous.

If the constitution of the patient is weakly, strumous, or lymphatic, or if there is any syphilitic taint, the appropriate constitutional treatment must be added to the one above named; and any complications will require the treatment adapted for their removal.

Section of the ciliary muscle is stated by Hogg and others to have effected great benefit, and even cures, in this disease; it certainly is worthy of a trial in cases not too far advanced.—Since the discovery of the extraordinary efficacy of many medicinal agents in solution, by means of subcutaneous injections, it is to be hoped that some article may be discovered that will, at least, permanently arrest the further progress of posterior staphyloma in any given case. I have found considerable benefit to follow the hypodermic use of a Solution of a mixture of Sulphate of Morphia and Sulphate of Quinia; as well as of Solution of a mixture of Acetate of Morphia and Acetate of Strychnia.

Oculists have sought to discover the principal cause, the nature of posterior staphyloma. Sichel attributes it to a choroiditis that produces atrophy, a thinning of the sclerotica which then yields to muscular pressure. Jøger considers its commencing point to be a sclerotitis; Gräfe to a sclero-choroiditis; Curlt to a mechanical distension produced by the muscles during the efforts at accommodation; and others, to an augmentation of activity of the external and internal muscles of the eye during the efforts at accommodation, when the subjects are predisposed to the disease by age, anterior diseases of the eye, diatheses, and a more or less marked myopia.

2. *Glaucomatous Sclerotico-choroiditis. Glaucoma.* This is a disease which was very imperfectly understood, previous to the discovery of the ophthalmoscope, which reveals as the characteristic signs, excavation and alteration of the papilla or optic nerve-entrance, and pulsation of the central vessels. Glaucoma is a form

of blindness, attended with peculiar morbid changes in all the various tissues of the eyeball; it is a disease common among persons advanced in years, seldom being met with previous to middle life. It is a much more common affection in Europe than in this country. It has been divided into two stages, *acute* and *chronic*.

According to Gräfe, the elder, glaucoma is an irido-choroiditis with serious intra-ocular hypersecretion, which increases the interior pressure, compresses the retina, and determines the characteristic phenomena; according to others, it is a sclero-choroiditis, and the symptoms accompanying it are due, not to an intra-ocular pressure, but to a concentric pressure which results from a particular mode of morbid alteration of the sclerotica, characterized by its thickening and retraction, and which is effected by a congested or inflammatory condition of the choroid. It appears to be much more common among rheumatic and gouty subjects than among others. Dark-eyed persons are more disposed to it than those having blue or gray eyes, and myopia is often present with glaucomatous patients. Sometimes it is met with at the cessation of menstruation, among females; or, following the cessation of a hemorrhoidal flow; and again, it may accompany a disturbance in the abdominal venous circulation. It almost always appears successively in both eyes. "Glaucoma comprehends a series of morbid changes, which, in general, develops itself only in the course of years, to involve at last all the structures of the eye." (*MacKenzie*.)

"Donders supposes that the influence of certain nerves produces an increase of secretion of the fluid contents of the eyeball. . . . I intend to show that nervous influences produce contraction of the branches of the retinal artery, and that by the diminution of the quantity of blood in the vessels, or by the diminution of lateral pressure in the arteries, a partial vacuum is produced, which in its turn induces hypersecretion of the choroid." (*J. Homberger*.)

The *symptoms* in the *acute* form sometimes come on spontaneously and suddenly, so that vision may become wholly extinct after a few hours of agony, and all the inflammatory changes in the several tissues of the eye, except the opacity of the lens, be apparently completed within a few days. At other times, on the contrary, the glaucoma comes on more gradually, being preceded by prodromic symptoms, as an appearance of sparks, flames, bright flashes, or colors passing before the eyes; a transient dimness of sight, appreciable especially in the latter part of the day; a marked presbyopia; photobia; and pains which shoot from the fundus of the eye toward the forehead and temple. These neuralgic pains

are increased by various influences, as, strong emotions, from heat of the bed, moisture of the atmosphere, etc.; they disappear after some time, and then after an indeterminate period suddenly return, especially during the night, and terminate by leaving, after their cessation, a more or less considerable disturbance of sight. Such are the phenomena which sometimes precede the formation of glaucoma.

In all cases, if the disease is developed, the conjunctiva becomes injected, the pupil dilated, deformed, and immovable, the iris loses its natural brilliancy, and becomes dull, the eyeball hardens, feeling like a marble, and presents a greenish tint, deeply seated back of the pupil, the cornea becomes less convex, dull and loses its sensibility, the field of vision becomes diminished, and finally the patient loses his sight permanently.

If the *ophthalmoscope* be used, we will observe some ecchymoses on the retina, suffusions on the choroid, a well-marked excavation of the optic papilla, spontaneous pulsations in the retinal arteries from over-tension, and a peculiar displacement of the vessels, which appear to sink down and curve over toward the papillary circumference, out of their usual course.

The *chronic* form of glaucoma comes on very insidiously, the pain and dimness of vision are at first evanescent and separated by long and complete intermissions, but finally become more frequent and last longer, until at length they are never entirely absent; the eyeball becomes harder, feeling like marble when pressure is made upon it through the lids; the symptoms are of less intensity than in the acute form. The patient complains of seeing bright flashes or colors passing before his eyes, though not in all cases; there may, or may not, be a dull pain in the eye or head; if there is pain, a faint vascular zone will be seen in the sclerotica around the margin of the cornea; a remarkable contraction of the field of vision occurs; the humors become cloudy; the iris becomes dull, of a slaty tint, gradually loses its briskness of movement, and enlarged veinlets are often visible upon it; the pupil dilates, not uniformly, but so as to assume an irregular, instead of a circular form. This may continue for several months, when the convexity of the cornea diminishes, its surface becomes dull, sometimes vesicated, and its sensitiveness reduced to a minimum; by this time vision is reduced to a slight quantitative perception of light, or is wholly extinct. Then opacity of the lens comes on slowly, the lens and iris gradually advance toward the cornea, and large, dark, purple veins, manifest themselves on the surface of the sclerotica. "The lens is sometimes rather milky-looking, and indistinctly stri-

ated. Its threefold division is often very well marked, as if, by undergoing maceration in water, it had swollen up, and were about to burst its capsule. It may be grayish or greenish-drab, dirty yellow, or dull orange, and marked with opaque, earthy patches or streaks." (*Dixon.*)

If, previous to the opacity of the lens, while it is still transparent, it be viewed by transmitted light, it, and especially its nucleus, will be found of a more or less deep amber color; if by reflected light, it will present a greenish color.*

As in the acute form an *ophthalmoscopic* examination will detect ecchymosed patches, whitish spots due to fatty degeneration of the retina, exudative patches, papillary excavation or cupping, displacement of the vessels, and spontaneous arterial pulsation. In the last stage, the lens will become opaque, the retinal arteries atrophied, the veins dilated, the cornea ulcerates and becomes perforated, and the disease terminates by atrophy of the eyeball.

The *prognosis* of glaucoma is decidedly unfavorable; in the acute form, favorable results may be hoped for by an appropriate treatment; in the chronic form, it is generally incurable, though treat-

* With regard to the color of the lens, Dr. Jas. Dixon remarks: "Even before the middle period of life, the lens always acquires a yellow tint, which gradually deepens, until it assumes in old persons a decidedly amber color; and this quite irrespective of any cataractous change.—The fundus of the healthy adult eye is, as we know, from ophthalmoscopic observation, of a more or less reddened bluff tint, except where the optic nerve presents its white disk; and the rays of light, reflected from such a surface, and transmitted through the yellowish lens, appear to the eye of an observer as a grayish or drab-colored spot. This reflection it is which the inexperienced, or those upon whom experience is thrown away, so often mistake for the opacity of cataract. Dilatation of the pupil with atropia, by admitting a greater flood of light to the retina, renders the spot still more distinctly visible; and a patient, who may perhaps really require nothing more than a pair of spectacles, is told that he is the subject of 'Incipient Cataract.'

"The student can not be too soon made aware of the fact—that pure and absolute blackness is not, under any condition, the characteristic of the pupil in elderly persons; a knowledge of this will save him from falling into constant errors of diagnosis. Any whitish deposit on the surface of the retina will increase the intensity of the reflection; and if, at the same time, the contractility of the iris be diminished, and vision impaired, the phenomena of 'Glaucoma,'—in the sense so commonly attached to the term—will all be present.—A well-marked, grayish, drab-colored, or bottle-green reflection from the pupil of a patient's eye, may, then, co exist with good sight; but, if the reflection is accompanied by impairment, or even total loss of vision, still, the reflection is not the essential sign or characteristic of the disease; nor is the case to be set down as one of *Glaucoma*—however *glaucomous* the pupil may be deemed,—unless other very marked changes be present in the eye."

ment may arrest the progress of the disease, and, perhaps, improve the vision to a certain extent.

Dimness of vision toward the close of the day, or under the influence of emotion, vague pains in the eye and about the brow and temple, occasional flashes, the appearance of a halo around the flame of a lamp, and rapidly-increasing presbyopia, are the forerunners of glaucoma; when these symptoms are present, prompt measures should be taken to check the further advance of the malady.

The *treatment* of glaucoma in the acute stage consists in the employment of means to relieve the pains, and to remove the phenomena of congestion and intra-ocular pressure; for this purpose, anodynes, intestinal derivatives, counter-irritation, etc., will be required; the treatment being similar to that named on page 1416, for Rheumatic Ophthalmia, but conducted more energetically. The patient must keep his eyes in a state of rest, use a moderate diet, avoid the use of alcohol, tobacco in any form, and coition, and keep the skin, bowels, and kidneys, in as healthy a condition as possible. The following will be found an excellent preparation: Take of Sulphate of Quinia one scruple, Sulphate of Morphia fifteen grains, Alcohol three fluidrachms, Elixir Vitriol one fluidrachm; mix, dissolve the alkaloidal salts, and then add Tincture of Black Cohosh twelve fluidrachms, Tincture of Aconite Root two fluidrachms. The dose is ten or twenty drops every hour or two, in a tablespoonful of water. If the patient be anemic, small doses of some preparation of Iron must be given, as soon as the more active inflammatory symptoms have subsided. The use of a solution of Atropia to keep up dilatation of the pupil, will be serviceable; and, if it does not occasion a dazzling of sight, increased haziness, etc., a drop or two of the solution may be placed in the eye every day or two. In both the acute and chronic forms, hypodermic injections of solutions of Morphia, Atropia, etc., should not be neglected; they should be made in the temporal region of the affected eye, and be repeated once or twice daily, if the urgency of the case requires. If this treatment does not completely re-establish the functions of the eye, it has been recommended to relieve the internal pressure by puncturing the sclerotica and choroid, and thus take off the pressure of the accumulated fluid (dissolved vitreous humor) on the retina; and which, undoubtedly, affords a transient relief. The operation of iridectomy has also been recommended. It should be performed as soon as the glaucoma becomes complicated with an inflammatory attack. Should iridectomy, or iridodesis, be found, hereafter, the true remedy for glaucomatous

affections, it will immortalize its discoverer, who, at present, considers it the correct and only successful mode of treating these diseases. Hancock, however, has recommended section of the ciliary muscle as much preferable to, and less dangerous than, the above operations. So far, however, iridectomy has been preferred by the majority of the most eminent oculists. Perhaps, a timely and proper employment of subcutaneous injections may render either operation unnecessary.

Mackenzie considers a removal of the lens as a means of checking the progress of the disease, and preserving vision; the operation should be performed only at that period when the lens assumes a muddy-green color, the pupil being sluggish, the vision more or less obscured, and the eyeball rather firmer than natural. The operation will prove unsuccessful if incomplete amaurosis also be present. This operation, however, is now superseded by iridectomy.

The treatment above named may also be pursued in the early period of the disease, before it has assumed a definite acute or chronic form. In the chronic form, the treatment is wholly therapeutical, all surgical measures proving useless. It principally consists of measures to combat the presumed causes of the affection, or the prominent diathetic condition, as gouty, rheumatic, etc. *Cimicifuga*, *Aconite*, *Colchicum*, *Bromide of Ammonium*, *Iodide of Potassium*, *Iodide of Ammonium*, etc., are the principal agents to be employed. A Compound Tar Plaster should be applied alternately to the nape of the neck and behind the ears; the bowels and skin should be properly attended to; an occasional Spirit Vapor Bath should be taken; and, every few days, dry cupping should be performed along the whole length of the spinal column, or, Firing. The system must be sustained by tonics, or chalybeates if anemia be present; and the diet should be of a nutritious character. The eye should be kept in a perfect state of quiet, and also be protected from the too intense rays of light by wearing cobalt-blue spectacles. Of course, in the more advanced stages, the blindness will be permanent.

Section of the ciliary muscle including also the triangular canal of Schlemm, (in all cases where the operation is performed), has been found of much advantage in acute glaucoma. "In more advanced cases, also, of chronic glaucoma, the improvement, if more gradual, is most decided and gratifying. The fixed, immovable pupil resumes its natural size and functions. The cupping of the optic nerve disappears, the general congestion of the fundus and the turgid varicose appearance of the retinal vessels also subside; the tension of the eyeball becomes normal; and sight, previously perhaps all but lost,

is again restored." (*J. Hogg*.) The operation is stated, by some oculists, to be superior to and more successful than iridectomy, but should not be undertaken in long-standing cases where the ophthalmoscope reveals a very advanced state of atrophy of the papilla or optic nerve and its central vessels.

In this operation, the only instrument required is an ordinary Wenzel's knife, which is introduced about the tenth of an inch from the outer margin of the cornea, where it joins the sclerotica. An incision obliquely backward and downward is then made of little more than one-eighth of an inch in extent, cutting through the triangular canal of Schlemm, the ciliary muscle, and the fibres of the sclerotica. It is not necessary to the success of the operation that either the aqueous or vitreous humors should be invaded, although fluid sometimes escapes by the side of the knife.—This operation, however, has not met with much favor.

3. *Irido-choroiditis*, *Cyclitis*, or inflammation of the ciliary body, is a disease frequently met with, presenting itself under a great variety of forms. It may follow an iritis, or a choroiditis.

Beside the *causes* occasioning an iritis or a choroiditis, I may refer to two, that exist more frequently, viz., wounds, and the sympathetic action that one inflamed eye exerts upon the other. The greater portion of eyes that become atrophied after having been wounded, have passed through the phases of an irido-choroiditis. The more extensive the wound the more readily is the disease developed, and especially when a portion of the substance occasioning it remains in the eye, as, a piece of percussion-cap, grains of powder, small shot, fragments of stone, etc. A foreign body in the eye is almost always a source of danger to this organ; and we recognize its presence in an eye affected with choroiditis, by the persistent and often very intense ciliary pains; the sensibility of the eye to the touch, even when a manifest atrophy has commenced, and the occurrence of which, in ordinary cases, gives complete relief to the pains; by the exaggerated tension persisting in the globe until the termination of the disease, at which period in ordinary cases of irido-choroiditis the eye has a certain flaccidity from the commencing atrophy, or from a retinal detachment.

The presence of a foreign body in the eye, not only proves destructive to the organ in which it is lodged, but also sympathetically exerts a very deleterious influence upon the other eye, occasioning in it, amblyopia, amaurosis, opacity of the transparent media,

cataract, functional changes, inflammations, irido-choroiditis, etc. How this sympathetic excitation is effected is not known.

Sympathetic irido-choroiditis is very variable as to the period of its appearance, with regard to the degree and the age of the inflammation determining it. It differs in no respect from any of the other varieties, though it more frequently affects the serous form. The plastic exudation is generally absent at the commencement, and only slowly appears at a quite advanced period of the disease. One of its essential characters is its malignity, and its extreme obstinacy to all therapeutical measures. It may not only follow an irido-choroiditis of the other eye, but also other inflammations of the deep-seated membranes, in which the products of exudation or the neoplastic masses become incrustated with calcareous salts; and often in these cases, even fifteen or twenty years may elapse without any disturbance in the healthy eye, when suddenly, and without any appreciable cause, it becomes very painful, and sympathetically irritated. The first symptom of this influence is, in many cases, a diminution in the range of accommodation, and fatigue from using the eye steadily for a short time only; then, a tendency to weeping, with an extreme sensibility of the eye to the action of light. This is followed by a rose-colored injection around the cornea from the slightest irritation, and a slight turbidity of the aqueous humor and the vitreous body, which renders vision as if interfered with by a more or less thick cloud.—In other cases, the irido-choroiditis comes on suddenly, and soon after the accident to the other eye.

Spontaneous irido-choroiditis may arise from a hereditary predisposition, and may be complicated with scrofula, syphilis, and rheumatism. It frequently occurs among females at the turn of life. Indeed, there exists a certain correlation between the condition of the uveal tractus and that of the uterine system.

Irido-choroiditis is consecutive to an iritis, especially when a total synechia prevents any communication between the chambers of the eye; in which case the anterior parts of the choroid are unceasingly subject to twitchings; the equilibrium between the pressure of the fundus and of the chambers of the eye is interrupted, in consequence of the interposition of the diaphragm formed by the adherent crystalline and iris, and the internal tension becomes considerably changed. If we puncture an eye attacked with a total synechia, only an incomplete discharge of the aqueous humor occurs, and the lens does not become placed directly against the posterior face of the cornea, as happens in the normal state.

As soon as the periphery of the iris bulges and projects forward, the symptoms indicating the participation of the choroid in the

iritis soon manifest themselves. The ophthalmoscope will discover, (provided the pupillary field is not occupied by plastic exudations), very fine opacities, especially in the anterior parts of the vitreous body, which ultimately become filamentous or membranous; a hypopion may also be observed in the anterior chamber, the very rapid and sudden appearance and disappearance of which indicates its origin in the anterior parts of the choroid.—The vessels enlarge, especially the veins of the iris; the large vessels around the cornea, in the vicinity of the episcleral tissue, also manifest themselves more distinctly. The touch (through the closed lids), discovers much tenderness around the cornea, in the ciliary region. The field of vision gradually becomes smaller. In the acute stage of the disease, the eyeball is hard to the touch, but it gradually becomes softer, owing to detachment of the retina.

When the irido-choroiditis commences in the choroid, the disturbances in the functions of the eye generally precede the symptoms of inflammation of the iris, and this membrane does not present the mark of a primitive inflammation. Abundant effusions may occur in the vitreous body, with detachment of the retina, and opacities in the lens; and when a plastic exudation occludes the posterior chamber, and the iris projects forward, an atrophy of the eyeball may be the result. Even at an advanced period of the disease, it is often possible to tell its commencing point.

There are three symptoms that should guide us in this research, viz.:—1. A preservation of the integrity of the tissue of the iris in disproportion with the functional disturbances of the eye. 2. The very frequent presence of opacities in the lens, without the iris even becoming the seat of an abundant exudation. 3. The considerable diminution of the acuteness of central vision, or the absolute loss of a part of the visual field, (from retinal detachment), which is much less frequent when the disease proceeds from iritis, in which case, the visual field contracts, but without disturbing central vision to any considerable degree.

There are three principal varieties of irido-choroiditis, as follows:—*a. Plastic irido-choroiditis* which is very difficult to diagnose, the affected parts of the choroidal surface, and the ciliary body being inaccessible to an examination, even when the pupil is strongly dilated. Attention is first called to a more or less considerable injection around the cornea, and which can not be attributed to the condition of either the cornea or the iris. The iris may be discolored and manifest a marked hyperemia; sometimes we may observe a certain number of vessels in it, and also from time to

time, quite a considerable increase in the depth of the anterior chamber; but at this period, little or no plastic exudation appears in the pupillary field, and at a further advanced stage, the symptoms of the iritis become more apparent. The injection around the cornea, the vascularization of the iris, the increase in the depth of the anterior chamber, the sensibility of the eye to the touch, and at a later period, disturbances in the vitreous body, are the only symptoms of plastic irido-choroiditis.

b. Serous Irido-choroiditis presents a less marked injection around the cornea, *very slight opacities in the anterior part of the vitreous body appear suddenly*, and at the same time symptoms of a serous iritis supervene; the posterior surface of the cornea becomes covered with many small points barely perceptible by the lens and oblique light. There is an increased tension of the eye, the anterior chamber becomes considerably deeper, and the iris loses much of its mobility. Vision is disturbed, and it is by no means rare for the disease to suddenly become transformed into a plastic, or, suppurative choroiditis.

Parenchymatous, or suppurative irido-choroiditis, presents a very decided injection around the cornea, complicated with a slight chemosis, which remains for several days, without our being able to account for its presence. Vision is altered but little or not at all; the iris performs its functions well,—aside from the hyperemia and a feeble vascularization of which it is the seat, this membrane undergoes no apparent modifications. No exudation occurs in the pupillary field. Suddenly, a considerable hypopion appears, and after a time wholly disappears; it may be reproduced, and then remains more and more in the anterior chamber,—after which vision becomes considerably disturbed, the vitreous body becomes flocculent, the iris decidedly inflamed, and in its tissue and in that of the anterior parts of the choroid, we may determine a purulent inflammation associated with a hypergenesis of the cellular elements.

Irido-choroiditis generally progresses as follows: The inflammatory phenomena may gradually disappear, and the hypopion be absorbed, leaving only a slight opacity on the posterior surface of the cornea. If, on the contrary, the disease advances, plastic and purulent exudations may form in the substance and upon the surface of the choroid, and, becoming organized, constitute vascular patches or crusts, sometimes quite thick. Gradually they reach the posterior parts of the iris, and become readily inflamed under the influence of the least direct irritation of this membrane. In consequence of the compression which its vessels undergo, the irian tissue

becomes successively atrophied, and the nutrition of the vitreous body and of the eyeball is gradually so obstructed that this organ becomes atrophied.

In an advanced period of the disease, there will be a general choroiditis, with more or less atrophy of the nervous elements of the retina, which is sometimes infiltrated with pigmentary granulations, at others, it is detached by the products of serous exudation, and projects into the vitreous body, which is reduced in volume, and filled with opacities, or, globules of pus, if it be a suppurative cyclitis.

The *prognosis* of irido-choroiditis is very unfavorable in the plastic and parenchymatous forms; it is more favorable in the serous form, and in the early stage of the suppurative. It is a lengthy, insidious disease, may suddenly change its character, and, from the reiterated inflammatory attacks, greatly discourage both the physician and the patient. Purulent cyclitis is more serious when it follows the operation for cataract, than when it occurs spontaneously, without the presence of a purulent iritis.

There are few diseases of the eye that require so much experience, skill, and perseverance in its *treatment* as irido-choroiditis. This is so much more true, because the greater part of patients, either from carelessness, or because they entertain no apprehensions regarding the commencing symptoms, do not consult an oculist until at a period when considerable changes have already been effected in the tissue of the iris and of the choroid; and when the vitreous body is filled with numerous opacities indicating a considerable alteration of its nutrition.—Whenever active inflammatory symptoms present themselves, the usual means for their removal must be pursued, the same as for acute iritis or choroiditis; not forgetting hypodermic injections of Muriate of Morphia, or other sedatives, in the temporal region, and around the eye. These injections have already proved very valuable in nearly all the acute and chronic inflammatory conditions of the various coats and tissues of the eye, as well as in most painful affections of this organ.

In *plastic irido-choroiditis* frequent perspirations will be found to have a good effect. In the absence of active inflammation, the Iodine or Bromine Salts may be used, together with occasional hypodermic injections around the eye of dilute solution of Chloride of Gold and Soda. When the disease presents either multiple synechiæ or a total posterior synechia, we must not lose time by trying a medical treatment, but should immediately perform iridectomy, comprising, in the excision, a considerable part of the iris. And as soon as the iridectomy is finished, we must ascertain if the

site of the new pupil is not partly obstructed by exudative masses, because we will then run the danger of seeing it become obliterated. The margins of the new pupil become inflamed, as well as the neoplastic and vascular masses that occupy the opening made by the operator. As soon as the new pupil is obliterated, we must resort to a second, and sometimes, with certain subjects, to several successive operations, to attain the desired object; and if we attain it, not only does the disease become arrested, but the alterations it has produced begin to disappear.

Serous irido-choroiditis, which is often accompanied by an increase of the intra-ocular pressure, requires, on this account, a careful supervision. In addition to the means already named for the active inflammatory symptoms, cold applications over the eye, and leeches to the temples, will often be useful. Beside, we must be ready to perform reiterated paracenteses, or even iridectomy, if symptoms of glaucoma supervene.

Purulent irido-choroiditis is less amenable to treatment when it follows an operation. Especially in aged or feeble persons, warm compresses or cataplasms, as well as a tonic medication, will be found to have a better influence than any other treatment. When the cyclitis is kept up by the presence of a foreign body (as for instance a depressed crystalline) all other treatment is useless if we do not remove the injurious cause. With this object, we are often obliged to excise a portion of the iris and extract the lens, if the foreign body is lodged there, or has wounded it in penetrating the eye. If this can not be done, the eye is irrevocably lost, and then it only remains for us to do all in our power in order to prevent the destructive influence which this condition of the eye may exert upon the other.

When all other means fail to lessen morbid action in the diseased eye, it must be removed, in order to save the healthy eye. But all eyes are not to be enucleated; only those that present certain dangerous symptoms. The rules for resorting to enucleation of the lost eye are:

1. In all cases in which the healthy eye remaining completely intact, the other suffers from intolerable pains, unyielding to palliatives, and thus threatening the healthy eye.

2. In all cases in which the lost eye provokes even a very feeble irido-choroiditis in the other, for this operation will be the only method of curing the latter affection.

3. In all cases in which the remaining sound eye becomes affected with amblyopia, even in a slight degree; in which its range of accommodation rapidly diminishes; and in which this eye, very

irritable under the action of strong light, can not undergo a prolonged application, these last symptoms being often the precursors of irido-choroiditis. It will be so much the more urgent to perform enucleation, when an attentive examination can discover, either in the eye itself, or in the general condition, no other origin for these derangements than the sympathetic influence heretofore referred to. Beside, in cases of doubt it is much better to operate too early than too late, for we have often had occasion to observe the inutility of the enucleation, when the irido-choroiditis was fully confirmed.

In some cases, iridectomy is of no service, the new pupils become successively closed by exudative masses or vascularized neoplastic formations, forming, as it were, a second diaphragm, and of such a resistance that quite strong forceps or crotchets, introduced through a linear section, can not tear them. Beside, a crystalline cataract is frequently found behind the exudative crusts. The cornea has its nutrition deranged, from the obliteration of a more or less considerable number of the vessels of the ciliary body, and becomes reduced in its diameters. The whole plane of the iris bulges forward, not from a collection of fluid behind it, but from the hypergenesis of the cellular elements of the irian substance, and of the thick exudative deposits which crowd upon it; and the anterior chamber is very small.

In these cases, when a close examination authorizes us to believe that there is a sufficient preservation of the nervous elements of the retina, this membrane not being detached, instead of iridectomy, we may extract the lens and remove a portion of the iris with the crusts of exudation attached to it. We will, in most instances, have to make a new artificial pupil, after the performance of the above operation. (*Wecker.*)

4. *Apoplexy of the Choroid* proceeds from the rupture of one or several of the vessels of this membrane. It is produced without any appreciable cause, but more frequently after prolonged night watchings, violent paroxysms of anger, blows on the head, cerebral apoplexy, or a very chronic congestive condition of the choroid. When choroidal apoplexy is produced, the blood is effused into the most dependent part of the eye and detaches the retina at this point, or else, it perforates this membrane and enters the vitreous humor, where it coagulates in the form of a dark and diffuse-red patch. At other times, when the effusion is somewhat considerable, it occupies all the continuity of the retina, and forms at the bottom of the eye a thick veil which interferes with the light.

The *diagnosis* may be readily made out by an *ophthalmoscopic* examination, which will reveal retinal sanguineous patches; there may be several of these of different size, scattered over the fundus, and they may traverse the retina and pass into the vitreous humor, where they may become diffused or appear as distinct clots. These clots may be absorbed more or less rapidly, and when this process is going on, they lose their bright-red appearance, and become more or less brown; but those which remain unabsorbed a long time, often retain their primitive-red color, and character. The impairment of vision depends upon the situation of these deposits; if they involve the immediate vicinity of the macula lutea, vision will be very much interfered with; but considerable bloody deposits may exist in other parts, and be more or less permanent, without materially impairing vision. White patches may often be seen, indicating the disappearance of pigment. When the patches are from effusion in the retina, the retinal vessels will be seen in front of them, and at no point of their tract can blackish points, indicative of the rupture of a vessel, be seen.

The *prognosis*, always unfavorable, varies according to the abundance, and the seat of the effusion.

The *treatment* consists in active revulsive and counter-irritating measures, and the internal use of agents to promote absorption, as, Iodide of Potassium, Bromide of Ammonium, etc.

5. *Atrophy of the Choroid* is a concomitant or a consequence of many of the internal inflammations of the eye, and is always a grave symptom. The *ophthalmoscopic* appearances differ according to the particular portion of the membrane. If it affects the first layer, the fundus instead of the usual rose-color, presents a pale orange-yellow or brown tint, and perhaps we find brownish patches and streaks, giving the appearance of a scratched picture. Secondly, where the arterial layer (*chorio-capillary*) has become affected, we have obliteration of the capillary net-work, and we see the larger vessels beyond with unusual distinctness. Thirdly, where the venous layer has become involved, we find pigmental deficiencies and accumulations in such a manner, that the fundus has a spotted appearance, like that of a tiger's skin. *Treatment* is rarely of service.

6. The choroid may also be affected by various kinds of *tumors*, or, it may become the seat of various *degenerations*, which may be

diagnosed by the ophthalmoscope, but which are not amenable to treatment.

DISEASES OF THE RETINA.

1. *Pigmentary Retinitis. Choroido-retinitis Pigmentosa.* This is a peculiar form of choroido-retinal inflammation which is characterized by commencing near the ora-serrata, from which it creeps backward toward the optic disc, in a very gradual manner. It is frequently met with and is *caused* by whatever produces ocular congestions, such as, the sudden impression of brilliant light, prolonged study of near and small objects, etc. It also appears to be hereditary, and to manifest itself more especially among the offspring of consanguineous marriages.

Sometimes it commences suddenly, at other times, on the contrary, it begins in a slow and insidious manner, by a slight dimness of vision, twitchings in the eyeball, and various luminous appearances. After a longer or shorter time, the sight grows weaker, the extent of the visual field becomes narrowed, the recognition of objects placed laterally is difficult, and the patient, whose eyes seem agitated by a continual trembling, is obliged to direct his looks immediately toward an object presented to him, in order to see it; night-blindness also occurs. Nothing is learned from the outward aspect of the eye, until aniblyopia occurs, when the pupil becomes large and sluggish.

The *diagnosis* is determined wholly by an *ophthalmoscopic* examination, which reveals, upon the surface of the retina, blackish specks and flakes of every conceivable shape, at first scattered, but subsequently, as they become more abundant, running together into a tangled web, the stronger lines of which often accompany the retinal vessels, which are much reduced in size. These specks first appear near the ora-serrata, and spread very slowly backward upon the bottom of the retina, and even on the papilla. The choroid in the meshes of this web is poor or wholly deficient in pigment; from the various abnormal changes it undergoes it presents exudations, atrophic spots, bloody specks, etc. The vitreous body itself participates in the disease, becomes softened sometimes, and contains blackish flakes proceeding from the depigmentation of the choroid. The optic nerve eventually becomes atrophied.

The prognosis of this disease is very slow, frequently extending over several years; and sometimes it remains stationary for a long period. Its *prognosis* is unfavorable, as it almost invariably involves a gradual loss of vision even to its complete extinction.

The *treatment* is rarely efficacious. It consists in the proper use of the means applicable to choroidal congestions, or choroiditis.

2. *Sub-retinal Dropsy. Serous Detachment of the Retina.* Under the influence of an inflammation of the deep-seated membranes of the eye, an effusion of serous matter may form between the choroid and the retina, detaching the latter and pushing it forward. This pathological condition is termed sub-retinal dropsy, and may be caused by choroiditis, retino-choroiditis, irido-choroiditis, a choroidal hemorrhage, etc. Under these circumstances the effusion occurs slowly, and is accompanied with other lesions observable with the *ophthalmoscope*, which will always clear up the diagnosis; at other times, the serous detachment is produced suddenly and without any secondary lesions, as, after an exposure to cold, an erysipelas of the face, or during the course of an albuminurous disease, in which case the effusion may detach the whole surface of the retina, or only a portion, generally the most dependent. We will examine these two conditions.

a. *General Dropsy, or Complete Detachment*, which may be recognized by direct or oblique light; but the *ophthalmoscope* will afford the best indications of its presence. The fundus of the eye will present the appearance of an opaline surface traversed horizontally by folds and minute projections of a pearly appearance, and furrowed by vessels of a larger size than in the normal state. The papilla can not be distinguished any longer, and if the patient moves his eye in various directions, the retina can plainly be seen undulating from the communicated movement of the eyeball, and under the influence of the agitation of the effused fluid; the ramifications of the retinal vessels may likewise be seen. It is by no means rare to observe hemorrhagic spots upon its surface, floating bodies in the vitreous body, and at a more advanced period, false membranes which obstruct the pupillary field and conceal the retinal detachment, or else, an ordinary soft and incurable cataract. These lesions always produce a total blindness.

b. *Partial Dropsy, or Partial Detachment*, will present under the *ophthalmoscope*, at the dependent portion of the retina, a floating mass of a white or grayish tint, furrowed with the flexuous vessels; the sudden curvature of which, produced by the passage of the portion of the detached retina from the healthy portion, as well as the contrast between the normally-colored fundus and that where the image of the choroid is damped, or wholly obscured by the detached

retina and the serum behind it, indicates the extent of the detachment. As to the other parts of the retina, they preserve their normal aspect; and sometimes, the papilla may be readily discovered. A retina which has been long detached is pearly white, but this color may be modified by the admixture of blood with the serum which is behind; and in rare cases it glistens with cholesterine.

The first physiological symptom resulting from this disease is an interruption or mutilation of the field of vision corresponding with the seat and extent of the detachment, and as this usually occurs at the inferior part of the fundus, objects which ought to form an image in this part (lying in the upper part of the field of vision) are not seen, and the field appears cut through by a horizontal line, which is commonly more sinuous than straight; this is called *hemipopia*. This obscure veil which hides a part of objects varies in position with every movement of the patient, because the effusion undergoes an undulation each time, which produces a variation of its relations with the visual field.

The progress of retinal dropsy is very slow. The separation often creeps on so insidiously, being unattended with pain or any external signs of mischief, that sometimes the lower hemisphere of the retina is stripped off from the choroid before the patient is aware that anything is wrong with his eye; and indeed the discovery is sometimes made accidentally by closing the sound eye. In some cases the effusion remains stationary for a long time and then disappears, being followed by an improvement of vision; while in other cases, the detachment goes on, becomes general, is complicated with various abnormal changes, the globe atrophies, and the patient is incurably blind.

The *treatment* in the early stage consists in the use of agents directed at the same time against the cause of the disease, when we can determine it, and to favor absorption of the effused matter. As, Iodide of Potassium, Bromide of Potassium, Chloride of Gold and Soda, hydragogue cathartics, Compound Infusion of Parsley, counter-irritants behind the ear and to the nape of the neck, and collyria containing Iodine and Belladonna. A very good collyrium may be composed of Iodine half a grain, Iodide of Potassium four grains, Sulphate of Atropia two grains, Distilled Water two fluidounces; mix. We may favor the action of these agents by exerting a gentle pressure upon the eyeball. A complete detachment of the retina is incurable; if it be partial, treatment may prevent it from becoming complete.

3. *Hemorrhage of the Retina. Apoplexy of the Retina and Papilla.* Hemorrhage of the retina is occasioned by a rupture of one or several of the vessels of this membrane; when it occurs suddenly it is termed "apoplexy of the retina." In some instances it complicates congestive, pigmentary, and albuminurous retinitis.

The *symptoms* are, a sensation of weight in the eyeball, a sudden obscuration of vision, varying in kind and degree with the extent and locality of the clot. The external appearance of the eye may be healthy. Its invasion is sudden, and instances have occurred where persons going to bed well have awakened blind.

Under the *ophthalmoscope* the *diagnosis* may be readily made out. Large reddish-brown patches are observed, sometimes a fine speckled appearance, analogous to the sanded appearance or red points observed in certain cerebral affections, and, at other times, a true clot which has undergone modifications corresponding with the period since it was formed. In some instances, a hemorrhagic spot occupies the papilla wholly concealing it; in others, the region of the yellow spot will be the seat of the lesion. Fresh blood spots have a rich crimson color, deepest at the center and fading off toward the edges; older ones are blacker, or brownish-red, rusty, or buff. The retinal vessels will be deformed, and at some point of their track will be seen one or several minute patches of black or dark-red blood which indicate the seat of their rupture; but, generally, we will be obliged to wait until some absorption has taken place before we can detect the exact point of rupture. Sometimes the vitreous humor is penetrated by a certain quantity of blood, which is very slowly absorbed. The clots do not present the crimson color in which they appear by reflected light out of the eye, but are dark, or even black, in consequence of the small amount of light that they reflect, affecting the observer's retina much less sensibly than the flood of light which sweeps past the clots from the fundus around.

The progress of these sanguine effusions, ordinarily retrogressive, may be followed by the *ophthalmoscope*, which we use to determine the gradual absorption of the blood, and which, after a certain time, shows the blood spot replaced by an atrophic white spot, often surrounded by a fringed border; as a general thing, vision is then recovered.

The *prognosis* of this affection is always grave; it varies according to the amount of effusion, its seat, and its duration.

In the *treatment* there are three indications to fulfill, viz.: 1, To diminish the hemorrhagic tendency; 2, to overcome any existing congestion; and, 3, to adopt means to favor the resorption of the

effused blood. To fulfill the first, the bowels must be kept regular, the skin be attended to, and diuretics be given, and which also assist in removing congestion. To fulfill the last indication, cold douches to the eye, ioduretted lotions, and a slight pressure exercised from time to time upon the eyeball, will be found beneficial. The following pills will be of service: Take of Bromide of Potassium two drachms, Podophyllin half a drachm, Guaiac Resin one drachm, Extract of Aconite one drachm, Extract of Black Cohosh a sufficient quantity; mix, divide into sixty pills, of which one may be taken for a dose, repeating the dose two or three times a day.—If the hemorrhagic tendency be due to a general cause, it should be treated by the proper hygienic and therapeutical means.

4. *Anemia of the Retina* is a pathological condition characterized under *ophthalmoscopical* examination by a pallor of the optic disc, or a dull whiteness, with a diminution of the number and size of the retinal vessels, and even by their complete disappearance. The arterial branches sometimes appear empty, contracted, and thread-like, and the veins more or less collapsed. *Atrophy of the papilla* or optic disc* frequently accompanies it, and which is indicative of

* *Progressive Atrophy of the Optic Nerve*, by Dr. Quaglino, of Milan. "Progressive amaurosis, following atrophy of the optic nerves, is an affection which is, unfortunately, too often met with in practice. By means of the ophthalmoscope we may recognize it from its commencement, and follow it through its progress to its complete development.

"It is a fact well known to ophthalmologists, that, when the papilla of the optic nerve becomes whiter at any point, or over its whole surface, and at the same time the arterial vessels are less developed in the white part, there is a commencing atrophy of the papilla and of the optic nerve. When the papilla presents a pearly, tendinous aspect, strongly reflecting the light, and the arterial vessels have become filiform; when its center is sunken or hollowed, and its form irregular, we may, without any fear of being mistaken, affirm that the patient is already hemiopic, amblyopic from diminution of the extent of the visual field, or, amaurotic. In this last phase of the disease, experience has demonstrated that art is almost always powerless, and that the blindness is irremediable.—It will, then, be very important to determine both the exterior and interior causes which may lead to this extremity; in a word, to point out precisely the morbid process which is its proximate cause, that an efficacious treatment may be undertaken at its very commencement.

"Atrophy of the optic nerve is the disappearance of the nervous substance of its fibres, which is superseded by hypertrophy of the connective tissue, and converted into a fibrous substance, which ordinarily contains fatty globules. But what is the determining cause of this progressive metamorphosis?—Observation has demonstrated that the defect of nutrition and the compression of the nervous substance, produced directly by neurilemmatitis, or pia-meningitis, are

some serious disease, as, a compression of the optic nerve by a cerebral or extra-ocular tumor. It may be known when examined by the

well-known causes of the atrophy. Beside, the last is the more frequent. Let us now point out the causes which may, in a more or less direct manner, impede the nutrition of the optic nerve. A diminished arterial circulation, a sudden loss of blood from any hemorrhage whatever, an imperfect hematosiis, as in chloro-anemia and hydroemia, an insufficient nourishment, are very frequent causes of atrophy of the vessels and nervous substance of the papilla. These cases are far from being rare in practice, and they are not serious, when we can recognize them and treat them from the commencement; heretofore, these cases have been termed 'asthenic amauroses.'—Defect of nutrition may also be caused by a compression exercised upon the ophthalmic arteries, or, upon the optic cord, by tumors at the base of the cranium, or of the cerebrum, by specific periostitis, orbitoceles, or abscess of the orbit; but we will not dwell upon these cases.

"The most common *causes* of atrophy are congestion or inflammation of the membranes of the brain, and of the neurilemma of the optic nerve, or even of the spinal cord.—Hemorrhage and softening of the cerebral optical centers, as well as epilepsy, may also lead to the same alterations.—Beside the causes already pointed out, we have met with atrophy of the optic nerve as a consequence of long-standing neuralgia of the superior branch of the fifth pair, of venereal excesses, too sustained application of the eye, deep sorrows and prolonged watchings. Among old persons, there is a progressive atrophy of the optic nerves, which appears to be the result of atheromatous degeneration, and of dilatation of the arteries of the anterior circle of Willis, which produce a compression upon the optic nerves. We have never observed atrophy with persons poisoned by lead, nor after emboly of the central artery of the retina.

"Inflammation of the optic neurilemma, primitive or secondary, from an extension of phlegmasia of the retina, or of the cerebral membranes, is, as already stated, the most frequent cause of atrophy, and may be easily determined from the commencement by means of the ophthalmoscope.

"From what has been stated, it is natural to conclude that atrophy of the papilla and of the optic nerve is rarely an idiopathic disease of the nervous pulp; it is rather a consequence of pathological changes which it is of the highest importance to determine. The diagnosis will rest upon the appreciable characters of the papilla, upon the constitutional symptoms, and upon an exact commemorative account.

"There are two stages of this affection; the one acute, congestive, or inflammatory; the other chronic, with atrophy of the nervous fibres, anemia, and paralysis. The acute stage, which precedes the atrophy, and which presents an optical neurilemmatitis, is only of short duration, and, if the amaurosis is already advanced, the symptoms of compression of the papilla will almost always have disappeared. Succeeding them, will soon appear the atrophic process of the optic fibres, resulting from the compression and from the degenerations which it develops in the nervous cellules. Almost always, notwithstanding the efforts of art, this alteration pursues its progress more or less rapidly. It is this regressive morbid process, independent of any congestion or inflammation, which we call *progressive atrophy of the optic nerve*. (1.)

"The amaurosis which manifests itself in this affection, whether it be present at the period of the meningitis or of the neuritis, or whether it exists with that

ophthalmoscope, by its tendinous or brilliant pearly-white appearance, by being generally small and arched in the middle, and by

of the atrophy, almost always presents a group of symptoms, which we will describe in a few words. The disease may be developed in one eye, or in both at the same time. When it is associated with a unilateral neuritis, the alterations of vision may be limited to a single eye; but, if the point of departure is in the general weakness of the constitution, in a disease of the spinal cord, or a meningitis of the cerebellum, the disorder almost invariably affects both eyes at the same time. In both cases, the amaurosis commences by a diminution of the visual field, more commonly peripheral, with suppression of the corresponding phosphenes.

"Sometimes the retina becomes insensible to a feeble light, and presents the phenomenon of symptomatic hemeralopia, while the visual field contracts more and more, until the sight is wholly lost.—When hemiopia is present with both eyes at the same time, it often occupies the external side with one eye, and the internal side with the other; sometimes, on the contrary, it is the two external sides of the retina which are affected. Perhaps, in the first case, there will be only a single nerve affected, while, in the second both will be involved. This fact will find its explanation in the partial decussation, generally admitted, of the fibres of the optic nerve.—In some cases, the perception of color is deranged; the patients see small globules of different colors, red, yellow, blue, especially during the night; while, during the day, the pavement and all the surrounding objects often appear dazzling white.—The patients have alternations of feeling well and ill; certain days they are quite well, and on others complaining; sudden atmospheric variations are apt to cause more disturbance of vision, as well as mental troubles, prolonged fasting, and an insufficient light. During the evolution of these symptoms, vision is gradually extinguished by paralysis of the optic fibres, and the patient preserves only a faint perception of light on the internal sides of the retinae, which are always the last points struck with anæsthesia.

"The progress of this disease is very slow; it often remains stationary,—and may require months, and even years, to run through its fatal cycle.—A very limited vision is sometimes preserved at the internal side of the retina; the course of the disease will be more rapid only when bad hygienic conditions, or excessive labor, add their unfavorable influences.

The external membranes of the eye present only very insignificant indications; indeed, the pupils almost always preserve a certain degree of contractility; among old persons, we have almost always observed myosis.—Mydriatic dilatation of the pupil is rarely met with, except in the acute atrophy which accompanies hydrocephalus, violent meningitis, eclampsia, and neuralgia of the fifth pair caused by a rapid and intense compression upon the quadrigeminal bodies, the optic bands, and upon the roots of the third pair. In slow and progressive atrophy of the optic nerve, the patients sometimes experience transient lancinating pains in the bottom of the orbit, the temple, or in the nape of the neck.

"The general symptoms vary according to whether the commencing point of the atrophy is in the cerebral centers, or in the spinal marrow. When the disease is seated in the sensorium, we almost always observe giddiness, ringings in the ears, hardness of hearing, vertigo, weakness of memory, and a certain degree of hebetude.—When the disease commences by that affection of the spinal marrow, termed *ataxie locomotrice*, the patients complain of very acute, lancinating,

the retinal vessels being small, some branches obliterated, or, somewhat dilated, and of a varicose aspect. When not due to pressure,

shooting pains, located in various places, following the track of the crural nerves. They experience cramps, a kind of feebleness of the inferior extremities, which is due to a want of co-ordination of their movements. There will be incontinence of urine, obstinate constipation, often very extensive paralysis, seizing, for instance, a whole member, or being limited to the hands, the feet, the extremities of the fingers, etc.; impotence is likewise frequently observed.

"The affection of the spinal marrow, which induces atrophy of the optic nerves, is almost always the result of venereal excesses, of abuse of liquors, and tobacco, and of mental troubles. In many instances, the myelitis is a consequence of typhus, miliary fever, or pellagra,—constitutional syphilis, erratic rheumatism and gout, are etiological elements which play a considerable part in the generation of atrophy of the optic nerves. Wounds of the head, the forehead, coup de soleil, sudden passage of lightning before the eyes, sleeping during the night with the head near a recently built wall, or on moist earth, as often happens to soldiers, are also, frequent causes of the atrophy under consideration.—When this affection is congenital, it almost always depends upon an intra-uterine hydrocephalus.

"From what has been said, it follows that the treatment must vary according to the period of the disease, and the cause which determined it. If there still remains any congestion of the papilla, which may lead us to suspect the existence of a congestion of the cerebral membranes, or of a neuritis, we will employ a moderate antiphlogistic treatment, or else, we must produce a revulsive action on the bowels, by means of purgatives, aloes, etc. We may also employ counterstimulants (*sedatives*), such as cherry-laurel water, extract of belladonna in small doses, especially if there is photobia with crethism. In those cases where the spinal cord is involved, which will be recognized by the special phenomena common to this affection, or, if the cause is a weakness of the ganglionic and vascular nervous system, due to venereal excesses, to anemia, mental sufferings, etc. great advantage may be drawn from a regular hydrotherapeutic (*hydropathic*) treatment, consisting of tonic excitant douches applied the length of the spinal column, and on the eyeballs themselves.

"When the atrophy is well-marked, presenting the papillary symptoms, and instead of congestion a diminution and decrease in size of the arterial vessels, and even exhaustion of the innervation, we must be very careful not to bleed, nor to weaken the constitution by a debilitating medication, as such a course would be dangerous to vision, and would only precipitate the amaurosis. Ferruginous waters, cinchona, bitter tonics, strychnia, camphor, arnica, electricity, pure healthy air, good diet, absolute rest of the eyes, will often arrest the disease, and maintain the hemiopia or the amblyopia in the stage which they have reached. If the disease be due to a specific cause, as syphilis, we must insist upon an anti-syphilitic medication. When the disease is of long standing and associated with a well-marked arthritic diathesis, treatment has always failed in our hands.

"The atrophy which supervenes with neuralgia of the fifth pair, is sometimes arrested in its progress by a proper tonic treatment; but if there exists at the same time a constitutional syphilis, amaurosis is unfortunately the rapid and inevitable result. We may say as much regarding the atrophy observed among old persons.

"Paracentesis of the cornea, which we have sometimes attempted in the

it may frequently be removed by attention to hygienic measures, aided by tonics and chalybeate preparations. If due to tumors, etc., it will continue progressing, and terminate in permanent blindness, unless the mechanical causes can be removed.

5. *Cysticercus of the Retina.* The parasite *cysticercus tenuicollis* has been occasionally met with in the eye. It is distinguished at the fundus of the eye by a tumor or small translucent projection, of an oval or button-like form, bluish-green, and giving off a more or less elongated portion which is its head. This singular affection involves morbid changes in the tissues of the eye, followed by loss of sight almost invariably. The choroid around the parasite becomes grayish-yellow, the neighboring retina becomes raised by serum, and the vitreous humor becomes turbid or opaque. The movements of this entozoon also reveals its character. There is no successful treatment known for it. A cataplasm composed of finely-powdered Balmony, White Indian Hemp, Pomegranate and Assa-fetida, worn over the eye, might possibly be of service in destroying the vitality of the entozoon; or a solution of the same frequently applied to the eyeball.

6. *Encephaloid of the Retina, and of the Optic Nerve. Intra-ocular Cancer.* This affection also termed *medullary sarcoma, fungus hæmatodes* is more common among young persons than adults, and is rarely met with in old age. It commences with a more or less dilated, sluggish, and irregular pupil, through which is seen, by the

treatment of atrophy, in cases where there were tension and abnormal hardness of the globes, has not produced the hoped-for result, although it appeared to produce a slight amelioration in some cases. This was manifested immediately after the escape of the aqueous humor, and which we attributed to the return of blood in the atrophied and anemic vessels, the consequence of the kind of vacuum which the sudden evacuation of the aqueous humor produced.—Iridectomy has given no successful results, although it was performed in one case where there was tension of the globes and evident pulsation of the arteries of the papilla."

(1.) ["Atrophy of the papilla, consecutive to retinitis, whether simple, syphilitic, or of any other nature, or, to posterior atrophic choroiditis, may easily be distinguished from primitive atrophy of the optic nerves caused by neuritis or an affection of the nervous centers, if we will pay attention to the morbid changes which are produced in the retina, and the choroid, such as pigmentary degeneration, maceration of the pigment, and atrophy of the choroid.—Glaucomatous atrophy, caused by the internal compression exerted by the vitreous body on the papilla, is distinguished from those which result from retraction of the optic nerve, by the pulsations of the central artery, the abrupt interruption of the veins at the periphery of the papilla, the flattening, paleness, and diminution of the caliber of the arteries."]

ophthalmoscope, a yellowish-gray or reddish-yellow patch upon some point of the retina, somewhat resembling that in the eye of a cat. This patch enlarges, assumes an amber color, becomes unequal and embossed or nodulated, and eventually occupies the whole of the fundus. In this condition, if the eye be explored by twilight, or by a weak light, a deep-seated opacity will be seen, which gives a brilliant reflect'on like that of a brass or copper-plate; it will be seen more satisfactorily when the pupil is dilated. The other parts of the eye may be still healthy, there being only some visual disturbances; sometimes hemeralopia, and a slight sluggishness in the contractions of the pupil. At times strabismus is first noticed; or blindness may occur from the commencement. Ordinarily, there is no pain or inflammation in the early stage. Sometimes the disease will remain stationary for two or three years, but as soon as it begins to advance from the bottom of the eye it progresses rapidly.

In the *second stage* the fungous growth invades the vitreous humor, advances toward the iris, destroys the lens, and makes its appearance behind the cornea; the pupil becomes enlarged, the iris almost disappears, the sclerotic assumes a leaden color around the cornea, the cornea is increased in diameter, the eyeball becomes enlarged and misshapen, the eyelids swollen and pervaded by enlarged veins, with more or less severe pains, various inflammatory symptoms, and constitutional disturbance.

In the *third stage* the fungus destroys the cornea, a fetid, bloody, yellowish fluid is discharged, together with the lens, and the tumor protrudes and grows with great rapidity in the form of an encephaloid mass, which ulcerates, bleeds, and sloughs, and is accompanied with such exhaustion, painful, and grave phenomena, that the patient sinks in an agony of torture and suffering, or else expires comatose or convulsed. The only chance is extirpation of the eye at a very early period; but this is by no means uniformly successful.

7. *Albuminurous Retinitis. Albuminurous Amaurosis or Amblyopia.* This disease often coincides with the appearance of symptoms which characterize albuminous nephritis, as, swellings of the face and the inferior extremities, headaches, convulsive attacks, etc.; at other times, on the contrary, a disturbance of vision is the first manifestation of the albuminous affection. Patients then become fatigued after a slightly-prolonged reading, they complain that their sight is weak, has become shorter or longer, and no glasses can be found to improve the condition of their eyes; they experience interruptions in the field of vision, are annoyed by *muscæ volitantes*.

tantes, sparks, various optical illusions, and ultimately they become blind.

At the commencement we notice, by means of the *ophthalmoscope*, only a slight hyperemia of the papilla, (redness, vascularity, and, in severe cases, an indistinctness of the papilla), which soon disappears and presents nothing characteristic. At a later period, many pathognomonic lesions are observed; as, irregular red apoplectic patches scattered upon the retina, either around the papilla, or along the tract of the vessels; as the disease progresses the fundus of the eye becomes more and more confused, the pupil dilates, and the retina loses its normal color, becoming dull and appearing œdematous. The papilla soon participates in this infiltration; it appears larger and more prominent, and its outlines become less distinct; and, in the last stage, fatty degeneration of the retina is still more marked, and the surface of this membrane is studded with bright, yellowish-white spots, which form a ring around the papilla; these spots enlarge, from large (fatty) yellowish-white patches which cover nearly the whole of the retinal surface, and which are separated only by some very small vessels. In some instances, we may also observe, as where the choroid becomes the seat of secondary lesions, pigmentary patches, yellow atrophic spots, exudations, etc. The existence of all these lesions results in total blindness.

The progress of albuminurous retinitis is very irregular. Sometimes it commences suddenly and disappears in the same manner, to re-appear again; but more frequently the fatty transformation commences, and weakness of vision follows in a slow and progressive manner up to its last terminal stage.

The *diagnosis* is easy under an ophthalmoscopic examination; sometimes, we may throw great light upon the nature of the disease by an examination of the urine, especially if diabetes be also present.

The *treatment* consists in the employment of such agents as will remove the nephritic affection. (See *Treatment of Bright's Disease, and of Diabetes.*)

When symptoms of local congestion are present, the preparation of Aconitina and Hydrocyanic Acid, on page 1276, may be rubbed in around the orbit, and the following preparation may be given in doses of a teaspoonful two or three times a day: Take of Tincture of Digitalis one fluidounce, Tincture of Aconite half a fluidounce, Tincture of Opium three fluidrachms, Spirit of Nitric Ether three fluidounces and one fluidrachm; mix.

When the period of cogestion has passed away, pursue the treatment necessary for the nephritic disease, as above remarked.

8. *Morbid changes in the Papilla of the Optic Nerve*, or in the *Optic Disk*. The optic papilla is frequently the seat of lesions which, added to those discovered in the retina and choroid, reveal various affections, which, from being formerly unknown, were classed with amauroses. In some cases, an examination of the papilla alone by the *ophthalmoscope* will suffice to detect modifications in its form, color, extent, etc. These morbid changes, which are the frequent indices of deep-seated affections of the brain, of the spinal marrow, or of the optic nerve reflecting upon the functional phenomena of the organs of vision, give rise to peculiar symptoms which characterize a class of amauroses known heretofore by the name of "cerebral," or "extra-ocular amauroses." They are as follows:

a. *Changes of Form*. Instead of being round, as in its normal state, the papilla sometimes presents a somewhat angular and indented border, and is then usually accompanied with exudations, pigmentary accumulations and blood spots. Sometimes, it is sloped or somewhat concave, and its outline appears less distinct; in this instance it nearly always coincides with a posterior staphyloma.

b. *Changes of Color*. In *hyperemia of the papilla*, this disk assumes a very red tint, and is pervaded by turgescient vessels. In *apoplexy of the papilla*, extravasations of blood are observed, in the form of irregular reddish spots or specks. In *anemia of the retina*, which is often the commencement of *atrophy of the papilla*, we will observe this disk dull-whitish, with a diminution in the size and number of its vessels; in atrophy, it assumes a tendinous, brilliant, white, pearly aspect. Greenish papillæ are indicative of cerebral affections.

c. *Changes of Extent*. A diminution of the extent of the papilla characterizes *atrophy of the papilla*, as well as *of the retina*. The *ophthalmoscope* will show the papilla white and pearly, but smaller than natural, while the arteries and veins have lessened in diameter or are obliterated and replaced by whitish tracks. This group of lesions generally indicates compression of the optic nerve by a cerebral tumor.—The *atrophy* may also be symptomatic of a chronic affection of the membranes of the eye; but in this case we will also observe deposits of pigment, yellow spots, exudations, or floating bodies in the vitreous humor, etc., which will assist the diagnosis. As to the smallness of the optic disk when unaccompanied by a change of color, excavation, or other symptoms already pointed out, it is not of itself sufficient to evidence disease, and may coincide with perfect vision.

d. *Changes of the form of the Papillary Surface*. The alterations undergone by the surface of the optic disk are, excavation or depression, and an abnormal projection or elevation. *Depression* is

the more common, and is one of the pathognomonic characters of glaucomatous sclero-choroiditis; but we must not mistake for an abnormal depression, the slight hollow which naturally exists where the retinal vessels pierce the papilla. This excavation may also be met with when extra-ocular tumors have, by their pressure, effected an atrophy of the optic nerve; and, in this instance, the papilla will appear sunken, and its vessels seem to become bent or crooked after having passed through to the surface of the retina. Papillary excavation effects a progressive weakness of vision, and even its total loss.

Elevation of the papilla almost always coincides with its enlargement and its œdematous infiltration. It then appears large, swollen, projecting forward, of a dirty-yellow color, its outlines irregular, and its veins having a varicose appearance. This condition is found in albuminurous retinitis, and in some cases of œdematous infiltration of the papilla and retina caused by the compression of a cerebral or orbital tumor upon the optic nerve. This is always a grave lesion.

These alterations of the papilla being nearly always indications of an affection of the brain, spinal marrow, or orbit, etc., when they have been recognized by the ophthalmoscope, we must endeavor to ascertain all the local and general symptoms which are present, and which may enable us to positively diagnose, a softening, a cyst, an abscess, or tubercles in the brain, dropsy of the optic nerve, atrophy of the optic nerve, or any infra-orbital tumor whatever. The lesion being determined, we must adopt the most rational treatment for it.

9. *Musæ Volitantes. Scotomata. Myodesopia.* This is an affection in which a person observes floating before his eyes various objects, frequently called motes, and which are often very annoying, giving rise to much uneasiness and anxiety. They are of various appearances, being described as resembling small particles of soot, black spots of various sizes, sometimes straight lines, or waved, twisted, etc., and often with a luminous edge. At other times they resemble a convoluted string of beads, convoluted tubes, transparent bladders, luminous chains, or assume the figure of a small worm, spider, web, etc. These little bodies move in every direction with the movements of the eye, and then as soon as this organ is at rest, they slowly float across the field of vision. Vision is seldom, if ever, affected by the floating musæ, and, although not removable by any treatment, they do not indicate any serious disease of the eye. They are more distinctly observed when the eyes are exposed to a strong light, as looking long at white objects well illuminated,

at flame or at a clear sky. They may likewise be rendered more distinct, or be brought into view when not before apparent, by looking through a pin-hole at the clear sky. Those who are myopic or presbyopic are often relieved from the annoyance of these spots, at least to a certain extent, when they use the proper glasses to render vision distinct. Those who are subject to them experience them in greater abundance after loss of sleep, overexertion of the eyes, fatigue, dissipation, sexual excesses, etc. The causes of these floating *muscæ* are very imperfectly understood; though supposed by some to be due to certain vascular conditions of the retina, or to bodies floating in the vitreous humor near the retinal surface. Mr. Hogg considers them as being due to detached granules or nodulated masses of pigment, or to an irregular arrangement of the pigment cells, in many instances.

As long as the sight continues good, the iris being perfect, the pupil of a natural color, and the patient can discern minute objects, there is no cause for alarm; vision is in no danger. But when they are accompanied with a failure of vision, which can not be attributed to myopia or presbyopia, or other changes observable by the eye of the observer, or under the ophthalmoscope, then we may fear the commencement of a cataract or amaurosis.

The best treatment for them, is, regularity of the bowels, moderate diet, rest of the eyes, regular habits, and frequent douching the eyes with cool or tepid water. No other medical treatment is required.

Fixed muscæ volitantes are those which, when observed, are always in the same position with regard to each other, as well as to the optic axis. Their motion is only apparent, depending on the motion of the eyeball. Sometimes there will be but one black spot, surrounded with a halo or outer ring, or there may be several of them. In reading, they appear like specks on the paper, or dance along as the eye moves, keeping constantly in the point of the field of vision, frequently in its center. The spots are generally black, though their color often changes.

Fixed *muscæ* are owing to insensible spots of the retina, frequently at its central part, and are indicative of commencing amaurosis, cataract, or posterior internal inflammation of the eye. Microscopists sometimes are troubled with these fixed *muscæ*, which are very troublesome when making examinations under the microscope, interfering with the view of objects in the center of the field, or at whatever part of the field of vision, the spots are stationed. Sometimes these spots are quite large from the first; at other times, from

a minute speck, they gradually increase in size until objects can no longer be seen.

When fixed *muscæ* are present, the eye should be carefully and thoroughly examined, and such medical measures adopted as the symptoms discovered will indicate. And, at all events, if no disturbances in the eye can be discovered, the progress of the *muscæ* should be carefully watched, and the eye be examined with the ophthalmoscope from time to time, keeping the patient upon a hygienical course of treatment calculated to check or postpone the presence of any serious symptoms. And, as soon as any lesions are observable, the necessary therapeutical means, as indicated by the lesions, must be promptly pursued.

10. *Atrophy of the Eyeball, and the Adaptation of an Artificial Eye.* Atrophy of the eyeball is a pathological condition characterized by a diminution of its size. Sometimes it is *passive*, as when it succeeds the evacuation of intra-ocular humors, from destruction of the cornea, penetrating wounds, rupture of the eyeball, and phlegmon of the eye. In this case, the membranes become weak and the eye retracts or shrinks into a small stump at the bottom of the orbital cavity. At other times it is *active*, and follows an inflammation of the iris or of the choroid which is accompanied with absorption of the effused inflammatory products and of the normal fluids. Several degrees of active atrophy are distinguished, as, when the eyeball is somewhat soft with a slight diminution of its size, or, when the ocular walls become flaccid and retract within the orbit in the form of a nucleus, of variable size.—Atrophy involves loss of sight and deformity, and is incurable. The deformity may be overcome by the use of *artificial eyes*. Neuralgia of the ocular branches of the fifth nerve often attends atrophy of the eye; it may be benefited by the internal use of Aconite, Belladonna, Quinia, etc., and, if severe, by counter-irritation behind the ear.

An artificial eye is a light, thin, concavo-convex shell of enamel, perfectly smooth on both of its surfaces, the convex one being prepared so as to exactly, or nearly so, resemble the natural one. It should not be worn until the atrophied eyeball has perfectly cicatrized, and is free from inflammation and morbid sensibility; its use should occasion no pain or uneasiness, and it ought to move in harmony with the natural one, more especially from side to side. When worn, it should always be removed at night, and wiped clean, as the secretions from the eye ultimately roughen it, and impair its polish, and when this occurs to such an extent as to irritate the eye

when worn, it should be either repolished, or a new one be used, else troublesome growths will arise from the shrunken eye. With a little care, an artificial eye may be made to last eight or ten years, during which time it may require repolishing some three times. An artificial eye should not be allowed to remain in water, as this softens, and may crack it. After removing it, it may be dipped in tepid water, and then be gently wiped quite dry, with a soft rag. Great care should be observed in procuring an artificial eye, that it be neither too large nor too small, that it perfectly corresponds with the natural one in appearance, being neither too convex nor too flat. Patients can procure good eyes of this kind for about twenty or twenty-five dollars each. The best artificial eyes are made by Boissoneau of Paris.

To introduce the artificial eye, dip it in water, then raising the upper eyelid, slide the longest end, or that which is to correspond to the external canthus, up behind the lid as far as possible; then, turning this end toward the outer canthus, draw down the lower lid and make the lower edge of the artificial eye slip into the lower palpebral sinus, after which allow the lower eyelid to rise. At first, the eye should be worn only an hour or two at a time, and, as the parts become habituated to its presence, several hours, or all day. It should never be worn during the night, nor while sleeping through the day.

To remove the artificial eye, draw down the lower eyelid, and pass the head of a large pin, or a piece of wire bent like a hook, under and behind its lower edge, the eye-shell will, upon being slightly drawn forward, drop out. In order to prevent its falling on the floor and breaking, it will be better for the person to incline his face over a soft cushion or a bed, at least, until he is able to safely secure it in his hand at the time it drops out.—Both before introducing it, and after its removal, the person should bathe his own atrophied eye with cool or tepid water.

ABNORMAL CONDITIONS OF THE OPTICAL REFRACTION AND ACCOMMODATION OF THE EYE.

In the normal state, the eye possesses a faculty belonging to no other optical instrument, namely, that of adjusting itself almost imperceptibly and unconsciously to a distant, close, or medium distance. This faculty is called the “faculty of accommodation to different distances,” and is due to certain conditions of the dioptric apparatus of the eye, to wit:

1. Contraction of the pupil. 2. The projection forward of the pupillary margin of the iris. 3. The increase of convexity of the anterior surface of the lens. 4. A slight increase in the posterior surface of the cornea, a phenomenon which appears to be under the direct dependance of the ciliary muscle, and, perhaps, also of the external muscles of the eye. 5. Certain asymmetries of the cornea and lens, which will be referred to when on the subject of *astigmatism*.

When these several conditions so affect the refractive power of the eye as to prevent objects situated at divers distances from being brought to a focus upon the retina, various disturbances in vision result, and which will be referred to hereafter.

The distance of *perfect vision* with a normal eye has been fixed at ten inches, and all persons who, at this distance, can see small objects or fine print very distinctly, are said to possess perfect vision. It must be recollected, however, that this distance will vary according to the size of the objects, and the sight of each person. Beside this perfect vision, the eye, by virtue of its faculty of accommodation, also perceives in a distinct manner both beyond and within the limits of this fixed distance, ten inches; and in these limits, only, the sight is *distinct* instead of *perfect*, that is to say, the person sees objects very well, but the details, the color, etc., lack that distinctness which constitutes perfect vision, and which is due to the luminous rays being dispersed upon the retina instead of exactly forming their focus there, as occurs when the objects are placed at what is termed "the distance of perfect vision."

The limits of perfect vision vary among different persons, being for ordinary printed letters, from four to sixteen inches. Beyond or within these limits, the sight may be distinct, but it is no longer perfect. This extent of four to sixteen inches, expresses then the *field or range of accommodation* for normal sight. If the objects are larger they will be seen more distinctly farther off, and the range of accommodation will be more extended. With myopes, this range is restricted, for they can distinguish small objects only at varying distances of a few inches. On the contrary, it is more extensive among presbyopes.

As to the limits of distinct vision in the sense of distance, they depend upon the degree of sensibility of the central part of the retina, and the perfect transparency of the dioptric apparatus, and which condition we may ascertain by placing before the eye, a card in which a pin-hole has been made, and looking through it, successively, at near and distant objects. By this experiment, we annul the effect of the lens, and suppress the faculty of accommodation,

and all objects in front of the aperture in the eard, form a focus upon a point of the retina and are seen in a distinct and perfect manner, allowing, however, for the diminution of the luminous intensity due to distance. If, then, an object placed at twenty inches, for instance, is seen dim and confused (with the eye); but, on the contrary, is observed distinctly by means of the perforated card, we may conclude that the sensibility of the central part of the retina, and the transparency of the dioptric apparatus are perfect.

We may ascertain the individual differences of the faculty of accommodation, that is, the *range of distinct vision*, by placing before the eye under examination a card perforated with two pin-holes, at a distance from each other less than the diameter of the pupil, and also placing very fine print at various distances from the eye. At four inches from the eye, for instance, suppose the image is made behind the retina, then, the rays which pass through the two holes will make an impression upon the retina before intersecting each other, and the sight will be double; but at ten inches, if the rays meet each other upon the retina and at the same point, the sight will be simple; ten inches then will represent the nearest limit of distinct vision. If we remove the characters to an indefinite distance, the image will remain distinct if vision be perfect; but if the accommodating power, as usually happens, has a limited distance, at twelve, fourteen, or sixteen inches, the double images will re-appear.

The extent, then, comprised between the four and sixteen inches is the measure of the limits of the accommodating power. These limits vary, they are sometimes nearer, as two to ten inches, sometimes further off, as eight to twenty inches, sometimes very near, as two to two and a half inches, and in this case there is more or less complete paralysis of the accommodating power. The greatest power of accommodation varies between three and twenty-four inches.

The best eye is that which possesses the greatest accommodative power, with a perfect sensibility of the retina, and a complete transparency of its dioptric organs. However, as both eyes take part in the visual act, one condition, still, for perfect vision, is, that the movements of convergence for the vision of near objects, and of divergence for that of distant objects, be in harmony with the internal changes due to the accommodation. Now, this degree of convergence of the optic axes, which varies with the distance of objects, ought, in perfect vision, to have no other limits than those of the accommodating power. The limit of the convergence of the two eyes may be estimated as follows:

A black line is traced on a white piece of paper, and placed horizontally before our eyes at a distance of two inches; we observe that this line is bifurcated before starting from a certain point which is the superior limit of the convergence of the optic axes; now, if vision is normal, this point should correspond to the minimum point of distinct vision with a single eye, four inches, for instance. As to the limits of the divergence, it is the parallelism toward infinite distance.

Donders states that "*normal* or *emmetropic* eyes are those, in which, when the eye is at rest, parallel rays are brought to a focus on the retina. When the normal eye is in a state of rest, the focal point of its dioptric system is situated on the bacillar layer of the retina."

Before proceeding further, I will explain some of the signs or expressions made use of by oculists, and which will materially aid the reader in understanding the estimations, etc., made by them:

Positive glasses, or convex, or +.

Negative glasses, or concave, or —.

— $\frac{1}{20}$, means concave glasses of 20 inches focal distance; — $\frac{1}{6}$, concave glasses of 6 inches, and so on.

+ $\frac{1}{20}$, means convex glasses of 20 inches focal distance; + $\frac{1}{6}$, convex glasses of 6 inches.

Infinite distance; at or beyond eighteen feet from the eye, or a distance at which the rays coming from an object fall parallel upon the eyes, and are brought to a focus upon the retina without any effort of accommodation.

Finite distance; within eighteen feet from the eye, or a distance at which the rays coming from an object fall in a divergent direction upon the eye, and are not brought to a focus upon the retina, but behind it.

Positive accommodation; adjustment of the eye for near objects.

Negative accommodation; adjustment of the eye for distant objects.

Range of accommodation; the distance between the farthest and nearest points of distinct vision.

a. An ideal lens, (a meniscus), which placed upon the anterior surface of the crystalline lens, would afford to rays emanating from the near point of distinct vision, a direction as though they came from the far point.

A. Range of accommodation. $A = \frac{1}{a}$.

1: A, Absolute range of accommodation.

1: A₁, Relative range of accommodation.

1: A₂, Binocular range of accommodation.

r. Far point of distinct vision, = ∞. Or,

r. Absolute far point of distinct vision.

r₁. Relative far point of distinct vision.

r₂. Binocular far point of distinct vision.

r'. Far point, when a convex lens of 6" or 10" focus is placed before the eye.

p. Near point of distinct vision, = 4" or 5". $\frac{1}{p} - \frac{1}{r} = \frac{1}{a}$. Or,

p. Absolute near point of distinct vision.

p₁. Relative near point of distinct vision.

p₂. Binocular near point of distinct vision.

p'. Near point, when a convex lens of 6" or 10" focus is placed before the eye.

∞. Infinite distance.

' Foot.

" Inch = 1 Eng. in. or 0.94 Paris in.

in H, in the horizontal principal meridian.

in V, in the vertical principal meridian.

c, Simple cylindrical glasses.

c[, Bicylindrical glasses.

s C, Spherico-cylindrical glasses.

V, Degree of acuteness of vision. $V = \frac{d}{D}$.

d, The distance at which an object, or print, is actually seen.

D. The distance at which an object, or print, is apparent at an angle of five minutes. In Snellen's Test Types, the numbers above

the type or letters express in Paris feet the distance at which the letters are seen, by a normal eye, at an angle of five minutes.

Acuteness of vision, or sensibility of the retina, in the normal eye, has assigned to it, 1, as the standard degree. Thus, if a normal eye distinctly distinguishes No. XX of Snellen's Test Types, at 20 Paris feet, then

$$V = \frac{d}{D} = \frac{20}{20} = 1, \text{ the normal standard of acuteness of vision.}$$

But, on the contrary, if No. XX can only be seen at 10 Paris feet, then $V = \frac{10}{20} = \frac{1}{2}$, the degree of acuteness of vision.

If No. L can only be seen at 10 Paris feet, then $V = \frac{10}{50} = \frac{1}{5}$, the degree of acuteness of vision, and so on.—If d be greater than D , that is, if No. XX can be seen at a greater distance than 20 Paris feet, or No. L at a greater distance than 50 Paris feet, then the vision is more acute than the normal average.

In this experiment for determining the acuteness of vision, M. Giraud-Teulon prefers that the person look through a pin-hole pierced in a black card, which guards the vision against any influence of accommodation, and, as this may tend to diminish the quantity of light, the test types must be well illuminated, and the eye likewise be protected from all neighboring incident light.

The *range of accommodation* is estimated by ascertaining the far and near points of distinct vision. Thus, if the near point be at 6", and its far point at an infinite distance, and as $A = \frac{1}{p} - \frac{1}{r}$, therefore, in the present case, $A = \frac{1}{6} - \frac{1}{\infty} = \frac{1}{6}$. If the near point be 4", and the far point 8", from the eye, $A = \frac{1}{4} - \frac{1}{8} = \frac{1}{8}$.

1. *Asthenopia; Copyopia; Weakness of Accommodation; Paralysis of the Ciliary Muscle.* (See note to *Strabismus*, on page 1387.) This disease, heretofore considered as the commencement of amaurosis, is only the result of prolonged efforts of accommodation, of too long-continued application of the eyes in reading, writing, sewing, etc., or in performing work with a too feeble or a too intense light, and, perhaps, using improper spectacle glasses. It may also occur under the action of general debilitating influences, such as, loss of blood, prolonged lactation, etc., and all the chronic diseases which exhaust the constitution and enfeeble the energies of the

nervous system. The affection commences in early life, and may remain during the patient's existence; occasionally, but rarely, it commences about middle age. It is frequently due to hypermetropia, and is also met with among the myopic and the presbyopic. It is, however, more frequent among the latter at the close of continued efforts of accommodation in viewing near objects, as with engravers, watch-makers, tailors, clerks, seamstresses, stereotypers, etc. Two degrees of this affection may be distinguished: 1st degree, or asthenopia proper; 2d degree, or paralysis of accommodation.

*a. Asthenopia Proper.** This first degree of the affection commences by the eyes becoming fatigued, and an indistinctness of

** Muscular Asthenopia, by A. Von Graefe.* "Although not a rare disease, muscular asthenopia is, however, much less frequent than asthenopia of the apparatus of accommodation, and its study is the more important, as it yields to proper treatment. Patients laboring under it complain of nearly the same symptoms as those affected with ordinary asthenopia; and, although there are certain differences in the subjective symptoms, which will be pointed out hereafter, they are not so clearly marked as to serve as the foundation of the diagnosis. This can be positively assured only by an attentive observation of the objective symptoms.

"The principal points to which attention should be given, are the following:

"1. In ascertaining the nearest points of binocular fixation, we find that it is further off in muscular asthenopia than in the normal condition. However, it is only the more advanced stage of the disease that is thus manifested.

"2. On placing an object at the ordinary distance of reading, and then covering one eye, we find that this undergoes a certain deviation toward the external angle; which evidently proves that, during the fixation (looking steadily at an object), there exists an excessive tension of the internal rectus muscle. The degree of the deviation will equally indicate that of the tension. Although this is a perfectly exact method, it is not applicable to deviations of very slight importance, which escape measurement.

"3. We know that, by placing a prism with its base turned downward, before an eye, diplopia is produced. Simple vision finding itself thus interrupted, the eyes soon endeavor to replace themselves in the muscular equilibrium, which has been suppressed, favorable to simple vision. In muscular asthenopia, we not only obtain superposed images in the vertical line and corresponding to the position of the prism, but likewise images superposed and crossed at the same time. This method may also serve to measure the angle of the muscular insufficiency, the degree of which is indicated by the angle of the prism required to replace the crossed images in the vertical position.

"4. In ascertaining the strongest prisms which the internal and external recti muscles may overcome, as well in the adduction as in the abduction of the eye, we will find a very marked difference in favor of the external rectus, a difference which may be relative or absolute according to the physiological circumstances—the different positions of the eye. This method is complementary of the third; and although this shows us the degrees of the muscular insufficiency, we can calculate its influence in the production of asthenopical symptoms, only by comparing the results of the last two methods.—We have, then, this

vision, which symptoms are more frequently observed in the evening than during the day. They persist for some time; finally, although the vision is good, yet the patients will remark that, after having used their eyes for a short time, in reading, writing, or at work, etc., a sense of fatigue comes on, they are obliged to close their eyelids, to momentarily suspend their occupations, or else experi-

fundamental law for asthenopia; *that the greater the muscular insufficiency, relatively to the adduction of the eye, the greater will be the asthenopia.*

"The causes of the disease are not yet perfectly known. It appears, however, that the commencing point is a relative preponderance of the external rectus. The exclusion of an eye from the act of ordinary vision appears equally to dispose certain persons to it. Debilitating diseases and certain narcotics also weaken the external muscles. But, undoubtedly, the chief cause is, a disproportion between the force of the external recti muscles and the refraction of the visual organ. Thus, myopic persons require a relatively greater convergence of the visual axes, and if the external recti muscles are not developed in consequence, that is to say, if they are not stronger than in the physiological state, they give rise to *relative asthenopia*.

"As to the treatment, all means should be rejected having for their object gymnastic exercises of the eyes at very close distances, as such exercises must necessarily occasion fatigue to the muscles. The principal remedy is *tenotomy* of the external rectus; and the limits to which the operation should be carried are indicated by the maximum of abduction that the patients can produce with prisms in looking steadily at distant objects; or in other words, the previous trial made with the prism indicates in a very precise manner the degree of the recoil which we must make the muscular attachment undergo." (M. Knapp states, that all other means, except tenotomy, almost always fail in curing the affection.)

"The second method, it is true, is not curative, but it enables the patient to work; it consists in the use of *prismatic glasses* for reading. They must be selected so as to sustain an abduction proportioned to the degree of insufficiency. By diminishing the convergence of the visual axes, these glasses exert an influence on the relative state of the accommodation, so that we are sometimes obliged to combine them with convex glasses, even when these are not required by a co-existent hyperopia or presbyopia.

"The third method consists in giving *weak concave glasses* to the patient, provided that he is myopic and that the measure of the insufficiency demonstrates a very marked diminution of the latter with a moderate separation of the object of vision. We must, however, take into account the causes of the myopia, although the reasons for which we generally hesitate to recommend concave glasses for near work, are less applicable to patients affected with muscular asthenopia, chiefly because, with them, the latitude of the relative accommodation is otherwise disposed.

"The fourth method consists in the *exclusion of an eye*. It is frequently produced spontaneously; but we may facilitate it by different methods. It is the least perfect method, and is not without inconveniences to the eye thus excluded. But, under certain circumstances, especially in excessive degrees of myopia, it is the only resource; for it is impossible to bring the eyes back to the binocular act while there is constantly in operation a convergence of three inches and less."

ence pain from persisting in them. This sensation of fatigue and pain frequently extends throughout the entire frontal region. At a still later period, these symptoms come on as soon as the eyes are fixed a little attentively upon a near object, and eventually terminate by being constant. The eyes of these patients seem dull, heavy and inactive, and are directed toward objects in a weak, indecisive, hesitating manner. Sometimes, the pupils are quite lively, at other times very sluggish in becoming dilated. An *ophthalmoscopic* examination will occasionally detect a congestion of the choroid and retina, due to a want of nervous energy in the blood-vessels, or to some cerebral difficulty.

The *diagnosis* is readily made out; we arrive at it by exclusion, after being satisfied that the dioptric apparatus of the eye is transparent, that the retina is sensible, and the deep-seated membranes are healthy. We *distinguish* it from *amaurotic amblyopia*, or the first stage of nervous amaurosis, by observing that in this latter disease the weakness and obscurity of sight are constant, for small as well as for large objects, distant or near; while in asthenopia the indistinctness of vision occurs only when the eyes have been exerted upon near objects. Again, in amblyopia the objects appear clearer after the patient has fixed his eyes upon them for some time, while, in asthenopy, the longer he fixes his eyes upon them the more confused they appear.

The *prognosis* of this affection is unfavorable, especially if it has existed for a long time, and particularly if it be due to a cerebral disease, or to a lesion of the nerve of the fifth pair. It rarely, if ever, passes into amblyopia, or terminates in blindness, but it frequently causes paralysis of accommodation.

b. Paralysis of Accommodation, is the second or more advanced degree of asthenopia. There is paralysis of this faculty in *myosis* or contraction of the pupil, in *mydriasis* or dilatation of the pupil, and among those who have been operated upon for cataract. It may be distinguished from simple weakness of accommodation, by observing that, in this, the limits of distinct vision are much nearer, while in the first the two limits of distinct vision are almost entirely blended together, and objects are seen distinctly only in a particular, limited space, always invariable in its position. Thus, certain patients can readily distinguish near objects, and can not see those at a medium or far distance, while others can only distinguish them at a medium or far distance.—The *prognosis* of paralysis of accommodation is still more unfavorable than that of asthenopia.

Treatment. In the first degree, there must be rest of the eyes; cessation or diminution of such employments as require a long-con-

tinued use of the eyes, especially on small objects; application of cooling lotions and douches to the eyes, fresh water in particular being used; country air; exercise; promenades; cold bathing; exercise of vision at long distances; and the use of neutral glasses in broad daylight, or by intense artificial light, are the means more commonly pursued. The lotions should be applied upon the lids and brow, and, when pain is present, may consist of Tincture of Aconite, Tincture of Cannabis Indica, or the Hydrocyanic Acid and Aconitina mixture on page 1276. The vapor of Bisulphuret of Carbon, or, of a mixture of one scruple of Iodine dissolved in two fluidounces of Chloroform, should also be directed upon the eyeball, once or twice a day, by means of an eye-cup and bottle, continuing the vapor each time until it occasions a sensation of heat. If there be much contraction of the pupil, *myosis*, a drop or two of a solution of Atropia may be placed upon the eye once a day; and if there be much dilatation, (*mydriasis*), this may be overcome by a drop or two, daily, upon the eye, of a solution of Morphia, or a very dilute solution of the Calabar Bean.

We must second these means by the use of very weak convex glasses, or still better, prismatic or concavo-prismatic glasses of a very weak degree, placing the angle *within* for the presbyopic, and *without* for the myopic. If the asthenopia be due to hypermetropia, the patient must gradually use stronger and stronger convex glasses, until that number is reached which really neutralizes his hypermetropia, which he required when his power of accommodation was paralyzed by atropia. (*See Hypermetropia*). If we wish to permanently cure the patient we must prevent all undue straining of his accommodation, and this can be done only by completely neutralizing his hypermetropia, enabling the eye to see distant objects perfectly, with scarcely any exercise of the power of accommodation.

In the *second degree* the same means will be pursued, in connection with stimulants; thus, Tincture of Camphor, of Arnica, of Prickly-ash Bark, etc., may be added to the douches, and excitant frictions be made upon the eyelids and in the neighborhood of the eye, and electricity or electro-magnetism may also be made use of. Any irritation of the retina occasioned by the circles of dispersion, (blurred vision), caused by the inefficient action of the accommodative apparatus, may be lessened by having the spectacles of a blue tint. But, as all blue and some green-colored glasses increase the chemical action of light, and may augment the excitement of an already overwrought or irritable retina, it is recommended to use for weak sight only *neutral-tinted* glass, without any admixture of blue.

In both degrees constitutional treatment is often necessary, adopting the proper means to overcome any local or general disease present, which may produce or aggravate the asthenopia, as, debility, leucorrhœa, seminal emissions, etc. Ordinarily, vegetable and chalybeate tonics will prove very beneficial. As a general thing, counter-irritation will be found of little value. Sometimes solution of Strychnia will prove of great service, taken internally.

Asthenopia from a deficient power of the Internal Rectus Muscle, is described in the selection from Gräfe, in the Note on page 1517. I may briefly remark here, that although this variety of asthenopia, is principally met with among myopic patients, yet it may occasionally be observed in hypermetropes. The character of the asthenopia may be determined by the following symptoms: 1, The nearest point of binocular fixation is further off than in the normal state; 2, if we have the patient to look steadily at an object, placed at the ordinary distance of reading, and then cover one eye, we will observe that the covered eye deviates toward the external canthus; from whence we must conclude that, during the steady gaze, there exists an excessive tension of the internal rectus muscle; 3, we place before the eye a prism with the base directed downward,—the eyes resume their muscular equilibrium which had been interrupted during the exercise of simple vision,—and the patient complains of seeing double images, not only *superposed in vertical lines* and corresponding to the position of the prism, but also *crossed* at the same time; the diagnosis is completed, by ascertaining the strongest prisms that the external and internal recti muscles can sustain, without vision ceasing to be simple. This test will give a marked difference in favor of the external rectus. The cure is effected by total or partial division of the external rectus muscle.

2. *Myopia, or Near-sightedness.* Myopia is due to an imperfection in the accommodation of vision, which permits one to see perfectly only at a very short distance, a distance less than that constituting normal vision; and is more common among males than females. It presents variable degrees, according to the persons, some of whom can only see at a distance of one or two inches, while others can see distinctly at two or three inches, or even six or seven. These differences establish the various degrees of near-sightedness. (*See note to Strabismus, on page 1387.*)

This imperfect state of the accommodation is due either to an increase of the antero-posterior diameter or axis of the eye, or to an

increased refractive power of the refractive media, so that, in either case, the parallel rays emanating from distant objects are brought to a focus before reaching the retina in consequence of which, a confused and indistinct image of them is formed upon the retina. But when the objects are brought nearer, the rays from them becoming more divergent as they are approached toward the eye, (and consequently do not form a focus so soon), the indistinctness of the image becomes less and less, until at a certain distance from the eye, the image is formed upon the retina; at this point the vision is distinct.

Donders states that "*myopic or brachymetropic eyes*, are those, which are adjusted, when in a state of rest, for divergent rays. In this case, parallel rays are, even when the eye accommodates itself for its furthest point, brought to a focus *before* the retina; so that distinct images are formed on the retina only of those objects, the rays from which impinge divergently upon the eye. In the myopic eye, when in a state of rest, the focal point of the dioptric system lies *before* the retina."

This affection is sometimes hereditary, and frequently acquired. Among the *causes* which may produce it, we may name, the necessity required in certain professions of looking at objects very close to the eye, as, watch-makers, printers, proof-readers, engravers, etc.; it may also be produced among scholars who stoop forward in reading and writing, as well as by dwelling in dark places, wounds of the cornea, conical cornea, posterior sclero-choroiditis, hydrophthalmia, intra-orbital tumors which compress the eyeball laterally, strabismus, and the prolonged use of concave glasses, gradually increased in strength which, some young men are in the habit of wearing to avoid being drafted into the army. Von Roosbroeck's researches tend to establish the fact that *posterior staphyloma* is present with nearly all myopes, nine times out of ten.

Myopia is rare in the country and among sailors, because country people and seamen seldom fix their looks upon near objects, their vision being carried almost always to considerable distances; in cities, on the contrary, the kinds of business pursued therein, nearly always require the exercise of vision at short distances. Young folks read, write, or draw from morning to night, frequently employing strong lens, and commence at an early period to assist vision by using badly-selected or improperly-adapted concave glasses, which they renew from time to time, and which, instead of correcting their defect of vision, constantly aggravates it.

In general, myopes have large and projecting eyes; the cornea and the sclerotica are prominent; they readily wink, appear as strangers to those around them, and can not pay attention to the

looks of those with whom they are conversing, on which account their eyes, as well as their features, often present a dull, stupid appearance.

To determine if a person is myopic, it is sufficient to know that he is obliged to hold his book close to his eyes, or at a distance of from one to three or four inches, in order to read, or distinguish characters, and, that beyond six or nine inches he can not read at all, nor distinguish characters; and if, under these circumstances a concave glass enables him to distinctly read or distinguish characters at a considerable distance, we may pronounce him to be myopic; and the number of the glasses indicates the degree of the myopia. If, instead of improving vision, concave glasses disturb or confuse it, the patient is then affected with *amblyopia*.

A more difficult question to determine is whether the myopia be pure or complicated. It is frequently met with in connection with posterior sclero-choroiditis, in which case amblyopia is apt to be present.* Sclero-choroiditis is always a dangerous complication, and is apt to be present when the far point of distinct vision is less than five inches, and occasionally ten or twelve inches from the eye. Simple myopia can be completely corrected by suitable concave glasses; if amblyopia be present this will not be the case. A person suffering from a simple myopia should, with the proper concave lens be able to read the same print at the same distance as the normal eye, that is, No. XX and No. XV of Snellen's test-types at a distance of twenty feet. If, however, with the most carefully-selected glasses he can only read No. XX at that distance, he is also amblyopic. The less the concave glasses correct, the greater is the

* Donders makes the following important remarks: "During youth, every myopia is, perhaps more or less progressive; the progress of the affection is then accompanied by symptoms of irritation, which, according to Von Græfe, may even assume the character of sclerotico-choroiditis posterior. This is the critical period for the myopic eye; if the myopia does not at the same time increase too much, it may remain stationary; or, at a more advanced age, even decrease. If, however, it becomes greatly developed, we shall find it almost impossible hereafter to arrest its progress. At this stage, we must therefore avoid everything that may cause determination of blood to the eye, and thereby tend to increase, not only the sclerotico-choroiditis, but also the tension within the eye. I can not lay too much stress upon this. *Every progressive myopia is threatening to the eye.* If it remains progressive, the eye will soon become less and less usable, (troublesome symptoms at the same time showing themselves), and not unfrequently vision is irrevocably lost at the age of fifty or sixty, (if not sooner), through detachment of the retina, extravasation, or atrophy and degeneration of the yellow spot." Hence, young people having myopia, should not engage in pursuits requiring too close an application of the eyes, as, to reading or writing, at short distances, to watchmaking, fine writing or engraving, reading fine print, etc.

degree of the co-existing amblyopia, and *vice versa*. It must, however, be recollected, that hypermetropia interferes with distant vision, as well as myopia.

Myopia may also be complicated with a diminution of the sensibility of the retina, or acuteness of vision; indeed, this is the case with most myopes. If the person, in looking at distant objects, through a pin-hole in a blackened card, can see them distinctly, the retinal sensibility is normal. An evidence of diminution of the retinal sensibility is, that very small circles of diffusion occasion a disturbance of vision, that is, the myope having selected the appropriate number of concave glasses to distinctly read letters at the distance he selects, by removing these letters only a short distance further, his sight becomes confused.—Posterior sclero-choroiditis, obscurities of the dioptric system, hyperemia of the retina, etc., affections which sometimes complicate myopia, may be determined by an examination under the ophthalmoscope, or by means of oblique light.

Myopia may be recognized under the *ophthalmoscope*. If we examine the myopic eye without any convex lens in front of it, the fundus will be seen, as it were, at some distance from the eye. If we look at one of the retinal vessels, or the papilla, and move our head to one side, we will observe that the image moves in an *opposite direction*; if we move to the right it moves to the left, and *vice versa*, so that we get a reverse image of the fundus. Again, in order to obtain a distinct image of the fundus, we must place a concave lens behind the mirror, (the greater the myopia the stronger must this concave glass be, and the nearer must we approach ourself to to the eye); the field of vision will appear smaller, and the image nearer the eye of the observer, than in the normal eye. The image is less bright in color, and less illuminated, but apparently larger; for we can not, as in the normal eye, (the size of the pupil being equal), overlook the whole optic disc at a glance, but only a portion of it.

The *progress* of myopia is variable, on which account we should accurately determine its degree, so as to be able to judge at after periods whether it has remained stationary, or has progressed. The most favorable cases are those in which it remains stationary; when it progresses, it is unfavorable, and is a source of danger to the eye. It may, though not generally, diminish with age, and cases have occasionally occurred where persons who during the first period of their life used strong concave glasses, were in the latter period obliged to employ very weak convex ones. On the contrary, instead of improving, the myopia often becomes increased, which is indica-

tive of some deep-seated lesion of the eye, which may, at the age of fifty or sixty years, lead to a complete loss of sight.

The *treatment* of myopia is palliative and curative. The *first* consists in properly-selected biconcave glasses; and it is recommended always to choose the weakest or lowest power possible, that will enable the person to see objects distinctly, and in their natural proportions. Glasses which lessen the size of objects looked at should never be worn.—The biconcave glasses should never be used for near vision, as they fatigue the eyes, and dispose them to deep-seated congestions. If the myopia is very marked, two pair of spectacles should be obtained, one, very weak for near objects,—the other, stronger, for distant objects; and in cases where the vividness or brilliancy of the light fatigues the eyes, slightly-neutral glasses should be employed.

As a general rule myopic persons may be allowed glasses for the purpose of seeing things a few feet off, or for reading the notes when playing on the piano, etc.; but, they should not use them for reading, writing, sewing, or other purposes of near vision, except in those cases where there is a tendency to posterior staphyloma, or sclerotic-choroiditis, because, they soon increase the myopia. And when spectacles are allowed in the cases referred to, the patients should always read, write, or sew, etc., with their head well thrown back, so as not to determine an increased flow of blood to the eye, and the desk upon which they write, should be sloping.—It must be borne in mind, however, that concave glasses do not always absolutely correct myopia. The myope may, by means of proper glasses, be enabled to see objects at a short distance, but, at the same time, can not find glasses that will permit him to see distant objects. Again, certain myopes find it impossible to procure concave glasses that will enable them to distinctly see beyond a certain distance, and for vision at a greater distance they are obliged to use an opera-glass.—In myopia of a very high degree, it is often impossible for the patient to read simultaneously with both eyes, because the book must be brought so close to them, that a sufficient amount of light can not be thrown upon the printed page, and the two optical axes can no longer coincide at this short distance; in such cases, the patient usually employs but one eye, and the other being inactive and unemployed, loses more or less of its retinal sensibility.

When we are consulted by a myopic person regarding the selection of proper glasses for his sight, we determine this by the following calculations: Suppose he can read with the naked eye at a distance of six inches, and wishes to procure glasses to enable him to read at the distance of twelve; we multiply these two numbers

together, $6 \times 12 = 72$, and then divide the product by their difference, $6 - 12 = 6$, so that $6 \div 72 = 12$, which represents the number of inches the focal length of the glass required should be, which may be between twelve and fifteen, as it is best to make use of the lowest power consonant with distinct vision. If the glasses make the objects appear small and very bright, cause straining or fatigue of the eyes, or produce dizziness, or confusion of vision after laying them aside, they are too concave. Having once fitted himself, a person should not too hastily change his glasses, although they may appear not to enable him to see quite so clearly as when he first begun their use.—The nearer the object to be seen or read by a myopic person is to the eye, the weaker must be the concave lens.

Donders' method of determining the degree of myopia, the range of accommodation, and the focal length of concave glasses required, is as follows:

Suppose, a myopic person can read No. I of Snellen's, or Jäger's types at a distance of ten inches, his far point lies at $10''$, and his myopia $= \frac{1}{10}$, and he would require ten inch focus concave glasses

to unite parallel rays, or rays from a distant object, upon the retina. But in order, at the same time, to favor the accommodation of the eye for its far point, he will for practical utility require somewhat weaker glasses, say of $12''$ or $13''$ focus. We can readily determine whether or not these glasses accurately suit his sight, in the following manner: place No. XX of Snellen or Jäger at twenty feet distance from his eyes, and tell him to read this with the above-named glasses of $10''$; he can do so, and can also see but indistinctly the next lowest number of type. We now place before his spectacles a low power convex glass, say of $60''$ focus, and find that this renders the letters clearer, convex $50''$ improves his vision still more as he can read No. XVIII with it, while convex $40''$ renders it more indistinct. The concave glass $10''$, is therefore too strong for him, and to exactly suit his sight

we must deduct $50''$ from it, thus $\frac{1}{10} - \frac{1}{50} = \frac{1}{12\frac{1}{2}}$, the amount of his myopia. We now give him concave $13''$, and find that neither concave nor convex glasses placed before them render any improvement,—he is therefore accurately suited.

To determine the range of accommodation, Donders gives the patient those glasses which neutralize the myopia, and enable him to see distant objects distinctly, by means of which he can, therefore, unite parallel rays upon the retina. Let us again suppose that concave $10''$ is the weakest glass with which he can read No.

XVIII or XIX of test type quite distinctly and sharply at twenty feet distance. His far point, therefore, with concave 10'', lies at infinite distance (∞). With the same glass we now try how near he can read No. I comfortably and with ease; let us suppose that this be at five inches, his A therefore = $\frac{1}{5}$, for $r = \infty$, $p = 5$, and

$$A = \frac{1}{5} - \frac{1}{\infty} = \frac{1}{5}.$$

Von Gräfe gives a good method for testing the range of accommodation, and also for quickly discovering whether the eye is myopic, hypermetropic, or presbyopic.—A convex lens of 6'' or 10'' focus is placed before the eye, with which the patient reads No. I of Jäger's or Snellen's types, and his far and near point noted. The far (r') and near point (p') thus found stand in such a relation to his real far (r) and near point (p), that the rays coming from r' are refracted by the lens as if they came from r , those from p' being also refracted as though they emanated from p . With convex 6'', r' would in the normal eye lie at 6'' from the eye, for rays from an object at 6'' distance, falling on this lens would be rendered parallel by it, and would, consequently, impinge upon the eye as if they came from an infinite distance (the normal far point). The near point (p') would lie at about 2 $\frac{2}{3}$ ''. This varies according to the eye of the patient.

The range of accommodation is therefore easily found by the formula $A = \frac{1}{p} - \frac{1}{r}$. The lens, and the distance from the eye (about $\frac{1}{2}$ '') is omitted in the calculation. If, with convex 6'', the far point (r') lies at 6'', and the near point (p') at 3'', then

$$A = \frac{1}{3} - \frac{1}{6} = \frac{1}{6}.$$

Again, if with convex 6'', $r' = 5''$, and $p' = 3''$, the eye is myopic, for it is not adjusted for the normal far point 6'', but for a nearer one, the rays from which impinge in a divergent direction upon the eye:—and $A = \frac{1}{3} - \frac{1}{5} = \frac{2}{15} = 7\frac{1}{2}$.

Now what glasses are required for infinite distance? By means of our strong convex lens (6'') we have changed this eye into a very myopic one, in fact, into a myopia of $\frac{1}{5}$, for we should have to place a concave glass of 5'' focus before concave 6'' in order to enable it to see at a distance; for this concave glass would render parallel rays so divergent as though they came from 5'' distance. In order, therefore, to find the proper concave glass for infinite

distance, we deduct concave 5" from convex 6", thus $\frac{1}{6} - \frac{1}{5} = \frac{1}{30}$, hence, the proper concave glass will be of 30" focus, or No. 30.

If with convex 6", $r' = 8''$, and $p' = 3''$, the eye is *hypermetropic*, for its far point lies beyond the normal far point 6"; its range of accommodation would, therefore, be $A = \frac{1}{3} - \frac{1}{8} = \frac{5}{24} = 4\frac{1}{3}$. (*J. S. Wells.*)

A very important indication is, to determine the distance of distinct vision with each eye, separately, as, sometimes, the degree of myopia in one is more marked than in the other eye. If this distance is not the same with both eyes, we must give to each eye its proper concave glass.

The *curative treatment* of myopia consists in the exercise of vision with the aid of very feeble biconcave glasses. Unfortunately, this treatment requires a length of time, as well as great patience, but it is almost always salutary. A very weak biconcave glass, say No. 24, 20, 16, or 14, is given to the person, and after having placed him against a wall we request him to read large and clear characters at a distance of thirteen or sixteen inches; this exercise is to be pursued every day, once, twice, or three times per day, gradually increasing the distance one-half or three-quarters of an inch at a time, and so on. By degrees, weaker glasses may be used, and eventually the myopia will be corrected by this course. This treatment must be seconded by rest of the eyes, looking at distant objects without glasses, in the open air, and by the local application of cold lotions repeated several times daily.

When, among young people, Nos. 12 or 10 do not suffice, we may suspect the myopia to be the result of a sclero-choroiditis posterior, of which we may be assured by an ophthalmoscopic examination; and in case our suspicions become confirmed by the examination, we must prohibit the least efforts at accommodation, having the eyes kept in a state of quiet, and prescribe neutral glasses, purgatives, cold lotions, mydriatic solutions dropped in the eye, and the other measures named for sclero-choroiditis on page 1481.

If the myopia is the result of a wound, or of a forming cataract, the biconcave glasses should be replaced by biconvex; also, when the myopia is complicated with a commencing insensibility of the retina. In these cases, biconvex glasses almost always improve vision for near and distant objects, because they concentrate the light more.

Several surgeons, believing that the myopia of certain persons is due to an elongation of the antero-posterior axis of the eye, the result of an exaggerated contraction of the muscles surrounding

the organ, or of an original shortness of these motor cords, have proposed and performed section of some one of these muscles; J. Guerin has cut the recti-muscles, by the sub-conjunctival method; Bonnet, of Lyons, prefers cutting the ocular insertion of the small oblique muscle. Considerable success is stated to have followed these operations, the far point of vision becoming considerably increased thereby, without the aid of spectacles.

3. *Presbyopia*, or *Far-sightedness*. Presbyopia is a normal change that occurs in the eye due to advancing years, in which the near point of vision gradually recedes from the eye, and the range of accommodation diminishes. After the power of accommodation has considerably decreased, a slight diminution of refraction gradually takes place.—The change in the eye that gives rise to presbyopia, commences as early as at the tenth or twelfth year, and gradually increases, until it first becomes appreciable at the fortieth or fiftieth year. The diminution of refraction commences at a much later period, and is not distinctly appreciable until at the sixtieth or seventieth year. Presbyopia is not the opposite condition of myopia.

In presbyopia, distant objects continue to be seen as usual, while near objects can not be seen accurately, and have to be removed further and further from the eyes, as the presbyopia advances. Thus, a book, for example, can only be read distinctly by a presbyope when he removes it farther from the eye than formerly; if held within the ordinary distance of reading when the eye was normal, the characters appear indistinct, more or less blurred, double, or running into one another. The various degrees of presbyopia depend upon the various distances at which near objects have to be placed in order to be seen distinctly, or, in other words, upon the distance at which the near point is removed from the eye. This defect of vision is usually first noticed at night, a greater degree of illumination being required, as well as a greater distance of the eye from the object, in order to read, write, see, etc., clearly.*

* I have no doubt that the present sources of artificial illumination tend considerably to produce asthenopia, and amblyopia, as well as to bring on premature presbyopia. The yellow rays from gas or coal oil are certainly injurious to those whose occupations require them to use their eyes at night—gas light, especially, being aided in its mischievous results by its constant flickering. The light from coal oil is the best artificial light to read, write, or work by, as its flame is steady and its light intense; but, in order to protect the eye from its injurious rays, a slight neutral blue-tint shade should be placed over it, and I am much surprised

Presbyopia is supposed to be due to a deficient power of the ciliary muscle, or to an increased density of the crystalline lens, which prevents it from undergoing the same degree of change in its curvature as formerly when subjected to the same amount of muscular action; consequently, parallel rays from near objects, instead of uniting upon the retina, as they do for distant objects, form a focus at some point behind it, but may be brought upon it by a convex lens whose focal distance will atone for the deficiency in the curvature of the lens. Presbyopia bears no relation to the refraction of the eye, strictly speaking, may equally affect normal, myopic, hypermetropic, or astigmatic eyes, and may be brought on prematurely by improper use of the eyes.

Weakness of sight, amblyopia, sometimes accompanies presbyopia, and, may, also be mistaken for it. It may be laid down as a practical rule that the nearer we can approximate, by means of the proper convex glasses, the vision and range of accommodation of a presbyopic eye to that of a normal one, the less is the impairment of sight due to amblyopia, and *vice versa*.

We *diagnose* presbyopia by observing that the patient sees at a distance about as well as formerly, while to see near or small objects he has to remove them further from the eye than previously; that convex glasses enable him to distinctly see near or small objects at about the usual distance of former years, and that he can see clearly at a greater distance with a convex lens than a normal eye can with the same lens.—In order to see a near object more distinctly, the myope leans his head forward, while the presbyope (as well as the hypermetrope) throws his head backward, or holds the near object at arm's length.

The *treatment** of presbyopia consists in the employment of

that, long ere this, some enterprising person has not prepared neutral blue-tint glass chimneys for coal-oil lamps, and for gas light, in order to preserve the sight of those who use this kind of illumination.

* Relative to presbyopia, Donders remarks: "Persons should be furnished with spectacles as soon as they are in the slightest degree annoyed or inconvenienced by presbyopia. Some medical men think that presbyopic patients should do without spectacles as long as possible, for fear the eye should, even at an early period, get so used to them as soon to find them indispensable. This is, however, an error; for, if such persons are permitted to work without glasses, we observe that the presbyopia soon increases.—The proper glasses for the presbyopic may be readily calculated. A convex glass of sixteen inches focus will bring the near point back again to eight inches from the eye. We must generally, however, give weaker glasses; because, on account of the greater convergence of the optic axes, the near point will, through these glasses (convex sixteen), be, in reality, brought nearer than eight inches. Late in life, when there is some diminution

properly-selected biconvex glasses; and, as a general rule, this selection should be made by the oculist, as there are only a few persons who sell spectacles who are enabled to make a proper and scientific choice. Eyes are often ruined, which might, by scientific and skillful treatment, have been preserved for years; glasses should be selected which, if anything, are rather too weak than too strong, for their object is not to magnify objects, but to enable the wearer to distinctly see things of their natural size.

The first thing, then, in order to select the proper glasses, is to determine the degree of presbyopia present in any given case. According to Donders, presbyopia may be considered as having commenced when the near point of distinct vision is removed further than eight inches from the eye. Then, in order to determine the degree of presbyopia, we must deduct the near point at which we consider presbyopia to commence, 8" from the presbyopic near point. Thus, suppose the presbyopic near point to be 12", then $\frac{1}{12} - \frac{1}{8} = \frac{1}{24}$, the degree of presbyopia, in which case, convex glass 24" focus would bring the near point back again to 8". Again, suppose the presbyopic near point to lie at 16", then $\frac{1}{16} - \frac{1}{8} = \frac{1}{16}$, the degree of presbyopia, and in which case a convex glass 16" would be required. For practical purposes, however, somewhat weaker glasses should be used; and, where there is a good range of accommodation, still weaker glasses may be allowed. In my own case, my near point is 24", and, in order to read well at 10" or 12",

in vision, the near point should sometimes be brought even to six or seven inches, and the greater the range of accommodation, the nearer should it be brought.

"When hypermetropia exists, the weakest glasses with which No. 1 of the type tests can be distinctly and easily read at about twelve inches distance, may generally be given.—*In choosing spectacles for far-sighted persons, we must also be particularly guided by the range of their power of accommodation.* If this is good, we may give them glasses which bring their near point to eight inches; but, if it is much diminished, weaker glasses should be chosen, so that it may lie at ten or twelve inches from the eye.

"It must be borne in mind that a very rapid increase of presbyopia is one of the premonitory symptoms of glaucoma. If, therefore, a patient tells us that his far-sightedness has rapidly increased within a few months, so that he has had repeatedly to change his spectacles during that time for stronger and stronger ones, our suspicions should be aroused, and we should, without fail, examine him as to the presence of other premonitory symptoms of glaucoma, as rainbows around the candle, periodical obscurations, etc. Von Graefe thinks that this rapid increase of presbyopia is most likely due to an increase of intra-ocular pressure."

I should, according to the above rule, use convex glasses of 24"—as $\frac{1}{24} - \frac{1}{12} = \frac{1}{24}$; instead of which I employ those of 36" for day, and 30" for night. I can not use 24" at all, but will require them after a few years.

The best rule that I can find for glasses, either concave or convex, is, for the person to select those which will enable him, without diminishing or magnifying objects, to see distinctly at the desired distance, say from 8" to 12", and which will also enable him, at the same time, to see, more clearly than with other glasses tried, objects at a more remote, as well as at a nearer point. Thus, suppose that with one glass I can distinctly see at 10", and somewhat indistinctly at a near point of 8", and at a remote point of 24", and that, with another, I can also see distinctly at 10", but it brings my less distinct near point to 6", and that of my remote to 36", I should undoubtedly prefer the latter. And this rule I prefer to all others, viz.: to select the glasses of the very lowest power that will enable me to see objects distinctly, comfortably, and of their natural size.

Mackenzie gives the following rules, which result in nearly the same results as those given by Donders: "If a person has a distinct vision of objects *moderately remote*, let him multiply the distance at which he can see minute objects most distinctly, say 20 inches, by the distance at which he wishes to read by the aid of glasses, say 12 inches, and divide the product by the difference between the two, 8; the quotient, 30, will be the focal length of the glasses required. But, if the distance at which he sees most distinctly is *very great*, then the focal length of the glasses required will be equal to the distance at which he wishes to see objects most distinctly."

The range of accommodation of a presbyopic eye is easily found by the formula, $A = \frac{1}{p} - \frac{1}{r}$, already given on page 1527.

Presbyopic persons, wearing spectacles for near sight, should always remove them when they are not thus employing vision, and should, as much as possible, practice looking at distant objects of considerable size, so as not to be obliged to use feeble glasses for seeing at a distance, which increases the presbyopia, and will require them to wear stronger glasses for near objects, in a very short time.

When, after having worn convex glasses for some time, it becomes difficult to read at the usual distance, having to hold the book farther off from the eye in order to distinguish the words, it

will be proper to select a pair of stronger glasses, being guided by the rule heretofore given. White, clear glass should always be used for convex glasses, unless there are symptoms of retinal irritability. The spectacle frame should be light, properly fitted to the nose, and the center of the glasses should correspond with the pupil or optic axis.

If presbyopia increases very rapidly, requiring the person to change his glasses every few months instead of every few years, we may suspect glaucoma, and especially when he sees rainbows about the candle, has periodical obscurations of vision, etc.

4. *Hypermetropia. Hyperopia. Over-sight. Hyperpresbyopia.* (See note to *Strabismus*, on page 1387.) This is an affection which is an opposite condition of myopia, and which has only been accurately and scientifically understood within the last few years, since the researches of Von Gräfe and Donders. It is very frequently a cause of asthenopia, which is always present when the degree of hypermetropia is great. According to Donders, hypermetropia is the most common cause of convergent strabismus.

In hypermetropia the refractive power of the eye is too low, or the optic axis (the antero-posterior axis) is too short; or both of these causes may exist together. The effect of these conditions of the eye is, that the focal point of the dioptric system lies behind the retina, so that, even in a state of rest, parallel rays are brought to a focus behind the retina, while convergent rays only are united upon the retina. If the degree of hypermetropia be moderate, and the power of accommodation good, the patient may read or write without much discomfort; but, if the hypermetropia be absolute, he will not be able to see well at any point.

In hypermetropia the accommodative power of the eye is exerted more or less considerably, according to the degree of hypermetropia, in order to unite parallel rays upon the retina; and the exertion increases in direct ratio with the nearness of the object, and also with the diminution of the refractive power of the eye. The eye can not keep up this great strain of its power of accommodation—its ciliary muscle—for any length of time, and hence the inability to continue working at near objects for any long period; hence, also, the whole train of asthenopic symptoms. It does not, however, follow, that all cases of hypermetropia must, of necessity, be accompanied by asthenopia. It may be absent if the range of accommodation is good, and the degree of hypermetropia but slight.

In the *diagnosis* of hypermetropia, the eye appears smaller and

flatter than the normal eye; it does not fill out the aperture of the lids (palpebral aperture) properly; between the eyeball and the canthus, especially the outer canthus, there is only a little space, like a little pouch,—sometimes the space is greater; upon turning the eye very much inward, the posterior portion of the eyeball is seen to be flatter and less rounded than it should be.—The patient states that, after reading or writing for a short time, the letters become blurred, indistinct, as if they run into each other; at a distance, he thinks he can see perfectly, though hypermetropic eyes see worse at a distance than normal eyes.

Under the *ophthalmoscope*, just the reverse obtains to what was seen in the myopic eye. The fundus may be seen in the erect image at a considerable distance, but we obtain an erect image of it, and not a reversed one as in myopia; if we look at the optic nerve or one of the retinal vessels, and then move our head to one side, the image will move in the same direction. If we approach nearer to the hypermetropic eye, the field of vision enlarges, the image becomes smaller and further removed from the eye, while the intensity of its light and color is much increased. If the hypermetropia be considerable, we can take in at a glance, not only the optic entrance, but also a considerable portion of the fundus around it. If our own eye is normal, in order to gain a distinct image, we will have either to place a strong convex lens behind our ophthalmoscope, or else accommodate for a nearer point.

Hypermetropia is sometimes congenital, and frequently hereditary; it is often latent, not manifesting itself until the eighteenth, twentieth, or twenty-fifth year, when symptoms of asthenopia manifest themselves, if the person works for a length of time at near objects, or in reading or writing. These symptoms, and the fact that he can distinguish distant objects much better with convex glasses than without, will arouse our suspicions.

In order to determine the real amount or degree of hypermetropia, we must first ascertain the *manifest* or *apparent* hypermetropia, which is ascertained by observing the number of a biconvex lens required to distinctly read No. XX of Snellen, at a distance of twenty feet, and which we will suppose to be 30". We now paralyze the accommodative power of the eye, by dropping into it a solution of Sulphate of Atropia, of sufficient strength to completely paralyze the ciliary muscle—say four grains of the Sulphate to a fluidounce of Distilled Water, and which will require two or three hours to act thoroughly. We again place before him No. XX of Snellen's Test Types, at a distance of twenty feet, and find that he can not read at all without the aid of a biconvex lens of 8"; then the *manifest*

hypermetropia is $\frac{1}{30}$, and the *total* $\frac{1}{8}$. The difference between these two shows the extent to which the accommodation had been exerted in looking at distant objects, thus giving the *latent* hypermetropia, which in this case is, $\frac{1}{8} - \frac{1}{30} = \text{nearly } \frac{1}{11}$.—The number of the convex glass with which he can see well at a distance, without the use of atropia, (No. 30) is the apparent degree of the hypermetropia; and that required after the use of atropia, (No. 8) is the real degree of hypermetropia.

Only one eye at a time should be examined with the atropia, as it frequently requires several days for its influence to pass away; after which the other eye may be examined. And in using the convex glasses, they should be held for a few minutes before the person's eyes, in order that he may gradually relax his accommodation, which he has been so constantly in the habit of exercising, even for distant objects.

The range of accommodation of a hypermetropic eye may be readily found, sufficiently accurate for all practical purposes, by the following method: First, change the eye to a normal one by placing before it a convex glass which will allow it to distinctly see distant objects, without scarcely any exercise of the accommodation. Then, while this glass is before the eye, find the nearest point at which No. I of Snellen, can be read distinctly and easily. If, before atropia was dropped in the eye, convex 20" was required for distant vision, and convex 10" after it, we should try its nearest point with a glass between the two, say No. 16". Now, let us suppose that with convex 16" his near point (p) lies at 7 inches, and his far point (r) has been found to be at an infinite distance (∞); for he can see distant objects well with convex 16" without much effort, although convex 20" is best. Then the range of accommodation (A) is found

by the formula, heretofore given, $A = \frac{1}{p} - \frac{1}{r}$. Now, in the present

case, $p = 7''$, $r = \infty$, hence $A = \frac{1}{7} - \frac{1}{\infty} = \frac{1}{7}$.—We should not test for the range of accommodation, until the effect of the atropia is thoroughly gone off.

How are we to determine what spectacles must be given to a hypermetropic person? We must first discover the amount of hypermetropia before using atropia, by having the patient read No. XIX or XX of Snellen's Test Types at a distance of twenty feet. Let us suppose that convex 20" is the strongest glass with which he can read No. XIX fluently and distinctly; his manifest hypermetropia, before

atropia, therefore, $=\frac{1}{20}$. We then try the nearest point at which he can read No. I comfortably; this is found to be 7". He is therefore not presbyopic. In order to find out to what extent he has strained his accommodation in reading No. XIX through convex 20", and to know what glass will completely neutralize the hypermetropia, we paralyze his power of accommodation, by atropia; after this has acted a couple of hours we examine the patient again. He now requires convex 10" for reading No. XIX fluently. The real amount of hypermetropia is therefore $=\frac{1}{10}$. He has, however, been so accustomed to strain his power of accommodation that he could not relax it completely, even when there was no occasion for accommodating at all, when we corrected the malconstruction of the eye by means of a convex glass.

Now, what spectacles must we give him? If we prescribe convex 10" they would be found too strong for distant objects, or even perhaps for reading. He could not all at once relax his accommodation, so as to be able to use the glasses which really neutralize his hypermetropia, and which must ultimately be used if we wish to free him permanently from the annoyances of his affection. We must therefore gradually accustom his eyes to stronger and stronger glasses, until convex 10" be reached. Let us begin with convex 18" or 20". He is to wear them both for reading, writing, and distant objects. Never, indeed, laying these spectacles aside when he is using his eyes. In the course of a few weeks we give him convex 16", then 14", 12", and, at last, after the lapse of a few months, he can wear No. 10" for reading and for distance. Sometimes it will be required to commence with very weak glasses, gradually exchanging them for stronger and stronger ones, until the proper convex glass is finally reached; if this be not done, great discomfort, a sensation of straining within the eyes, and pain around the orbit, will be the result.

When the degree of hypermetropia is great, or when presbyopia exists, two sets of spectacles will be required, a strong pair for reading, writing, etc., and a weaker pair for distant objects.

A hypermetropic eye may ultimately become presbyopic, while a normal eye may become presbyopic at forty-five, and hypermetropic at fifty or sixty,—being both presbyopic and hypermetropic at the same time, and requiring glasses to neutralize the hypermetropia (or distinct vision of distant objects), as well as glasses to lessen the presbyopia, and enable the person to have distinct vision at a near point. Thus, if biconvex 16" neutralizes the hypermetropia, and

convex 24" is required to overcome the presbyopia, he will require for near vision $\frac{1}{24} + \frac{1}{16} = 9\frac{3}{8}$. But as convex 10" would probably be too strong, on account of the influence of the convergence of the optic axes, convex 12" would be about the required fitting glasses.

5. *Astigmatism. Cylindrical Eye.* Astigmatism is the term applied by Rev. Dr. Whewell to an ametropic (not exact) condition of the eye, in which the rays coming from one point are not united on one point upon the retina, the refracting power of the dioptric media not being equal in the different meridians of the eye, or, in other words, the rays of light which fall upon the eye are not equally refracted to a point. According to Donders, regular astigmatism is met with among all men, but it is not reputed a disease until it has attained a certain degree so as to interfere with perfect vision, and then it may be mistaken for amblyopia. Without being absolutely common, it is by no means rare; it may be estimated at about the one-fortieth of the functional affections of the eye met with in practice.

Astigmatism is due to a congenital asymmetry of the curvature of the surface of the lens, of the cornea, or of both; more commonly of the cornea. Or, it may be due to an obliquity of the cornea and lens with respect to the visual axis. This asymmetry may exist in any of the meridians of the eye, more generally in the vertical and horizontal, or in one nearly approaching them; it may exist for many years during the first period of life, before its presence will prove a source of annoyance. "Astigmatism has nothing to do with accommodation and its anomalies, and is only characterized by a difference in the refractive powers of the different meridians of the dioptric apparatus, and consequently a different degree of ametropia (not exact) in different meridians of the same eye."

Whenever the asymmetry is accompanied with weakness of sight or amblyopia, without any other apparent cause, the astigmatism is pathological; all parts of the focal point are then augmented, and hence the clearness of the retinal image is lost in a proportional degree. "Suppose the curvature of the cornea in the vertical diameter is too convex; then the rays of light entering the eye in this meridian will be too strongly refracted, and will come to a focus in front of those rays which enter in the horizontal meridian (supposed to possess the normal curve); in other words, the patient will be myopic in the vertical meridian of his eye, although his sight is normal in the horizontal meridian; and when looking at a distant

object he will see its lateral edges distinctly, while its lower edges will be blurred. Again, instead of being too convex, the curve in the same meridian may be too flat, when the rays of light in the vertical meridian will come to a focus behind those of the horizontal meridian, and the patient will be hyperopic in the vertical meridian; or, again, the vertical meridian may be normal while the horizontal meridian is either myopic or hyperopic; while, still again, both the vertical and the horizontal meridian may vary from the normal type, both being either myopic or hyperopic, but each to a different degree, or the one may be myopic, and the other hyperopic." (*Dr. J. F. Bumstead.*)

From the above it will be seen that weakness of sight, blurred or indistinct appearance of objects in one meridian which are distinct in a meridian at right angles to it, or, a double image of objects, one being fainter than the true image and overlapping it, are among the principal symptoms of astigmatism.—Snellen, in his Test Types, observes:

"In astigmatism, horizontal and vertical lines can not be seen with equal clearness at one and the same time, because in it the focal distances in the two meridians are unequal. In consequence of this, the squares of a draught-board appear elongated in one direction as gray lines.—The extremes of difference in refraction, in cases of astigmatism, are found in meridian planes which are perpendicular to each other. The direction of these planes, however, usually deviates more or less from the horizontal and vertical."

The *diagnosis* of astigmatism is not difficult; under an *ophthalmoscopic* examination, in all degrees of asymmetry above $\frac{1}{20}$ " we find a marked elongation of the optic disk; by the upright image, (without the use of the collective lens), the diameter of the optic disk appears longest in the meridian of the greatest curvature of the cornea, and shortest in the meridian of least curvature; while the contrary is true when the reversed image (with the use of the collective lens) is employed. When we observe with the reversed image, we must be careful not to hold the collective lens inclined, which renders the optic disk oval. We may be assured that this lens is perfectly perpendicular to our visual line, when the images seen by the reflection of its two surfaces are superposed, a condition which the observer may readily fulfill by slightly inclining the lens. This elongation of the optic nerve-entrance is a very striking and characteristic symptom, except when it is present in eyes affected with posterior staphyloma, in which case, the optic disk appears equally elongated,—but, in most cases, it is caused

not by the asymmetry of the meridians, but by the oblique position of this spherical disk in relation to the visual axis of the observer. We only see the projection of the disk on a plane surface; the ophthalmoscopic visual field appears so to us; and the projection of a circle not parallel to a plane surface is always an ellipse. When we find an apparent elongation of the optic nerve in an eye affected or not with posterior staphyloma, if there is no sufficient morbid condition present to explain the amblyopia, we may be almost certain that the case is one of astigmatism, or pathological asymmetry of the meridians.

Other modes of diagnosis may be also employed, thus: Examine the eye by means of an optometer with fine lines, it will be found that the distance of distinct vision for lines of different direction, will require them to be brought nearer the eye when parallel with certain meridians of this organ, than with others; this examination will also enable us to recognize the principal meridians of the eye, as already indicated by the ophthalmoscope; these are the meridians of greatest and least curvature of the cornea.

Again, when a myopic or hypermetropic subject looks at a distant luminous point, say a coal-oil lamp, through a small circular orifice placed near the flame, say the gauge of an ordinary catheter, the luminous point represents a nearly circular section upon the retina, and the orifice will appear circular. But if the eye be astigmatic, the circle will be replaced by an oval or ellipse, the two axes of which correspond to the two meridians of the eye affected with maximum and minimum curvature. This peculiarity will enable us to determine the direction of these two curvatures, that is to say, the direction of the principal meridians. If, however, the stenopaic slit be held before the eye to look through, a normal circular image will be brought out when this slit is held with the fissure in the proper direction or diameter before the eye.

The stenopaic slit, is a narrow slit cut into an opaque card, having a width of about one-third of a line, and a length of about one-fourth or three-eighths of an inch. Upon holding this slit before the eye, successively in its various meridians, the patient will see objects distinctly when it is held in the normal meridian of the eye, and quite indistinctly when it is held in the abnormal meridian, which is at right angles with the former,—there will also be found more or less indistinctness of vision in the intermediate meridians or inclinations. This plan is now generally adopted by oculists to determine the direction of asymmetry.

The degree of astigmatism may be measured by placing the stenopaic slit successively in the plane of the maximum, and in the

plane of the minimum curvature, and successively presenting to these two meridians the ascending series of positive or negative (convex or concave) glasses; we thus obtain the degree of anomaly of each of them, and the difference of these anomalies in the two meridians is the degree of astigmatism.—Astigmatism may likewise be readily detected and its degree be measured by the astigmatic tests or diagrams of John Green, M. D., St. Louis, Mo. (*See Am. Jour. Med. Sci. January, 1867, page 117.*) These truly useful diagrams have only been made known to the profession while this work was going through the press, hence this short notice of them.

Donders admits three classes of astigmatism, viz.: Simple, compound, and mixed. In *simple* astigmatism, the eye has one of its meridians emmetropic or normal; the other meridian is ametropic or abnormal, and presents an abnormal refraction from excess or defect; it is myopic or hypermetropic.

In *compound* astigmatism, the two meridians present at the same time the same kind of anomaly, but in different degrees; for instance, they are both myopic, or hypermetropic.

In *mixed* astigmatism, we rank the anomalies of refraction which manifest themselves in an inverse direction one from the other, as, where one of the meridians is myopic while the other is hypermetropic.

As to the *treatment* of this defect of the eye, it consists wholly in the selection of proper glasses; we examine which cylindrical lens diminishes the amblyopia the most,—its refractive power represents the degree of the asymmetry, and, if the eye be otherwise normal, this cylindrical glass is the remedy.

But if, the eye is also affected with another disease of refraction, either myopia or hypermetropia, we must also determine its degree in the ordinary manner, and prescribe for the patient a glass which corrects at the same time the two kinds of defect in refraction. The glasses are then spherical, either concave or convex on one side, and cylindrical, concave, or convex on the other, according as the patient requires dispersive or collective glasses. This method of determination is without inconvenience, because in examining the patient all that is necessary is to put together the two required glasses, one against the other, in the lens-bearer accompanying the box of specimen lenses, etc.

Therefore, *simple* astigmatism will be corrected or neutralized by a cylindrical plane glass, the edges or axis of which will be directed perpendicularly to the abnormal meridian. *Compound* astigmatism may be corrected by selecting a *spherical* concave or convex

glass, corresponding to the least degree of the ascertained myopia or hypermetropia; we will thus have completely neutralized this anomaly in the meridian where it is the weakest. But for the meridian where it is the strongest, a certain degree, representing the degree of astigmatism, will remain, and require for its correction a *cylindrical* surface. To neutralize compound astigmatism we require, then, sphero-cylindrical glasses, convex in the hypermetropic, and concave in the myopic compound astigmatism.

To neutralize the double anomaly of *mixed* astigmatism, we oppose to each meridian a plane cylindrical glass, convex for one of the two, concave for the other, and of the degree corresponding to each anomaly,—having care also to direct the axis of each of these glasses perpendicularly to the meridian for which it is designed. By uniting these two glasses into a single one, we obtain bicylindrical, concave, or convex glasses, with intersecting axes, and by these glasses we may correct the ascertained anomalies.

It may be added, that we do not, as for myopia in ordinary conditions, counsel the employment of the glass which absolutely annuls the myopia, but rather that of a weaker glass which permits near vision; so in hypermetropia we do not choose the necessary convex glass to annul the latent hypermetropia; we must leave something for the accommodation to do.

The glasses for astigmatic eyes are not yet manufactured in this country. They may be had of Pætz and Flohr of Berlin, or of Natchez and Son, Paris; to whom the proper foci, and combination of glasses should be fully described, when ordering them.

In relation to the necessity for having these glasses placed at exactly the proper angle in the spectacle frame, Donders observes:

“In employing cylindrical glasses it is of the greatest importance to have the axes of curvature of their surfaces correspond with the principal meridians of the dioptric axis of the eye. The slightest departure from this will occasion considerable trouble, especially when using the stronger glasses. This may be best accomplished by inserting the glasses (which should be round), in a spectacle frame furnished with round supports or eye-pieces. By revolving the glasses the axes of the cylindrical surface may be readily brought into the desired position. By slightly moving the whole frame we quickly ascertain the direction in which the glass requires to be revolved, and we may test that it has obtained exactly the proper position, by slightly tilting the frame to one side or the other, as the slightest motion of this kind renders the correction less complete, the vision less perfect. If the correct posi-

tion for the round glasses be once found, they can be cut into an oval shape, and then set in another frame, the direction of the axes being preserved.

From these remarks it may be understood that a well-fitting frame, which will keep in place without much shifting, is an indispensable adjunct."

For the articles on myopia, presbyopia, hypermetropia, and astigmatism, I am chiefly indebted to Donders, J. S. Wells, and Gräfe.—I will call attention, at this place, to Gräfe's recent Optometer, designed for ascertaining the degrees of myopia, hypermetropia, astigmatism, and presbyopia, and determining the No. of the lenses required to neutralize these several conditions; it will be found a very valuable and useful instrument for the oculist, who should also have, boxes of test lenses, cylindrical lenses, prismatic lenses, and colored glasses; Snellen's test types; Green's astigmatic tests, etc.

AMAUROSIS.

Amaurosis is a more or less complete loss of sight due to a local or general nervous derangement, without any appreciable material lesion of the parts which contribute to the exercise of vision. Under the general term, "amaurosis," are, therefore, necessarily confounded a group of affections entirely different in their cause, their character, and their bearing. Many cases of obscurity or loss of vision, the cause, the extent, form, seat, character, etc., of which, were heretofore wholly unknown, the disease being classed among amauroses, have been satisfactorily determined since the introduction of the ophthalmoscope, and the vague and obscure term, "amaurosis," has been replaced by those terms which are recognized as referring to pathological conditions, always identical, having known causes, producing effects which are readily accounted for, and always requiring a treatment which, in being rational, must necessarily be much more efficacious; these terms, are, choroiditis, retinitis, papillary apoplexy, exudations, atrophy, atrophic sclerotic-choroiditis, etc.

However, there are patients with whom vision becomes more or less obscure, and the cause of which can not be satisfactorily determined by any of our present modes of examination. These cases may be termed, amaurosis, that is to say, a purely functional disease, involving no appreciable lesion of the integrant parts of the eye, and being caused by a partial or general derangement of the nerve-force or innervation. Ordinarily, several periods or stages are ob-

served in amaurosis; it commences with amblyopia or weakness of vision, and, at a later period, terminates in complete blindness. In some rare and exceptional cases, the blindness comes on suddenly. Three distinct stages may be described.

In the *first stage*, the patients observe a weakness or failure of sight, in order to read they are obliged to select a dull light; under the influence of a rather strong light, of a prolonged reading or writing, of any fatigue whatever of the visual organ, the eye becomes injected, tears flow freely, and a weight or heaviness is experienced in the eyelids, as well as pains in the eyes and surrounding parts sufficiently severe to cause the patient to momentarily close his eyes. These frequent pains from the action of light, are owing to an overexcitation of the retina and of the optic nerve which still preserve their integrity, although there is an irregular and pathological action of the iris. Indeed, the retina which is, in this stage, as if it were dazzled, will no longer permit the patient to distinguish objects by broad daylight, and requires a general diminution of light, being only able to normally execute its functions by the light of the night; this phenomenon is termed *nyctalopia*, or *seeing by night*. Upon examining the eye, nothing particular is observed, except that the pupil has but little mobility, is almost always dilated, and that the iris is relaxed and tremulous. Sometimes, however, the pupil will be contracted and irregular. As to the humors of the eye, they will be found transparent, and the membranes (cornea, choroid, retina) preserve their normal anatomical characters.

At other times, the first stage will be characterized by symptoms of irritability of the retina, which would cause us to mistake it for a hyperemia of the retina, if the ophthalmoscopic examination did not remove all doubts,—this stage presents itself with the characters of insensibility. Patients complain that they do not clearly distinguish objects unless they are exposed to a bright light; at night their vision is almost always gone, and the artificial light from lamps or candles, or the light from the moon, enables them to see very imperfectly. In this case, the iris not executing its functions so as to aid those of the retina, this latter membrane, in order to manifest the little sensibility which it preserves, requires a very great quantity of its natural excitant, the light. This condition of vision is termed *hemeralopia*, or *day-vision*. At the same time, the iris is always relaxed and tremulous, the pupil very much dilated, and no pains are present. This form of the initial period of amaurosis is always more serious than the preceding, for the want of retinal sensibility indicates a disposition to, or a commencement of, paralysis.

The *second stage* is characterized by similar symptoms, but they

are more marked. The patients can not apply themselves to any work; their vision becomes disturbed on the least application; they perceive muscæ (*myodesopia*). They often have true spectral illusions, or, fixed black spots (*scotomata*). Some are unable to distinguish certain colors, red from green, pink from blue, etc., (*color-blindness*, *dyschromatopsia*); others are able to see only one-half of objects presented to them (*hemioopia*); while some again see double (*diplopia*). The gait of these patients is embarrassing, their look uncertain, their countenance calm, impassive, and their head elevated; so to speak, they thirst for light. The known methods of investigation do not enable us to discover any kind of lesion; the internal parts of the eye are transparent, the iris is apparently healthy, the pupil dilated and immovable, there is nothing apparent to which so great a diminution of sight can be attributed. In this stage, there is almost always paralysis of the retina and of the optic nerve.

The *third stage* is marked by a total blindness. The symptoms of the preceding stage are still further augmented, and vision is generally lost. However, there are patients who, for some time, preserve the faculty of walking by themselves, and of distinguishing large bodies, but this state is not permanent. The amaurosis is now confirmed. Its prognosis is serious, and it may be considered incurable. Sometimes, if the attention of the patients is aroused for a time, their eyelids will wink as if they were agitated by convulsive movements. If, on the contrary, one of the eyes only is attacked, it will deviate from its direction, moving outward or inward, upward or downward; from thence, the particular varieties of strabismus. In this last stage there is paralysis simultaneously of the nerve of the fifth pair, of the ciliary and ophthalmic ganglions, of the retina, optic nerve, and all the visual nervous system.

The *progress* of amaurosis is subordinate to a crowd of circumstances inherent to the cause giving rise to its development, to the influences in the midst of which the patient is living, and to the mode of treatment adopted to cure it. Sometimes, the disease progresses rapidly, running through its three stages in a very short time, without anything being able to arrest it; at other times, on the contrary, it advances slowly, alternately becoming better and then worse; and again, it may remain stationary, or tend to a recovery, either because the causes giving rise to it disappear, or, because a rational treatment has been successfully opposed to it.

The *prognosis* is always unfavorable. In the first stage, however, when there are symptoms of retinal hyperesthesia there are some chances for restoring vision to its normal conditions; but in the

second, when paralysis of the retina and optic nerve is evident, we must be much more circumspect in giving an opinion upon the result of the treatment, because although energetic means may sometimes prove almost miraculously successful, the most appropriate and active medications are often without any beneficial effects. In the third stage the prognosis is always fatal,—the blindness is incurable.

The *causes* of amaurosis, like those of diseases of the nervous system in general, are very numerous and enveloped in great obscurity. The disease is met with among the young as well as among the aged, among females as well as men, with the sanguine as well as the bilious; however, nervous and irritable temperaments are more predisposed to it. It may be owing to a congested state of the retina, from plethora, exposure of the eyes to intense light, concussions, strong passions, etc. It frequently appears to be due to a general state of exhaustion of the nervous system brought on by regular bleedings, hemorrhages, prolonged lactation, abuse of study during youth, venereal excesses, onanism, spermatorrhea, prostaticorrhea, colliquative diarrhea, assiduous application of the eye to the lens or microscope, as with jewellers, watch-makers, engravers, microscopists, etc., also to prolonged abstinence and want, as well as to the continued use of salted meats without acids or vegetables, as may sometimes be observed among sailors and soldiers.—It must not be forgotten to likewise refer to the numerous causes which, in exhausting nervous action, occasion a violent shock to the whole economy, a deep-seated perturbation, as, cholera, typhoid fever, lead poisoning, so frequent among painters, manufacturers of white lead, and following the use of adulterated drinks. In the same rank may be placed, lively emotions, trouble, fear, convulsions, hysterical crises, hemicrania, etc. Amaurosis may also be developed by a prolonged residence in dark places, in a dungeon, for instance, where the complete inaction of the eyes terminates by destroying the retinal sensibility.

The knowledge of these causes is one of the principal indications which directs the practitioner in the employment of the appropriate medical agents. Unfortunately, we are obliged to confess that too great an importance has very often been attached to phenomena with which the development of the disease appeared to be associated in a very evident manner, and which were in reality only simple coincidences. These few considerations give but a glimpse at all the difficulties attending the treatment.

We now know what must be understood by amaurosis as a morbid entity; we know its symptoms, its progress, and the causes

which may give rise to it; it now remains for us to explain the most interesting and important points, namely, the differential diagnosis, and the treatment.

Differential diagnosis. In order to determine amaurosis, we firstly ascertain whether the obscurity of vision is due to an opacity of the cornea, to a cataract, to a glaucoma, or to an affection of the vitreous humor, as, synchysis, hemorrhagic exudations, cysticercus, etc. For this investigation, oblique light and direct examination of the eye by daylight or by candle-light, will suffice.—If our examination is without any result, we may then endeavor to ascertain if the affection is not due to a disease of the system of accommodation, as, copyopia or feebleness of vision, myopia, presbyopia, etc.; we may assure ourself of this by the aid of the experiment with the card perforated with two holes, (page 1513), which in case of paralysis of the power of adaptation, shows that the two limits of distinct vision are more distant, or much nearer than in the normal condition. Finally, we will ascertain if there is morbid sensibility of the retina, which may be determined by the perforated card for the middle part, and by phosphenic exploration for the peripheral parts.

If we discover that the feebleness or loss of vision be due to a morbid condition of the retinal sensibility, we will search for the causes, as well as for the lesions if any exist. We may learn considerable, at this point, by interrogating the patient; but the investigation is much facilitated by the *ophthalmoscope*, the use of which assists in discovering exudations, apoplexy, or atrophy of the choroid, effusions, detachment of the retina, atrophy, etc., of the optic disc, etc. After the ophthalmoscopic examination, we may complete our investigations by determining the extent of the field of vision;* a

*The *field of vision* is the extent of the space embraced by the eye when fixed upon a determined point. Thus, if the eye be steadily fixed upon a wafer pasted against a wall, at the same time that the wafer is seen very distinctly, we can, without moving our gaze from the wafer, see objects more or less distinctly around us to a considerable distance. This circle of vision of which the wafer forms the center, is the field of vision, which extends on all sides as far as the unmoved eye can see. It is not of equal extent in all directions, being more extensive outwardly, limited inwardly by the projection of the root of the nose; and is also greater downwardly than upwardly, owing to the projection of the superciliary arch. Above, it comprises a radius of about ten inches; below, of about twenty-one inches; inwardly, of about sixteen inches; and outwardly, of about twenty-three inches,—that is when the eye is about twelve inches from the central object looked at. It will vary some, however, according to the conformation of the parts of the face in the vicinity of the eye.

To ascertain the limits or extent of the field of vision, we place the patient at

diminution of its extent indicates an affection of the retina, as, hemorrhage, detachment, etc. Interruptions of the field of vision, on the contrary, more generally indicate granular exudations, an apoplectic retinitis, an opacity of the vitreous body which is often accompanied with *muscæ volitantes*.—If the *muscæ* are fixed, it is indicative of a retinal, choroidal or cerebral affection. In the latter case, the ophthalmoscope will detect anemia, atrophy, œdematous infiltration, or other morbid changes, in the fundus of the eye, and in the papilla especially.

These several methods of examination being successively employed, we exclude all diseases the characters of which we have not found by them, and may then more readily determine whether the feebleness or loss of sight, be due to an affection of the retina, or of the choroid, to a defect in the power of accommodation, or to a cerebral disease. When no morbid alteration has been detected, we may be almost certain that the disease is purely nervous, essential, and that the patient is attacked with amaurosis.

This diagnosis may then be completed by inquiring into the antecedents, avocation, habits, constitution, etc., of the patient, the causes of the disease, and other circumstances connected with the case.

The *treatment* of amaurosis will depend upon the stage of the disease, its cause, surrounding circumstances, etc. In the *first stage* we may have an excess of retinal sensibility, or a want of activity, in a word, the commencement of the paralysis.

The first thing to be done by the practitioner is to remove any morbid accumulations in the intestines, to keep the bowels regular,

one foot from a blackboard or a large sheet of dead black paper, in the center of which a small white cross is made. Then requesting him to fix his eye steadily upon this cross during the whole examination, by means of a long black handle, holding a piece of white chalk at its end, we mark with a dot, the various points in different directions, at which the patient can see the chalk, and then connecting these dots by lines from one to the other, we form an outline within which is represented the field of vision. One eye should be tested at a time, and a copy of each map or diagram should always be preserved, so as to ascertain in subsequent trials whether the field decreases or augments in size. There are two zones to the visual field, one *central*, in which vision is the clearest; the other *peripheral*, in which vision is more confused or indistinct.

The field of vision becomes diminished in extent, in chronic glaucoma, atrophy of the optic nerve, and in cerebral amaurosis; in retinal hemorrhage, retinal pigmentation, and certain cases of atrophy of the choroid, it is dark in some part of its extent, or there are dark, fixed spots. In partial detachment of the retina, a dark cloud, a kind of diaphragm appears, more commonly in the upper part of the field of vision. Sometimes this field may become so limited that the patient can only see a single letter of a word, at a time, etc. (See page 1350.)

to allay any gastric or intestinal irritation, and to overcome, as much as possible, any symptoms of dyspepsia or abnormal action of the liver. This done, the next thing is to attend to the functions of the skin and the kidneys; bathing with a stimulating fluid every day or two, and using the hot-air bath once in every one, two, or three weeks. Continuing these measures, as may be required, during the whole course of treatment. These points having been attended to, our patient is prepared for therapeutic treatment, as well as to be more readily influenced by it.

If the amaurosis be due to plethora, intoxication, sudden suppression of any habitual discharge, exposure of the eyes to strong heat or light, hard labor in a stooping position, pregnancy, gastric, hepatic, or intestinal irritation, strong emotions or passions, fevers, irritation of the nerve of the fifth pair, etc., there will probably be a congestion of the optic nervous apparatus. In this case, the active form of the disease will require to be treated by diuretics, sudorifics, purgatives, and cupping or leeching, in some cases, behind the ears and to the temples. Artificial leeches have been found very serviceable for the purpose. It is very rarely, however, that I employ either leeching, or cupping.—Sedative or narcotic applications may also be used upon and around the eyes, as, light compresses kept constantly moistened with infusion of Stramonium, Hyoscyamus, or Belladonna, or, Stramonium and Lobelia, etc. The following solution will also be found useful as a local application: Take of Dilute Hydrocyanic Acid ten minims, Distilled Water three fluidrachms; mix.—Frictions may also be made around the orbital regions with one of the following preparations: 1. Tincture of Aconite, Tincture of Lobelia, Tincture of Stramonium, of each, a fluidounce; mix. 2. Take of Aconitina one grain, Dilute Hydrocyanic Acid half a fluidrachm, Glycerin half a fluidounce; mix.—3. Take of Extract of Hyoscyamus two drachms, Extract of Aconite, Extract of Stramonium, each, one drachm, Lard one ounce; mix. 4. Take of Tincture of Arnica Flowers three fluidounces, Tincture of Aconite Root six fluidrachms, Tincture of Gelseminum, one fluidounce and a half; mix. As these agents are apt to give rise to dilatation of the pupil, the light enters the eye freely and gives rise to irritation which must be overcome by having the patient to wear neutral-tint glasses.

The vascular congestion having been subdued, if the vision does not return to its normal condition after a reasonable time, we must stimulate the retina and arouse its nervous sensibility. The same indications are to be fulfilled in the chronic form, *second* and *third* stages, when the disease presents the characters of paralysis.

At first, we must gradually and carefully apply local stimulants lest too great a degree of excitation be produced, under the influence of which, the phenomena of irritation and congestion may re-appear. Frictions or vaporizations may be made over the eyebrows, upon the temples, and outer surface of the eyelids with one of the following preparations,—remembering that the most expeditious and efficient method of improving incomplete amaurosis, is by applying our therapeutic agents so as to act on the frontal nerve, or fifth pair: 1. Take of Tincture of Arnica, Essence of Pepperment, each, equal parts; mix. 2. Take of Tincture of Arnica four fluidrachms, Aqua Ammonia, Ether, of each, one fluidrachm; mix. Put a small portion in a vapor eye-cup, and submit the diseased eye to the vapor from the mixture.

3. Take of Leaves of St. John's Wort, Leaves of Hyssop, Prickly-ash Bark, each, equal parts; mix. Make a strong infusion, and apply it over the eyes on cloths, also let a few drops fall upon the eyes two or three times a day.

4. Take of Bisulphuret of Carbon half a fluidrachm; put this into the vapor eye-glass, and expose the eye to the vapor three times a day, for two or three minutes at a time, or as long as the patient can bear it. Alternate with this, exposure of the eye to the vapor of Hydrocyanic Acid, which may be repeated twice a day; three or four drops of this acid should be placed in a vapor eye-glass, and be used by passing it near the eye just so that the patient may experience its effects *without* bringing the glass in contact with any portion of the eye.

These topical agents should be aided by warm vaporizations of Arnica Flowers, Rosemary Flowers, and other aromatics, as well as by light compresses or bags of linen filled with pulverized Camphor moistened with a few drops of Ether. Also by rubefacient applications to the temples, behind the ears, and to the nape of the neck, as, for instance, the following: Take of Croton Oil, Oil of Turpentine, Oil of Sassafras, Olive Oil, each, three fluidrachms; mix.

If these means effect no beneficial result, or if the amaurosis has been in existence for three or four years, we must employ more active medication, as one of the following:

1. Bisulphuret of Carbon, the vapor of which should be applied to the eye, and around the orbit.

2. Take of Strychnia one grain and a half, Acetic Acid a sufficient quantity to dissolve it, Distilled Water half a fluidounce; mix, and use as a collyrium.

3. Take of Strychnia one grain, Alcoholic Extract of Nux Vomica twelve grains, Simple Cerate one drachm; mix. Apply

with friction around the orbit, and upon the external surface of the lids.

4. Take of Veratria twelve grains, Alcohol a sufficient quantity to dissolve it, Simple Cerate one drachm and a half, mix, and apply similar to the preceding.

5. Take of Strychnia one scruple, Aconitina four grains, Oleic Acid two fluidrachms; mix, dissolve, and add Olive Oil one fluid-ounce. I have found this a very efficient application in several cases.

6. Vesication may be produced upon the eyelids, brow, or temples, by means of Gondret's Ammoniacal Ointment, or by Cantharidal Collodion, and upon the vesicated surface a very small proportion of Strychnia, or Nitrate of Strychnia, may be sprinkled; repeating the latter every day or two, according to the effects. Gondret's ointment may be used thus: Cut a piece of paper of the size of a silver twenty-five cent piece, and moisten one surface of it with a thin layer of this ointment. Place this upon the part, (the eyelids, brow, or temples), and hold it there for five or six minutes by pressing against it the piece of money serving as the pattern; vesication takes place almost immediately.—It is also in these circumstances where benefit may be derived from the intermittent use of Compound Tar Plaster, applied alternately to the nape of neck, and behind the ears.

In some instances powerful sternutatories will be found useful adjuvants, the shock occasioned by them imparting an energetic stimulation to the eyeballs. Colt's-foot, Bayberry, Bloodroot, Sneezewort, Black Hellebore, etc., variously combined, may be employed for this purpose. Hypodermic injections of very dilute solutions of one of the salts of Strychnia, have been recommended, but I have not yet tried them in this disease, although I believe that they will be found very useful in both the acute and chronic forms of the disease.

Electro-galvanism has likewise been advised in the treatment of amaurosis, and has occasionally proved successful; it should be so applied as to pass along the frontal, superciliary, temporal, and suborbital branches of the fifth pair,—thus, one of the conductors may be applied upon the closed eyelids, while the other is successively placed upon the forehead, temples, eyebrows, behind the ear, upon the occiput, etc. At first the application should be continued for only a few seconds, at a later period it may be kept up for five, ten or fifteen minutes as the maximum period, at each sitting; indeed, the length of each application will depend upon the degree of irritability of the patient, being very careful upon commencing. Powerful shocks should always be avoided, a slight tingling sen-

sation is all that should be felt by the patient; in many instances, the primary current will answer a much better purpose than the secondary. The sittings may be renewed every day, every other day, every five, ten, or twenty days, according to the effect produced, and the irritability of the parts acted upon. This is a powerful and energetic agent, and when improperly administered will not only fail in effecting favorable results, but will frequently increase the difficulties we desire to overcome. Of course it can not be of any service when the amaurosis is due to disease of the brain, or of the organ of vision, or is the result of diabetes or Bright's disease.

Another method has been advised by Schlesinger, which is to endeavor to excite the retina by the exercise of its natural stimulant, light, for which purpose plano-convex, or biconvex glasses are employed, unless the patient be myopic, when the eye is exercised by concave glasses of less and less strength. Those glasses which are found the best suited to the visual faculties of the patient, are given to him, and he is made to exercise the eyes with them every day, for several hours at a time, or until the eyes begin to feel fatigued. Fifteen days afterward other glasses are employed, having a quarter or a half inch less focus than the first; the patient uses these in the same manner as he did the previous ones, and, when he can clearly distinguish the characters selected as the basis of the treatment, we again change to weaker glasses, and so on. From No. $3\frac{1}{4}$ to No. 5, we increase only a quarter of an inch more focus each time; from No. 5 to No. 9, a half inch; from No. 9 to No. 12, an inch: from No. 12 to No. 24, two inches; from No. 24 to No. 36, three inches. While this method may frequently be very serviceable, it must be recollected that when the weakness of sight is due to irritation or congestion of the retina, it is very dangerous; it requires great care on the part of the practitioner, and much patience on that of the patient.

If the amaurosis be due to great loss of blood, protracted suckling, seminal losses, especially by masturbation, excessive discharges, depressing passions, low nervous fevers, or any other causes giving rise to general nervous exhaustion, and as a consequence, exhaustion of the optic nervous apparatus, the prognosis will be much less favorable than when it depends upon congestion. Tonic and alterative treatment will be required, as, Sulphate of Quinia, Black Cohosh, Iron, Muriate of Berberina, Iodide or Bromide of Potassium, or of Ammonium, Scrofulous Syrup, etc.; together with means to stimulate the retina, as, Strychnia, Veratria, vapors of Bisulphide of Carbon, Ether, Ammonia, etc., and Electro-galvanism.

Where there has been nervous exhaustion from excessive discharges, as referred to above, the following form very useful preparations:

1. Take of Red Oxide of Iron two scruples, Strychnia two grains, Extract of Conium, Extract of Cimicifuga, each, one scruple; mix thoroughly, and divide into twenty pills, of which one may be taken for a dose; to be repeated two or three times a day.

2. Take of Reduced Iron, Pepsine, Aletridin, Extract of Conium, each, one drachm. Mix thoroughly, and divide into sixty pills, of which one may be taken for a dose; to be repeated three times a day.

3. Take of Phosphate of Iron one drachm, Phosphate of Manganese two drachms, Hypophosphite of Quinia forty-five grains, Honey or Simple Syrup, a sufficient quantity,—adding, if necessary, enough powdered Prickly ash Bark, to aid in forming a pill-mass. Divide into sixty pills, of which one is a dose, and which may be repeated three times a day.

When the amaurosis follows an attack of cholera, low fever, depressing passions, etc., or when tonic treatment does not suffice, we should then employ stimulants, as, for instance, one of the following preparations:

1. Take of Extract of Arnica, one drachm, Pulverized Prickly-ash Bark, two drachms, Extract of Smartweed, one drachm; mix, and divide into sixty pills. The dose is one pill, to be repeated three times a day.

2. Take of Phosphorized Ether three fluidrachms, Tincture of Blue Flag, Tincture of Arnica, each, one fluidrachm, Tincture of Nux Vomica half a fluidrachm; mix. Dose, ten or twenty drops, three times a day.

3. Take of Saturated Tincture of Rhus Toxicodendron one fluidounce, Saturated Tincture of Arnica, Volatile Tincture of Guaiacum, each, half a fluidounce; mix. The dose is forty drops every three or four hours.

4. Take of the Oleo-resins of Prickly-ash Bark, and Blue Flag Root, each, one drachm, Horse-radish two ounces, Sweet Flag one ounce, Whisky two pints. Add the medicines to the Whisky and allow them to macerate fourteen days. The dose varies from a fluidrachm to half a fluidounce, three or four times a day, either alone or diluted with sweetened water.

At the same time that these agents are used internally, stimulating applications should be applied to the temples and eyebrow, as, a liniment or ointment of one or several of the following articles: Rhus Toxicodendron, Arnica, Oil of Turpentine, Capsicum, Oil of Prickly-ash Bark, Delphinia, Veratria, etc.

If the amaurosis be due to pressure on some part of the optic nervous apparatus, as from cerebral tumors, vascular distension, or other disease; if it be due to Bright's disease, or diabetes, or appears to be under the influence of lead-poisoning, hysteria, epilepsy, chorea, anemia, etc., the treatment must be especially addressed to whichever of these abnormal conditions are present; and, after its removal, should vision not be restored, the means already named to excite the retina and visual faculties into action, should then be made use of.

In the treatment of amaurosis it will always be found advantageous to exhibit, as adjuvants, such remedies as are calculated to remove certain diseases with which the amaurosis is complicated; thus, if the liver, stomach, kidneys, or intestines be disordered, the appropriate agents to meet the particular symptoms present must be given; if gout or rheumatism be present, the remedies for these diseases should be administered; if worms, vermifuges; if menstrual derangement, uterine tonics; if secondary syphilis, the proper anti-syphilitics; if scrofula, antiscrofulous remedies; and so on with any symptomatic, functional, or organic lesion which may be present simultaneously with the eye disease. An attention to this point will be found very important, the proper measures being frequently followed by a restoration of vision in cases where previously mere local applications to the eye failed to result in any benefit.

In the *third stage*, that is, in confirmed and obstinate amaurosis, the treatment will be the same, but it will almost always be unsuccessful, the blindness being incurable.

APPENDIX.

I. Table for determining the quantity of a medicinal agent required to enter into a definite amount of fluid, which is to be administered in certain doses, each dose holding a given quantity of said agent.

N. B. This Table I have given in our usual weights and measures, and not in the metrical. I have it already made out in metrical weights and measures, as well as the other Tables, which will be given hereafter, when the profession is better prepared for them. The metrical tables herein given will enable any one to convert our American weights and measures into them, and vice versa.

EXPLANATION.

The preceding tables are designed to facilitate the determination of how much medicine, in a given dose, must be added to a required quantity of fluid, so that this fluid may be prescribed in doses of a certain amount. 1. The *given dose of the medicine* will be found in the first column, at the left of the brackets, or, in other words, the *quantity of the medicinal agent* required to be taken with each dose of the mixture or solution into which it enters; 2, the *dose of the fluid solution* of this medicine will be found in the first column, inclosed within the brackets, or, in other words, the *size of the dose of the mixture or solution* prescribed; 3, the *quantity of fluid required or prescribed* to form the solution, will be found at the heads of the other columns; and, 4, the *quantity of medicine which must be added* to the required or prescribed amount of fluid, will be found in the column under the head of such amount. Thus:

1. It is desired to give four fluidounces of liquid to a patient, to be taken in half fluidrachm doses, each dose to contain Strychnia $\frac{1}{30}$ grain, Quinia $\frac{1}{2}$ grain, Morphia $\frac{1}{8}$ grain. How much of each of these alkaloids must be added to the four fluidounces prescribed?—As already explained, find the given dose of the Strychnia $\frac{1}{30}$ grain, and, opposite to it, inclosed within the bracket, find the dose of the fluid solution, viz., half a fluidrachm; from which follow out the line until the column under four fluidounces has been reached, when it will be found that $2\frac{2}{3}$ grains of Strychnia will be required. Again, find the given dose of the Quinia grain $\frac{1}{2}$, and inclosed within its bracket also find the dose of the fluid solution, viz., half a fluidrachm; from this, trace along the line as before, and in the column under four fluidounces, the quantity of fluid prescribed, will be found the required amount of Quinia, viz., 32 grains. For the Morphia, find the given dose, grain $\frac{1}{8}$, then the half fluidrachm inclosed in its bracket, and tracing along, as before, the quantity of this alkaloid required will be found, 8 grains.

2. It is desired to prescribe two ounces of fluid to be taken in doses of ten minims, each dose to contain one-fiftieth of a grain of Atropine;

how much Atropine must be contained in the two fluidounces?—As $\frac{1}{80}$ grain is not in the tables, find $\frac{1}{25}$ grain, and on the ten minims line under four fluidounces will be found $7\frac{1}{2}$ grains, or the quantity required were the given dose of Atropine $\frac{1}{25}$ for four fluidounces; one-half of which will be the amount of Atropine, at $\frac{1}{25}$ grain dose, for two fluidounces, viz., $3\frac{1}{2}$ grains, and one-half of this again will be the quantity of Atropine at $\frac{1}{50}$ grain dose for two fluidounces, viz., $1\frac{3}{4}$.

3. It is desired to add two grains of Veratria to a fluid, to be administered in twenty minim doses, each dose to contain $\frac{1}{25}$ grain of Veratria. How much of the fluid will be required for the two grains?—Find the given dose, $\frac{1}{25}$ grain, and the dose of the fluid, 20 minims; follow this line until the amount nearest to two grains is found, which in the present instance will be $3\frac{1}{2}$ grains, in the column under four fluidounces; $3\frac{1}{2}$ grains is $1\frac{1}{2}$ grains more than 2 grains, or an excess of forty-six $\frac{1}{25}$ grains=46 doses. By the following table it will be seen that four ounces contain 96 doses of 20 minims each; subtract from this the excess of 46 doses, and 50 doses remains for the two grains, and as each dose is to consist of 20 minims of the solution, 50 doses will=1000 minims=16 drachms and 40 minims of fluid. The same result may be obtained, as follows: One dose is to contain $\frac{1}{25}$ grain, therefore two grains will give fifty $\frac{1}{25}$ ths or 50 doses, which being multiplied by the number of minims required for each dose, 20, will give 1000 minims=16 drachms, 40 minims.

4. How much fluid will be required for 12 grains of Morphia; the fluid to be given in 20 minim doses, each containing $\frac{1}{2}$ grain of Morphia? Ans.—1 ounce.

5. I have one ounce of Iodide of Ammonium which I desire to give in solution in doses of a teaspoonful containing two grains each; how much water will the ounce of Iodide require?

Find the given dose of the Iodide, *i. e.*, 2 grains, and the line containing the dose of the fluid, *i. e.*, one drachm; follow this line along until the column containing one ounce or eight drachms are found, and at the top of this column will be found the required answer, viz., 30 ounces of fluid.

II. Table for determining the number of doses there are in a definite amount of fluid medicine, when given in a certain dose.

How many doses of 15 minims each, are there in 24 ounces of fluid?

By following the dose, (15 minims,) in the first line, along until the column under 24 ounces is reached, the answer will be found, viz., 768 doses.

How many drachm doses are there in 30 ounces of fluid? Ans. 240.

111. Table for determining how much fluid medicine must be given to a patient to last for a definite length of time, when taken in a certain dose, which is to be repeated three times every day.

Thus, 8 drops of a fluid repeated 3 times a day, will require $1\frac{1}{2}$ ounces to last a month. The small figures to the right of the drachms signify minims.

N. B. A drop here is considered equal to a minim.

EXAMPLE.

It is desired to give a patient enough fluid to last six weeks, to be taken in teaspoonful doses three times a day, each dose to contain 1 grain of quinia and $\frac{1}{8}$ grain of morphia. What quantity of fluid must be given, and what proportions of quinia and morphia must it contain?

By the above table, a teaspoonful or drachm dose given three times a day, will require 1 pint and 7 drachms of fluid to last for six weeks. Now, by referring to table *I*, on a line with the given dose, 1 grain, it will be found that for drachm doses 1 pint will require 2 drachms and 8 grains of the medicine, while 8 drachms or 1 ounce will require 8 grains, making two drachms and 16 grains; but as only 7 drachms are required, or 1 drachm less than the ounce, the amount of the dose for the superfluous drachm, which contains one grain, must be deducted, making 2 drachms and 15 grains of quinia. Again, by referring to the given dose, $\frac{1}{8}$ grain, in same table, and following the line of drachm doses, it will be found that one pint will require $42\frac{2}{3}$ grains, while 8 drachms will require $2\frac{2}{3}$ grains, making in all $45\frac{1}{3}$ grains; from which deduct the superfluous drachm which contains $\frac{1}{8}$ grain, and the result will be 45 grains of morphia.

EXAMPLE.

1. How much will it require to make 48 pills or powders, of Podophyllin at $\frac{1}{4}$ grain dose,—Quinia at $\frac{1}{2}$ grain dose,—Citrate of Iron at 1 grain dose,—and Cimicifugin at 1 grain dose?
Ans.—Podophyllin, (dose $\frac{1}{4}$ grain,) = grains, 12.
Quinia, (dose $\frac{1}{2}$ grain,) = grains, 24
Citrate of Iron, (dose 1 grain,) = grains, 48.
Cimicifugin, (dose 1 grain,) = grains, 48.

$\frac{1}{12}$ "	518.3352		
$\frac{1}{13}$ "	583.1371		
$\frac{1}{14}$ "	647.9192		

EXAMPLE.

How many Grammes are in $198.753 \frac{1}{10}$ Troy grains?

Grains.		Grammes.
100,000	=	6479.192
90,000	=	5831.371
8,000	=	518.3352
700	=	45.3543
50	=	3.2395
3	=	.1943757
$\frac{1}{10}$	=	.0012958
<u>198,753 $\frac{1}{10}$</u>	=	<u>12877.6876715</u>

To Calculate for Fractions between those given in the Table.

Thus, how many milligrammes are there in $\frac{1}{48}$ of a grain? We subtract $\frac{1}{45}$ grain=1.4398, from $\frac{1}{40}$ grain=1.6198, which leaves .1800. But as there are five steps between $\frac{1}{40}$ and $\frac{1}{45}$, we divide this .1800 by 5, which gives for each step .0360. Multiply this by 3 to give the three steps required to add to $\frac{1}{40}$ to make it $\frac{1}{48}$, which gives .1080. Subtract this from $\frac{1}{40}$ grain=1.6198, and we have $\frac{1}{48}$ grain=1.5118 milligrammes.

A similar course is required for the hundredths; thus how many milligrammes are in the $\frac{1}{338}$ of a grain.

$\frac{1}{300}$ grains	=	.21597
$\frac{1}{400}$ grains	=	.16198
100 steps	=	.05399 \div 100 and
1 step	=	.000539 \times 36 and
36 steps	=	.0019404 subtract
this from $\frac{1}{300}$	=	.21597
		.00194, and we have
$\frac{1}{338}$ grains	=	.21403 milligrammes.

EXPLANATION.

1. The figures in the first column, under Unit, have reference to Grammes, Metres, Litres, etc., and for convenience have been carried out by tens and hundreds, to 1,000; thus, 1 Gramme=15.43402 Troy Grains; 8 Litres=488.224 Cubic Inches; 60 Ares=7176.1963 Square Yards, etc. But in determining the different denominations of French weights or measures, above or below the Unit as, *Hectogrammes*, *Centilitres*, etc., we must confine ourselves to the first ten lines of the table.

2. In the line *below* the table, Unit is represented by a dot, and the prefixes to the units of French weights and measures are represented by one or more eiphers; those on the right of the Unit signifying that as many *whole numbers* contained in the answers to the Unit column as there are eiphers representing the prefix or given denomination of French weight or measure, must be cut off and placed to the right among the decimals; and those on the left signifying that as many *decimals* contained in the answer to the Unit column as there are eiphers representing the prefix or given denomination of French weight or measure, must be cut off and placed to the left among the whole numbers,—in order to convert these answers into those required for the given French weight or measure.—A few examples will more clearly illustrate:

Ex. 1 How many pints are there in six Kilolitres?

Find six in the Unit column, and trace along the line until the column of pints under Litres is reached; we now have the answer to the Unit column, that 6 Litres=12.6811 pints. In the lower table the prefix *Kilo* will be found on the left of Unit, and is represented by three eiphers; therefore, to convert the above answer into that for Kilolitres, we cut off three of its *decimals* and place them to the left among the whole numbers; then 6 Kilolitres=12681.1 Pints.

Ex. 2. How many Troy Grains in eight Centigrammes?

Find eight in the Unit column, and trace along the line until the column of Troy Grains under Grammes is reached; we now have the answer to the Unit column, that 8 Grammes=123.47218 Troy Grains. In the lower table the prefix *Centi* will be found on the right of Unit, and is represented by two eiphers; therefore, to convert the above answer into that for Centigrammes, we cut off two of its *whole numbers* and place them to the right among the decimals; then 8 Centigrammes=1.2347 Troy Grains.

Ex. 3. How many Cubic Inches are there in one Millilitre?

By the process above explained, we find 1 Litre=61.028 Cubic Inches, three whole numbers of which must be cut off and placed to the right among the decimals, in order to obtain the desired answer. But there are not enough whole numbers for this purpose, therefore, the deficiency must be made up by prefixing the necessary amount of ci-

phers to the whole numbers, and which in this instance is only one; then 1 Millilitre = .06102 Cubic Inches.

Ex. 4. In 1268 Steres how many solid Cubic Feet?

1000 Steres = 35316.5820 solid Cubic Feet.

200 " = 7063.3164 "

60 " = 2118.9949 "

8 " = 282.5326 "

Ans.—1268 " = 44781.4259 "

N. B. By a somewhat reversed process, American Weights and measures may be converted into French, by means of the above Table. Thus, in 642 Inches how many Centimetres?

393.7079 Inches = 1000 Centimetres.

236.2247 " = 600 "

11.8112 " = 30 "

.2360 " = .6 "

.0196 " = .05 "

641.9994 " = 1630.65 " = 16.3065 Metres.

TABLE IX,

For reducing minute parts of French Weights and Measures to American, suitable for Microscopists, Chemists, Physiologists, etc.

Parts of Millimetres, Milligrammes, Millilitres, Grammes, or Cubic Centimetres, and Milliares, reduced to American Weights and Measures.

DIRECTIONS.

§ 1. The first five divisions of the foregoing Table contain *fractional* parts of a Millimetre, Milligramme, Millilitre, Miliare and Millistere, arranged as follows: *a*, the first column of figures in each of these five divisions contains the parts of a Millimetre, Milligramme, etc., in *fractions*; *b*, the second column contains the same, but represented in *decimals*; *c*, the third column gives the unit dots and decimal ciphers which must be prefixed to the answers or figures opposite to them in the sixth to the fifteenth division.—The *answers* are in the divisions from the sixth to the fifteenth, inclusive.

§ 2. In reducing parts of a Millilitre to Troy Grains and Minims; parts of a Miliare to Square Inches; and parts of a Millistere to Cubic Inches, (as seen in the 12th, 13th, 14th, and 15th divisions), for every cipher found in the third column (*c*) of the first five divisions, and opposite the given fractional part of the Millilitre, Miliare, or Millistere, as represented in the first column (*a*) of one of the first five divisions, the *whole figures* in the *answer* thereto must be advanced one step to the right,—the whole figure on the left of the decimal dot or unit being carried over to the right side of it among the *decimal figures*; and when all the whole figures have been thus cut off to four decimals, ciphers must be prefixed to them as the decimals decrease in value, as described in the preceding section, in order to give the true decimal value to the answer. Thus:

1	Millitre is equal to	15.434	Troy Grains and	16.2319	Minims.
$\frac{1}{10}$	"	"	1.5434	"	" 1.62319 "
$\frac{1}{100}$	"	"	.15434	"	" .16231 "
$\frac{1}{1000}$	"	"	.01543	"	" .01623 "
$\frac{1}{10000}$	"	"	.00154	"	" .00162 "

§ 3. Parts of an inch may be obtained by prefixing an additional cipher to the decimals ascertained for a line, the $\frac{1}{10}$ th of an inch; thus .05 Millimetre=.0197 lines ($\frac{1}{10}$ inch)=.00197 inch.

EXAMPLES.

Ex. 1. What part of a line ($\frac{1}{12}$ inch) is $\frac{3}{80}$ or .06 millimetre?

In one of the first five divisions of the table find $\frac{3}{80}$ or .06, and by tracing the line along until we come under Millimetres, in the division headed "Line $\frac{1}{12}$ inch," we find the figures 2838, to which must be prefixed the decimal cipher in the third column of the division, opposite $\frac{3}{80}$. The answer, therefore, will be .02838 of a line $\frac{1}{12}$ inch.—But suppose we substitute $\frac{3}{5000}$ or .0006 millimetres for the $\frac{3}{80}$ or .06, the figures will be the same as in the preceding instance, requiring, however, to be prefixed by the three decimal ciphers opposite $\frac{3}{5000}$, and then the answer will be .0002838 of a line $\frac{1}{12}$ inch.

Ex. 2. What part of a Cubic Inch is $\frac{4}{10}$ millilitre?

Find .4 or $\frac{2}{5}$, follow the line along to Millilitre under the division of Millitres and in the column of Cubic Inches; the answer will be .024411 Cubic Inches.

Ex. 3. How many Troy Grains are in .17643 Milligrammes?

.1	or	$\frac{1}{10}$	Milligrammes=	.0154	Troy Grains.
.07	"	$\frac{7}{100}$	"	=.00180	"
.006	"	$\frac{6}{1000}$	"	=.0000926	"
.0004	"	$\frac{4}{10000}$	"	=.000006492	"
.00003	"	$\frac{3}{100000}$	"	=.000000463	"
Ans. .17643	"	$\frac{17643}{100000}$	"	=.017299555	Troy Grains.

To Divide Medicines into Fractions of a Grain.

1. Divide one grain of Strychnia into doses of $\frac{1}{15}$ ths each.

Take of Starch (or other inert or insoluble powder) *twenty-four grains*, Strychnia *one grain*; mix, and triturate thoroughly together, and then weigh out sixteen grains of the mixture, which will be equal to $\frac{1}{15}$ ths of the grain of Strychnia.—Or, for a solution, take of Distilled Water *forty-nine minims*, Nitric, or Phosphoric Acid *one minim*, Strychnia *one grain*; mix. When the Strychnia is dissolved, thirty-two minims of the solution will be equal to $\frac{1}{15}$ ths or $\frac{1}{15}$ ths of a grain of the alkaloid.

2. Required a dose of Aconitina, $\frac{1}{15}$ ths of a grain.

Take of Starch (or other inert powder) *fourteen grains*, Aconitina *one grain*; mix, and triturate thoroughly together. Eight grains of the mixture will equal $\frac{1}{15}$ ths of a grain of Aconitina.—Or, for a tincture, take of Alcohol *thirty minims*, Aconitina *one grain*; mix, and dissolve the alkaloid. Sixteen minims of the solution will be equal to $\frac{1}{15}$ ths or $\frac{1}{15}$ ths of a grain of Aconitina.—Or, for a solution, take of Distilled Water *one hundred and fifty minims*, Aconitina *one grain*; mix. Eighty minims of this solution is equal to $\frac{1}{15}$ ths or $\frac{1}{15}$ ths of a grain of the alkaloid.

3. Required $\frac{7}{15}$ ths of a grain of Chloride of Gold and Soda to add to a fluidounce of Water.

Take of Chloride of Gold and Soda *one grain*, Starch (or finely-powdered pumice-stone, sand, or emery, etc.) *fifteen grains*; mix, triturate well together, and then weigh out seven grains, equal to $\frac{7}{15}$ ths of the Gold Salt, and add it to the water, which will dissolve this salt but not the emery, or pumice, etc.

N. B. The balance of the triturated medicine, not employed, should be kept for future use in a small vial, with the proportions of medicine and inert powder labeled upon it.—In all cases where solutions or tinctures are to be made, and it is not desirable to have other matters to enter therein, triturate with some insoluble material, and when the solution is made, filter. Powdered emery, pumice-stone, sand, etc., may be used when the article is to be dissolved in water; and, if in

alcohol or ether, powdered starch, gum arabic, tragacanth, or sugar of milk, etc.

Dissolve $10\frac{4}{5}$ grains of Atropia in one pint of Alcohol.

First, weigh out *ten grains* of Atropia and add it to the Alcohol.

Second, triturate *one grain* of Atropia with *fourteen grains* of powdered pumice-stone, and of this mixture, add four grains to the Alcohol, making $10\frac{4}{5}$ grains of Atropia that have been added to the fluid. Filter, if required.

N. B. GLYCERIN No. 2, is frequently referred to in the work, and as it has been suggested to me that many will not understand what is meant by it, I will explain at this place. Glycerin No. 1, is the best deodorized article to be found in the market, and commands a very high price; Glycerin No. 2, is the next best article, it is not wholly decolorized nor deodorized, though its odor is hardly perceptible,—its price is about one-third that of the No. 1 article, and it is fully equal to this for the preparations in which it has been recommended.

Carbolic Acid is recommended in several parts of this work; it must, however, be borne in mind that this agent is a powerful and active caustic, very volatile, and corrodes and disorganizes the tissues with which it comes in contact, and may, consequently, effect much serious mischief when improperly employed. It is not soluble in water to any great extent, and should always be first dissolved in four times its volume of alcohol before being added to water, and it should also be sufficiently diluted before applying it to delicate mucous membranes, to the air passages, and internally, etc. In most instances, it may be as advantageously and much less dangerously employed in the form of what has been called *Phenol Sodique*, and which may be made by neutralizing pure crystalized carbolic acid in solution with caustic soda; press the resulting crystals between bibulous paper, and then dry them under a bell glass over a dish of sulphuric acid. It is a *phenate of soda*, stable, easily decomposed, and soluble in water, and carbolic acid.
